- Recommendations also include changing of gloves between tasks and procedures on the same patient if contact with material containing a high concentration of micro-organisms is made.
- Recommended that gloves be changed between contact with different anatomic sites on the same patient
- Handwashing or use of a hand sanitizer should always be performed after removal of gloves and prior to seeing the next patient.
 - Use of gloves does not replace the need for handwashing
 - Gloves may have small, inapparent defects or may be torn during use
 - Hands can become contaminated during removal of gloves

Mask, Eye Protection, and Face Shield

- Mucous membranes of HCW, including those of the eyes, nose, and mouth, at risk for exposure when performing procedures or patient care tasks that may generate aerosols or droplets
- Masks, eye protection, or face shields should be worn to protect mucous membranes

Gown

- Gown should be worn if expected direct contact with an infected patient or environment during procedures or routine patient care
 - Clean, nonsterile gown is adequate for protecting skin and preventing soiling of clothing during such procedures and patient care activities
 - Remove immediately after patient contact
 - Hands should be washed after removal of gowns

Patient Care Equipment

- Equipment soiled with blood, body fluids, secretions, and excretions should be handled in a manner that prevents skin and mucous membrane exposures, contamination of clothing, and transfer of micro-organisms to other patients and environments.
- Multiuse equipment should be appropriately cleaned or processed prior to being used for the care of another patient.
- Single-use items should be disposed of in the appropriate manner, including use of a puncture-resistant sharps container if indicated.

Environmental Control and Linen

- Procedures for routine care, cleaning, and disinfection of environmental surfaces, beds, bedrails, bedside equipment, and other frequently touched surfaces should be used.
- Soiled linen should be handled and transported in a manner that prevents skin and mucous membrane exposure and contamination of clothing.

Patient Placement

- Patients who may contaminate an environment, who do not or cannot assist in maintaining appropriate hygiene or environmental control should be placed in private room.

Occupational Health and Bloodborne Pathogens

- Handling of sharps during use, cleaning, or disposal should be done with extreme care.
 - Never recap used needles; avoid manipulation using both hands or a technique that involves the point of a needle being directed toward any part of user's body.
 - Used needles should not be removed from disposable syringes by hand.
 - Bending or breaking, or otherwise manipulating used needles by hand should not be done.
 - Used disposable syringes and needles, scalpel blades, and other sharp items should be placed in an appropriate puncture-resistant container.
 - Located as close as practical to the area in which the items are used
 - Reusable sharps placed in a puncture-resistant container for transport

Contact Precautions

- Designed to reduce the risk of transmission of epidemiologically important micro-organisms
 - Such as antibiotic-resistant Gram-positive or Gram-negative organisms
- Transmission of these organisms may take place either by direct or indirect contact
 - Direct contact transmission from patient to staff includes:
 - Physical transfer of micro-organisms to the HCW from an infected or colonized patient
 - Activities that are a risk for direct contact include:
 - Turning and bathing patients
 - Assisting patients with personal hygiene
 - Performing patient transfers, dressing changes, or other patient care activities that require physical contact
 - Can also occur between two patients sharing common areas in same room
 - Indirect contact transmission involves contact of a susceptible host or HCW with a contaminated intermediate object
 - Referred to as *fomites*
 - Described as sources of MRSA, vancomycin-resistant enterococcus (VRE), and Gram-negative organisms such as *Pseudomonas* and *Acinetobacter* because these organisms can potentially survive for months
- Applied to patients with known or suspected infection or colonization with epidemiologically important micro-organisms that can be transmitted by direct or indirect contact
 - Involve patient placement
 - Gloves and handwashing
 - Gowning
 - Precautions with patient transport and patient care equipment
 - Patients should be placed in a private room if possible
 - Door to the room may be left open
 - If private room not available
 - Patient can be placed in a room with a patient who has colonization or active infection with the same micro-organism (*cohorting*)
 - If private room not available and cohorting not achievable
 - Epidemiology of the micro-organism should be considered and patient population taken into consideration when determining placement
 - Example includes avoidance of placing immunocompromised patient in same room as one with resistant organism
 - Gloves and handwashing used as with standard precautions
 - Gowns used if substantial contact with the patient, environmental surfaces, or items in patient's room
 - Gown also worn if patient is incontinent, has diarrhea, or has an ileostomy, colostomy, or wound drainage not covered or contained by a dressing
 - Transport limited to essential purposes
 - Patient care equipment such as stethoscopes, thermometers, and IV pumps dedicated to a single patient (or cohort) to avoid transfer of organisms

Droplet Precautions

- Aim to reduce risk of spreading infectious agents by droplet transmission

- Transmission involves contact between conjunctiva and other mucous membranes (nose, mouth) of either a patient or HCW with large droplets ($>5\ \mu\text{m}$ in size) containing micro-organisms generated from a person who is either infected or colonized
- Droplets generated by coughing, sneezing, or talking and during procedures such as suctioning or bronchoscopy
- Requires close contact between source and recipient persons
 - Droplets do not remain suspended in the air and generally travel only short distances, usually $<3\ \text{ft}$
 - Special air handling and ventilation not required to prevent transmission
 - Door to the patient's room may remain open
- Apply to any patient known or suspected to be infected with epidemiologically important pathogens that can be transmitted by infectious droplets:
 - MRSA
 - Meningococcal infection
 - *Acinetobacter pneumonia*
 - Invasive *Hemophilus influenza* type B
 - Influenza
 - *Mycoplasma pneumonia*
 - Parvovirus B19
- In addition to standard precautions
 - Patients should be placed in a private room or cohorted
 - If cohorting is not possible, spatial separation of at least 3 ft between other patients and visitors should be maintained
 - Mask should be worn if working within 3 ft of the patient
 - Transport should be limited to essential purposes
 - When transported, patient should be masked

Airborne Precautions

- Designed to reduce the risk of airborne transmission of infectious agents
- Occurs by dissemination of either airborne droplet nuclei 5 microns or smaller in size, or dust particles containing the infectious agent
- Micro-organisms carried in this manner dispersed widely by air currents travel long distances through ventilation systems
- May be inhaled by susceptible host in the same room or by a patient several rooms or floors away
- Special air handling and ventilation are required
- Airborne precautions apply to patients known or suspected to be infected with epidemiologically important pathogens such as:
 - Tuberculosis
 - Varicella zoster virus
- Patient should be placed in a private room that has:
 - Monitored negative air pressure in relation to surrounding areas
 - 6 to 12 air exchanges per hour
 - Appropriate discharge of air outdoors or monitored high-efficiency filtration of room air before recirculation
 - Room door should be kept closed and the patient should be kept in the room
 - If private room is not available, patient should be cohorted
 - If private room is not available and cohorting is not possible
 - Consultation with infection control professionals
- Respiratory protection should be worn: N95 respiratory mask
 - Susceptible persons should not enter the room of patients known or suspected to have rubeola (measles) or varicella (chickenpox) if other immune caregivers are available
 - If susceptible persons must enter room, must wear N95 respirator
 - Persons immune to measles or chickenpox need not wear respiratory protection
- Patient transport should be limited to essential purposes only
 - If transport or movement necessary place N95 mask on patient

VIRUSES

- Major viruses of concern in the health care setting are human immunodeficiency virus (HIV), influenza virus, and the hepatitis B and C (HBV, HCV)
- Nosocomial outbreaks of herpes simplex virus I (HSV type I), pneumonia (13), and varicella zoster virus reported but generally rare
- Application of standard (universal) precautions recommended in all patients

Human Immunodeficiency Syndrome

- HIV causes acquired immunodeficiency syndrome (AIDS)
 - Two species of HIV—HIV-1 and HIV-2—infect humans
 - Thought to have originated in southern Cameroon as a species-jumping event from wild chimpanzees (HIV-1) and an old-world monkey, the Sooty Magabey (HIV-2)
 - Virus was first discovered in France in 1983
 - Named lymphadenopathy-associated virus
 - Confirmed in United States
 - Named human T-cell lymphotropic virus 3 (HTLV-3)
 - In 1986, the name was changed to HIV
 - Virus is a single-stranded RNA virus classified in the genus Lentivirus of the family Retroviridae
 - Upon entry into the cell, the virus uses reverse transcriptase to convert its genome into a double-stranded DNA that then integrates itself into host nuclear DNA for transcription of its genome using host cellular machinery
 - Transcribed virus then enters the cytoplasm where it undergoes translation
 - Later, under the influence of the enzyme protease, becomes cleaved to be incorporated into mature virions
 - HIV is transmitted primarily by exposure to blood and other body fluids
 - Three primary methods of transmission are:
 - Via unprotected sexual intercourse
 - Vertical transmission (mother to child)
 - Through contaminated needles (either occupational exposure or with the use of IV drugs)
 - Blood products screened routinely for HIV, and transfusion-associated transmission has been, for the most part, eliminated
 - After initial exposure, HIV replicates within dendritic cells of the skin and mucosa
 - Later spreads via lymphatics, infecting CD4+ cells
 - Process ultimately becomes a chronic disseminated infection

- Delay in systemic spread leaves window of opportunity for postexposure prophylaxis (PEP) using antiretroviral drugs
- Nurses are at highest risk for occupational exposure
 - Most common exposure was via percutaneous injury
 - Other types of exposures among HCWs include:
 - Mucous membrane exposure
 - Nonintact skin exposure
 - Bites resulting in blood exposure
- Average risk of HIV transmission to HCWs:
 - After a percutaneous injury estimated to be approximately 0.3% (95% confidence interval [CI], 0.2%–0.5%)
 - After mucous membrane exposure to be 0.09% (95% CI, 0.006%–0.5%)
 - Transmission of HIV via nonintact skin exposure has been documented but is much less than for mucous membrane exposures
 - Risk for transmission after exposure to fluids or tissues other than HIV-infected blood also has not been quantified but is considerably lower than for blood exposures.
- Several factors may increase risk of HIV transmission after an occupational exposure:
 - Larger quantity of blood from the source
 - Procedure that involves placing a needle directly into a vein or artery
 - Deep tissue injury
 - Blood exposure from a patient with terminal disease, as there is usually a higher viral load in AIDS
 - More blood is transferred by deeper injuries and hollow-bore needles

Postexposure Management

- Administration of antiretroviral medications only active outcome of postexposure evaluation
- Initial step is prompt treatment of exposure site including:
 - Washing wounds and skin sites with soap and water
 - Flushing mucous membranes with water
- Followed by immediate reporting to facilitate rapid evaluation of the HCW
 - Including testing for HIV and hepatitis B and C
 - Evaluation of source patient
 - Initiation of medications for HCW if indicated
- Potentially infectious fluids include:
 - Blood and blood-containing fluids
 - Fluids from other sites such as semen, vaginal secretions, and cerebrospinal fluid (CSF)
 - Synovial, pleural, peritoneal, pericardial, and amniotic fluids
- Source patient also needs to be evaluated, including:
 - Serologic studies for HIV using antibody testing
 - Hepatitis B surface antigen
 - Hepatitis C antibody
 - If the source patient not found to be infected with a blood-borne pathogen, further testing of the HCW may not be warranted
 - If the infection status of the source remains unknown, the comorbidities, clinical symptoms, and high-risk behaviors of the source patient should be considered
 - If source patient is considered high risk, PEP should be initiated
 - PEP regimens should be started within hours of exposure.
 - Exact course duration of PEP has not been determined. However, 4 weeks is recommended for HCWs and

other occupational exposures, such as law enforcement encounters.

- PEP has been shown to be protective in animal studies.
 - Basic regimen consists of two nucleoside reverse transcriptase inhibitors (NRTIs)
 - Examples of basic regimens include a combination of lamivudine or emtricitabine with either stavudine or tenofovir; Combivir (zidovudine and lamivudine) or Truvada (tenofovir and emtricitabine)
 - Expanded regimens include the addition of another drug class such as protease inhibitors (PIs) or nonnucleoside reverse transcriptase inhibitors (NNRTIs)
 - Preferred expanded regimen is one that includes the PI lopinavir/ritonavir (Kaletra) with two NRTIs

Influenza Virus

- RNA viruses belonging to the family Orthomyxoviridae
- Infection causes an acute febrile illness usually occurring during the winter months and characterized by:
 - Sudden onset of high fever
 - Headache
 - Myalgia
 - Arthralgia
 - Cough
- At risk for more severe disease include:
 - Young children
 - Elderly
 - Immunocompromised patients
- Infection can be self-limited
 - May also result in severe prostration in elderly patients
 - Primary influenza pneumonia
 - Secondary bacterial pneumonia
- Transmission occurs person to person via large virus-laden droplets
 - Droplet precautions are used for patients admitted with active or suspected influenza
 - Mainstay of disease prevention is annual immunization of both:
 - HCWs
 - At-risk patient population, which is defined as:
 - Age older than 65
 - Residents of nursing homes or long-term care facilities
 - Pregnant women in the second or third trimester
 - Patients with a chronic pulmonary or cardiac disease
 - Patients with diabetes
 - Individuals on dialysis
 - Immunosuppressed patients
 - Patients on long-term aspirin therapy
 - Children aged 6 to 23 months
 - Vaccination done with a live, attenuated influenza vaccine resulting in virus replication in the respiratory epithelium
 - Can result in active viral shedding
 - Inactivated influenza vaccine is recommended for HCWs with direct patient contact

Hepatitis

- Several hepatitis viruses described, including hepatitis A, B, C, D, E, and G

- Hepatitis A is caused by a picornavirus and is transmitted by the oral–fecal route, usually by contaminated food.
 - Causes only an acute form of hepatitis that is generally self-limited and confers immunity to future infections
 - Not usually a concern in the health care setting
- Hepatitis D is caused by a delta virus and can only replicate in the presence of hepatitis B.
- Hepatitis E is like hepatitis A in that it causes an acute, usually self-limited hepatitis and is also transmitted via the oral–fecal route.
 - In a small percentage of cases, hepatitis E can develop into an acute severe liver disease that is often fatal.
 - Pregnant women can develop severe disease with fulminant hepatic failure due to hepatitis E.
- **Hepatitis B.** A hepadnavirus endemic in certain parts of the world
 - Causes both an acute and chronic hepatitis, often with cirrhosis, and still remains a major cause of hepatocellular carcinoma, especially in Asia
 - Transmitted through exposure to blood and body fluids
 - Unprotected sexual contact—16% to 40% of unimmunized partners become infected
 - Blood transfusions
 - Use of contaminated needles and syringes
 - Vertical transmission—20% risk of transmission from mother to child without intervention in a hepatitis B surface antigen (HBsAg)-positive mother
 - Occupational exposure including needlesticks
 - Risk of transmission from a bloodborne exposure closely related to:
 - Volume of blood exposure
 - Number of copies of virus present in the blood of the source
 - Also related to the hepatitis B envelope antigen (HBeAg) status of the source patient
 - Patients both HBsAg and HBeAg positive, risk of developing clinical hepatitis from a needle injury was 22% to 31%; risk of developing serologic evidence of infection was 36% to 62%
 - If the source patient HBsAg positive HBeAg negative, risk of developing clinical hepatitis from a needle injury was 1% to 6%, and the risk of developing serologic evidence of hepatitis B infection was 23% to 37%
 - Hepatitis B survives in dried blood at room temperature for at least 1 week
 - Possible that contact with environmental surfaces is a potential risk for hepatitis B transmission
 - Shown in patients and staff of hemodialysis units
 - Key factor in preventing hepatitis B infection in the health care setting is vaccination
 - As with childhood vaccination, the protocol for adult immunization consists of three doses of the vaccine.
- In event that HCW is not immunized, postexposure prophylaxis available in the form of hepatitis B immune globulin (HBIG)
 - When indicated, HBIG should be given as soon as possible, preferably within 24 hours
 - Data on efficacy when HBIG was given after 7 days are not available
- Multiple doses of HBIG within 1 week of exposure are 75% effective in preventing hepatitis B infection.
- Postexposure hepatitis B vaccination is recommended in addition to HBIG because unimmunized HCWs continue to be at risk for exposure.
 - Data derived from vertical transmission regarding concurrent vaccination and HBIG administration show a better rate of prevention—85% to 95% with combined therapy as opposed to either therapy alone—70% to 75%.
- **Hepatitis C.** Hepatitis C is an RNA virus in the family Flaviviridae.
 - Replicates mainly in the hepatocytes after binding to specific receptors and entering the cells
 - Causes both acute and chronic hepatitis
 - Is a risk factor for development of hepatocellular carcinoma
 - Transmitted by direct contact with blood and body fluids containing blood
 - IV drug abusers seem to have highest incidence of hepatitis C
 - Due to the sharing of contaminated needles
 - Sexual transmission is possible but is largely due to blood contact.
 - Not other body fluids such as semen or vaginal secretions
 - Low incidence after accidental percutaneous exposure
 - Mucous membrane or skin exposures, both intact and nonintact, rarely result in transmission of hepatitis C.
 - No available vaccine for hepatitis C
 - No beneficial effect of giving immune globulin
 - Postexposure management aimed at early detection of hepatitis C infection and the development of chronic disease for which treatment can be given
 - Risk of acquiring hepatitis C varies depending on nature of exposure
 - Accidental percutaneous exposure from known HCV-positive source:
 - Incidence of seroconversion is 1.8%
 - Data limited on survival of HCV in environment
 - HCV-RNA is resistant to drying at room temperature for at least 48 hours

Herpes Viruses (HHV)

- DNA viruses that cause a variety of diseases in humans
- Several HHVs described including:
 - HHV-1 (also known as herpes simplex virus [HSV-1])
 - HHV-2 (herpes simplex virus [HSV-2])
 - HHV-3 (varicella-zoster virus [VZV])
 - HHV-4 (Epstein-Barr virus [EBV])
 - HHV-5 (cytomegalovirus [CMV])
 - HHV-6 (Roseolovirus)
 - HHV-7, and HHV-8 (Kaposi sarcoma–associated virus)
- Importance of these agents:
 - Seroprevalence of CMV documented to be up to 60% to 90% in adult populations
 - EBV generally self-limited mild disease
 - Can cause infectious mononucleosis in teenagers and young adults
 - HHVs of most importance in the health care setting are HSV-1, HSV-2, and VZV

- HSV-1 and HSV-2 cause blisters or sores either in the oral or genital area
 - Transmitted to HCW by direct contact with lesions, when present, and when appropriate use of precautions is forgone
- VZV the causative agent of chickenpox and shingles
 - Like other herpes viruses, VZV lies dormant in the dorsal root ganglia of the nervous system
 - Reactivates to produce zoster (“shingles”)
 - Transmitted both by direct contact with a patient who has active skin lesions (vesicles) as well as via respiratory secretions in which the virus is shed during active infection, such as disseminated zoster
 - Recommended approach to patients with varicella-zoster disease includes both contact and airborne isolation
- Exposure of nonimmune pregnant HCW to patients with CMV or VZV disease problematic
 - Primary infection with either virus during pregnancy can be devastating to both mother and child.
 - Up to 50% of pregnant women are seropositive for CMV.
 - Incidence of primary CMV during pregnancy is 1% to 4%.
 - Transmission of CMV requires prolonged or recurrent close contact and can also be transmitted sexually.
 - There are no effective therapies for treatment of CMV in pregnancy.
 - Prevention is best method to avoid complications of disease
 - Any patient can actively shed CMV without clinical signs or symptoms
 - This is the foundation for the CDC’s strong recommendation of meticulous adherence to handwashing before and after patient care as the best way to prevent disease transmission in *all* settings. In patients with proven or suspected CMV pneumonitis, mask and eye protection may be a consideration in the non-immune or seronegative pregnant HCW.
 - Vaccine available for VZV
 - Live, attenuated, and given in two doses spaced 4 to 8 weeks apart
 - 70% to 90% effective in preventing infection
 - 95% effective in preventing severe disease up to 10 years after administration
 - Recommended for nonpregnant women of childbearing age and is not recommended for pregnant women
 - Further stipulation being that women should not become pregnant for at least 1 month after each dose of the vaccine
 - If pregnant HCW who is nonimmune becomes exposed to VZV, postexposure prophylaxis is available.
 - VZV immunoglobulin recommended within 96 hours of exposure and has been reported to be up to 90% effective in preventing severe disease.
 - Recommended that nonimmune HCWs be vaccinated, especially female HCWs of childbearing age
 - If a pregnant HCW is not immune and has had exposure to VZV, prophylaxis should be instituted.
 - Contact and airborne precautions should be used at all times in patients with VZV disease.

Bacteria

- Standard precautions recommended for all patients
 - Additional precautions include contact precautions (MRSA, *C. difficile*, VRE) and airborne precautions (tuberculosis)

Methicillin-Resistant *Staphylococcus Aureus*

- A major problem both in hospital-acquired (HA-MRSA) infections as well as community-acquired (CA-MRSA) infections
 - Associated with both longer stays and higher costs
 - MRSA accounts for 55% of *S. aureus*-related infections in U.S. ICUs
 - CA-MRSA is microbiologically distinct isolate with a specific sensitivity pattern and the presence of the Panton-Valentine leukocidin (PVL) exotoxin
 - Factor responsible for the virulence of CA-MRSA remains uncharacterized
 - Methicillin resistance related to acquisition of a staphylococcal cassette chromosome (SCC) that is known as the *mecA* gene
 - CA-MRSA distinguished from hospital-acquired MRSA by the presence of type 4 SCC
 - Expression of the *mecA* gene leads to an altered penicillin-binding protein, PBP2a, which has a reduced affinity for β -lactam rings
 - CA-MRSA associated with significant skin and soft tissue infections
 - Often requiring emergency room surgical drainage
 - More severe infections, such as necrotizing pneumonia, necessitating hospital admission
 - Nosocomial infections with HA-MRSA include:
 - Catheter-related bacteremia, postsurgical wound infections
 - Postoperative neurosurgical meningitis
 - Ventilator-associated pneumonia
 - Device and graft infections
 - Risk factors for MRSA infection include:
 - Patients with open wounds or pressure ulcers
 - Invasive devices such as catheter, tracheostomy, gastrostomy, nasogastric tube, and indwelling bladder catheter
 - Recent antibiotic therapy
 - Hospitalization or significant health care contact within the past 6 months
 - Increased age
 - Male gender
 - Knowing the MRSA infection status of patients is helpful in determining who should be isolated or cohorted.
 - Nasal swabs for MRSA culture are a way to identify those who are colonized, but time delay in identifying these patients based on cultures makes this option less useful.
 - Polymerase chain reaction (PCR) has been proposed as a means of rapid identification of MRSA-colonized patients; however, this may not be cost effective.
 - There are differences in the ways that hospitals approach the issue of screening patients for MRSA.
 - But once isolated from culture patient should be immediately placed on contact precautions

- There are antibiotic options available to treat MRSA infections, as well as to decolonize carriers of MRSA.
- Prevention of spread is the most important method in combating MRSA infections.
 - The hospital should be placed on contact precautions.
 - Handwashing remains a critical factor in preventing spread.
 - HCWs must wash their hands before and after any contact with a patient.
 - Even when gloves are worn as part of MRSA contact precautions
 - Recommendations for preventing the spread of MRSA also include cohorting of patients if isolation in a single room is not possible.
 - Contact precautions should be observed meticulously.
 - Mask and eye protection are indicated if exposure to aerosols generated by the coughing patient is likely or when irrigating wounds.
 - Precautions for MRSA-infected or -colonized patients the same regardless of strain (HA-MRSA or CA-MRSA)
- Fomites implicated in transmission of MRSA
 - Environmental surfaces described as vectors of MRSA transmission include:
 - Plastic patient chart (survived 11 days)
 - Laminated tabletop (survived 12 days)
 - Cloth curtain (survived 9 days)
 - In the outpatient setting, environmental surfaces are important sources of transmission including:
 - Patient examination table
 - Computer keyboard
 - Pulse oximeter
 - Multiple patient chairs located in the triage station, the waiting room, and the examination room
 - Daily routine cleaning should be done with a disinfectant and performed in a sanitary manner as is done in all rooms regardless of the presence of MRSA.
 - Equipment should be routinely cleaned, disinfected, or sterilized per institution policy.

Clostridium Difficile

- *Clostridium* are Gram-positive rods that are anaerobic and spore forming.
- *C. difficile* is the causative organism of:
 - Pseudomembranous colitis
 - *C. difficile*-associated diarrhea (CDAD)
 - Occurs with the use of antibiotics that eradicate normal gut flora
 - Organism produces two toxins, enterotoxin (toxin A) and cytotoxin (toxin B), which are responsible for diarrhea and inflammation
 - Growing *C. difficile* in culture the gold standard for diagnosis
 - Enzyme-linked immunosorbent assay (ELISA) testing for toxin A or B has a high sensitivity and specificity when performed on three separate stool specimens
 - In addition to watery diarrhea, computed tomography (CT) scan of the abdomen demonstrating colonic wall thickening is a key finding.
 - Complications of untreated infection include toxic megacolon and bowel perforation.
- Major risk factor for the development of *C. difficile* diarrhea is the use of antibiotics.
 - Especially penicillins, clindamycin, and cephalosporins, particularly third-generation cephalosporins
 - Repeated enemas, prolonged nasogastric tube insertion, and gastrointestinal surgery increase the risk of developing a disease.
- The disease is spread from person to person by spores that are shed in stool.
- Spores can survive up to 70 days in the environment
- Can be carried on hands of HCW
 - Have direct contact with uninfected patients or with environmental surfaces—floors, bedpans, toilets—thus contaminating them with *C. difficile*
- Treatment of *C. difficile* colitis includes oral metronidazole or oral vancomycin
 - Newer agent, nitazoxanide, has not received U.S. Food and Drug Administration (FDA) approval for this indication, but shows promise in small clinical trials
 - Longer hospital stays and increased costs have been directly related to infection with *C. difficile*
 - Recommendations for preventing spread include:
 - Standard precautions and contact precautions if soiling of clothes is likely
 - Handwashing is the only method to be used in preventing spread of *C. difficile*.
 - The alcohol substitutes do not kill the spores
 - Mechanical action of applying the hand sanitizer may eliminate some spores from the hand of the HCW
 - Limiting the use of inappropriate antibiotics is central to lowering risk of developing *C. difficile*-associated diarrhea.

Vancomycin-Resistant Enterococcus

- Enterococci are Gram-positive, facultatively anaerobic organisms that colonize the gastrointestinal tract
- Two species commensal in the intestines of humans:
 - *Enterococcus faecalis* (90% to 95%)
 - *Enterococcus faecium* (5% to 10%)
- Organism not highly invasive, infections caused by enterococci include:
 - Catheter-related bacteremia
 - Urinary tract infections
 - Diverticular abscess
 - Cholangitis
 - Endocarditis
- Many strains of enterococci remain susceptible to ampicillin, penicillin, and vancomycin
 - An alarming increase in the incidence of VRE
 - Concern regarding resistance in other bacteria, such as *S. aureus*, as VRE appears to have an enhanced ability to pass resistant genes (such as vanA) to other Gram-positive organisms
 - Risk factors for VRE colonization and infection not clearly identified
 - Higher incidence in transplant and chemotherapy patients in ICU setting who have renal insufficiency
 - Higher risk of colonization and infection is logically associated with intra-abdominal surgery or gastrointestinal tract manipulation such as:
 - Endoscopic retrograde cholangiopancreatography (ERCP)

- Indwelling urinary catheters
- Enteral feeding tubes
- Central venous catheters
- Patients on broad-spectrum antibiotics
 - Especially oral vancomycin, at higher risk for colonization or infection
 - Use of intravenous vancomycin is associated to a lesser extent with VRE colonization and infection
- Transmission occurs from a colonized or infected patient to the HCW via direct contact with either the patient or contaminated environmental surfaces (fomites)
- Lack of proper hand hygiene appears to be the major factor in the spread of VRE from patient to HCW and back to other patients
 - Dramatic decrease in incidence of VRE with enforcement of proper hand hygiene
 - Either with alcohol-based solutions or with routine handwashing
 - Proper environmental cleaning decreases transmission of VRE
 - Colonized or infected VRE patients should be placed in contact isolation to prevent spread.
- Screening for VRE has been addressed
 - Advantage in a clinical active surveillance strategy (culture of a rectal swab on admission, weekly while patient in ICU, and at discharge)
 - Cost savings ranging from \$56,258 to \$303,334 per month
 - Decision should be made at the institutional level regarding the cost effectiveness of a screening program
 - Available data support strong consideration for a routine screening program with preventive measures (contact isolation) to help control spread of VRE

Tuberculosis

- *Mycobacterium tuberculosis* (MTb) the causative agent of all forms of tuberculosis—pulmonary, central nervous system (CNS), and disseminated
- Spread by aerosol droplets from persons with active infection when they cough, sneeze, speak, or spit
- Infectious droplets are 0.5 to 5 μm in diameter
 - About 40,000 can be produced in a single sneeze
 - 3,000 in a single cough
 - Transmission from person to person depends on several factors, including:
 - Quantity of infectious droplets expelled
 - Effectiveness of ventilation
 - Duration of exposure
 - Virulence of mycobacterial strain
 - Persons who are in direct contact with an infected patient, either frequently or for a prolonged time, have the highest risk of developing tuberculosis.
 - Estimated infection rate of 22%
 - Person with untreated, active tuberculosis can infect 10 to 15 people per year.
 - Others at risk for infection include:
 - Persons living in endemic areas—some parts of Asia, Haiti, and South America
 - Immunocompromised patients—those with HIV/AIDS and those on immunosuppressive medications
 - HCWs serving high-risk patients
 - IV drug abusers

- Single males, alcoholics, the urban poor—especially the homeless—migrant farm workers, and prison inmates have been associated with a higher frequency of tuberculosis
- Rate of tuberculosis in United States has steadily declined since a resurgence between 1985 and 1992 that correlated with the AIDS epidemic prior to the development of highly active antiretroviral therapy (HAART)
- Now majority of MTb cases in United States diagnosed in persons who are immigrants from endemic areas
- A recent deceleration in the yearly percentage of decline
 - From average of 7.1% per year (1993 through 2000)
 - To 3.8% per year (2001 through 2005)
 - Raised concerns regarding the progress toward the goal of eliminating MTb in United States
 - CDC has noted racial/ethnic disparities, as well as a disparity between U.S.-born and foreign-born MTb rates
 - 2005, Hispanics, African Americans, and Asians were respectively 7.3, 8.3, and 19.6 times more likely than whites to become infected with the disease
 - MTb rates were 8.7 times higher for foreign-born individuals compared U.S. counterparts
 - More than half of foreign-born cases were reported in patients from Mexico, the Philippines, Vietnam, India, and China
 - More alarming data from the most recent CDC report is the finding of higher rates of multidrug- and extended drug-resistant tuberculosis
- Most effective way to prevent the spread of tuberculosis to HCW:
 - Identify patients at high risk of active infection
 - Includes an assessment of symptoms
 - Fever, night sweats, shortness of breath, hemoptysis, and weight loss
 - Demographic factors including questioning about:
 - Immigration from an endemic area
 - Recent incarceration
 - Contact with patients known to have tuberculosis
 - Identified patients must be placed in a negative pressure isolation room with airborne precautions
 - Should have three expectorated or induced sputum specimens sent for acid-fast staining and culture for acid-fast bacilli (AFB)
 - Patients with suspected MTb infection cannot be removed from isolation until three adequate sputum specimens—or an equivalent, such as specimens obtained by bronchoscopy or bronchoalveolar lavage—have been obtained and are negative for AFB by smear.
 - AFB culture may take up to 6 weeks to grow organisms, and is therefore not used to decide on discontinuation of isolation unless there is a very high index of suspicion.
 - MTb DNA PCR can be used on a variety of AFB-negative body fluids or can be used to determine if early growth of AFB in liquid media is MTb or a nontuberculous mycobacteria

Gram-Negative Organisms

- Incidence of multidrug-resistant, Gram-negative infections has stirred debate as to whether isolation precautions as in place for resistant Gram positives should be instituted

- National Nosocomial Infections Surveillance System has reported increases in the prevalence of multidrug-resistant Gram-negative infections including:
 - *Pseudomonas*
 - *Enterobacter*
 - *Klebsiella*
 - Extended-spectrum β -lactamase (ESBL)–producing organisms
- Some institutions have reported outbreaks of highly resistant *Acinetobacter baumannii* infections
 - Interest in *Acinetobacter* is growing now that the organism has been found in soldiers returning from Iraq and Afghanistan
- Not sufficient evidence to determine that infection control measures would be effective in controlling the spread of multidrug-resistant Gram-negative bacteria
- Outbreaks of resistant Gram-negative infections associated with catheters and other intravascular devices including one report of *Stenotrophomonas* prosthetic valve endocarditis
 - Fatalities have been reported
 - Control of outbreaks has included both antibiotic restriction as well as institution of contact isolation
 - When dealing with multidrug-resistant, virulent, Gram-negative organisms, especially in such settings as the ICU
 - Contact isolation should be strongly considered for use in colonized and infected patients as suggested by CDC guidelines

CHAPTER 69 ■ AN APPROACH TO THE FEBRILE INTENSIVE CARE UNIT PATIENT

- Fever is a common problem in the intensive care unit (ICU).
 - Approximately 70% of patients developing a fever at some point during their hospital stays.
 - Infectious and noninfectious etiologies contribute almost equally to causation.
 - Discovery of fever in ICU patient has significant impact on health care costs due to:
 - Blood cultures
 - Radiologic imaging
 - Antibiotics that routinely follow
 - Important to have a good understanding of the mechanisms and etiology of fever in ICU patients, how and when to initiate a diagnostic workup, and when initiation of antibiotics is indicated
 - Temperature of 38.3°C or greater (101°F) in an ICU patient warrants further evaluation
 - Temperature below 38.3°C (101°F) may also require further investigation
 - Many variables determine a patient's febrile response to an insult
 - Daily fluctuation of temperature by 0.5°C to 1.0°C
 - Women having wider variations in temperature than men
 - With aging, the maximal febrile response decreases by about 0.15°C per decade
 - Accurate and reproducible measurement of body temperature important in detecting disease and in monitoring patients with an elevated temperature
 - Methods are used to measure body temperature:
 - Mixed venous blood in pulmonary artery optimal site for core temperature measurement
 - Infrared ear thermometry provides values a few tenths of a degree below temperatures in pulmonary artery and brain
 - Rectal temperatures obtained with a mercury thermometer or electronic probe often a few tenths of a degree higher than core
 - Patients perceive having rectal temperatures taken as unpleasant and intrusive
 - Access to rectum may be limited by patient position, with an associated risk of rectal trauma
 - Oral measurements influenced by events such as:
 - Eating and drinking
 - Presence of respiratory devices delivering warmed gases
 - Many tachypneic patients are unable to keep their mouth closed to obtain accurate temperature
 - Axillary measurements substantially underestimate core temperature and lack reproducibility
 - Body temperature therefore most accurately measured with an intravascular thermistor
 - Measurement by infrared ear thermometry or with an electronic probe in the rectum is an acceptable alternative

PATHOGENESIS OF FEVER

- Cytokines released by monocytic cells play a central role in the genesis of fever
 - Interleukin-1 (IL-1)
 - Interleukin-6 (IL-6)
 - Tumor necrosis factor- α (TNF- α)
- Interaction between these cytokines is complex
 - Each able to up-regulate and down-regulate their own expression as well as that of the other cytokines
 - Cytokines bind to specific receptors located in close proximity to preoptic region of the anterior hypothalamus
 - Cytokine receptor interaction activates phospholipase A₂

- Resulting in the liberation of plasma membrane arachidonic acid as substrate for the cyclo-oxygenase pathway
- Some cytokines appear to increase cyclo-oxygenase expression directly, leading to the liberation of prostaglandin E₂ (PGE₂)
- Is fever good or bad?
 - If fever of hospitalized patients admitted to a trauma ICU treated, a strong trend toward increased mortality
 - All patients who died in aggressive treatment group had an infectious etiology as cause of fever
 - Children with varicella treated with acetaminophen had a more prolonged illness
 - Patients with spontaneous bacterial peritonitis had improved survival if they had a temperature >38°C.
 - Thus, fever from an infectious cause should not be treated unless the patient has limited cardiorespiratory reserve.
 - In contrast, patients with cerebral ischemia or head trauma have worse outcomes with increased temperature.
 - Current recommendation to maintain patient's temperature in normothermic range
- Antipyresis must always include an antipyretic agent, as external cooling alone increases heat generations and catecholamine production
- Acute hepatitis may occur in ICU patients with reduced glutathione reserves (alcoholics, malnourished, etc.) who have received regular therapeutic doses of acetaminophen

FEVER PATTERNS

- Evaluation of patient's fever pattern fraught with uncertainty and not likely to be helpful diagnostically:
 - Most patients have remittent or intermittent fever
 - When due to infection, usually follows a diurnal variation
 - Sustained fevers have been reported in patients with Gram-negative pneumonia or central nervous system (CNS) damage
 - Appearance of fever at different time points in course of patient's illness may provide some diagnostic clues
 - Fevers that arise more than 48 hours after institution of mechanical ventilation may be secondary to a developing pneumonia
 - Fevers arising 5 to 7 days postoperatively may be related to abscess formation
 - Fevers arising 10 to 14 days after institution of antibiotics for intra-abdominal abscess may be due to fungal infections

CAUSES OF FEVER IN THE INTENSIVE CARE UNIT

- Any disease process releasing IL-1, IL-6, and TNF- α will result in fever.
- Infections are common causes of fever in ICU patients.
 - But noninfectious inflammatory conditions cause release of proinflammatory cytokines and induce a febrile response
 - Not all patients with infections are febrile.
 - Approximately 10% of septic patients are hypothermic, 35% normothermic at presentation
 - Septic patients who fail to develop a fever have a significantly higher mortality than febrile septic patients.

- Important ICU fever be evaluated in a systematic, prudent, clinically appropriate, and cost-effective manner

Infectious Causes of Fever in the Intensive Care Unit

- Prevalence of nosocomial infection in ICUs reported to vary from 3% to 31%
- The most common infectious causes of fever in ICU patients are listed in Table 69.1.

Catheter-Related Bloodstream Infection (CRBI)

- Intravenous (IV) catheters are a major source of infection in the ICU.
- Mean incidence of CRBI in United States is 5.3 per 1,000 catheter-days
 - Coagulase-negative staphylococci account for up to 40% of cases
- Other common causes of CRBI include:
 - Enterococci
 - *Staphylococcus aureus*
 - *Candida* species
 - Aerobic Gram-negative bacilli
 - Methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococci (VRE) are becoming important causes of CRBI.
- Different mechanisms lead to CRBI:
 - Skin pathogens can infect the catheter exit site and then migrate down the tract along the external catheter surface.
 - Pathogens can also contaminate the catheter hub, leading to intraluminal catheter colonization and infection.
 - Hematogenous seeding of the external surface of the catheter may also occur.
 - Despite rigorous skin disinfection, viable micro-organisms can be impacted during insertion of the distal tip of the catheter, causing infection.
 - A number of factors increase the risk of CRBI:
 - Number of lumens in the central venous catheter
 - Number of stopcocks
 - Transfusion of blood and blood products
 - Parenteral nutrition
 - An open infusion system

TABLE 69.1

MOST COMMON INFECTIOUS CAUSES OF FEVER IN THE INTENSIVE CARE UNIT

Catheter-related bloodstream infection
 Ventilator-associated pneumonia
 Primary septicemia
 Sinusitis
 Surgical site/wound infection
Clostridia difficile colitis
 Cellulitis/infected decubitus ulcer
 Urinary tract infection
 Suppurative thrombophlebitis
 Endocarditis
 Diverticulitis
 Septic arthritis
 Abscess/empyema

- Catheter-related thrombosis is associated with an increased risk of catheter infection.
 - Thrombocytopenia has been suggested to be protective against CRBI.
- AIDS and hematologic malignancies are independent risk factors for CRBI.
- Site of central venous catheter (CVC) placement and length of time it can be left indwelling a controversial topic
- Generally subclavian catheters have been found to have a lower risk of infection than femoral catheters.
- No difference in risk of CRBI between subclavian, internal jugular, and femoral catheter placement
- Risk of CRBI increases with the time the catheter remains *in situ*.
 - Changing catheters at regularly scheduled intervals not shown to reduce risk of CRBI
- Diagnosis of CRBI can be challenging.
 - Routine culture of blood withdrawn from catheter not recommended
 - Catheter exit site should be inspected daily for evidence of erythema or pus
 - Absence of local infection does not exclude CRBI
 - In patient with indwelling CVC developing a fever
 - Two sets of blood cultures should be drawn:
 - One from the catheter
 - One from a peripheral source
 - If patient has systemic signs of infection and no other identifiable source of infection, catheter should be removed and empiric antibiotics commenced pending culture results
 - In patients with limited venous access, CVC may be replaced with a new catheter over a guidewire.
 - Both catheter tip and the intracutaneous portion of the catheter should be sent for culture
 - If catheter culture returns positive (>15 colony-forming units [CFU]), or the blood cultures are consistent with a CRBI, the catheter that was changed over a guidewire must be removed and replaced with a new catheter at a clean site.
 - Follow-up blood cultures should be obtained in patients with CRBI:
 - If positive, thorough investigation for septic thrombosis, infective endocarditis, and other metastatic infections should be pursued
- Methods have been investigated for the diagnosis of CRBI that do not require removal of CVC.
 - Comparison of blood cultured from the central catheter with that from a peripheral venous site is a most useful technique.
 - In CRBI quantitative culture counts are greater and time to positivity shorter with blood withdrawn from the catheter as opposed to the peripheral site
 - Acridine-orange leukocyte cyto-spin testing, available in some countries, is a rapid, inexpensive test that can also be used to prevent unnecessary removal of catheters.
 - Endoluminal brushing, in which the CVC is sampled within 3 to 5 cm of the catheter tip, has also been demonstrated to be useful in the diagnosis of CRBI.
- Between 10% and 25% of patients on mechanical ventilation will develop VAP during ICU stay
- VAP is associated with significant costs and has an attributable mortality of about 25%
- Risk of acquiring VAP is highest in the first week, at 3% a day
 - Thereafter decreasing to 2% a day in the second week
 - Down to 1% a day in the third and subsequent weeks
- Risk of VAP is higher in trauma, burn, and neurosurgical units compared to medical ICUs
- VAP is usually categorized as either:
 - Early: occurring <48 hours after intubation
 - Late onset: occurring after 5 to 7 days of intubation
 - Distinction between these two phases of VAP is vitally important, as they are associated with different pathogens
 - Early-onset VAP is associated with bacteria that are normally sensitive to antibiotics:
 - Methicillin-sensitive *S. aureus*
 - *Haemophilus influenzae*
 - *Streptococcus pneumoniae*
 - Late onset is typically associated with antibiotic-resistant bacteria:
 - MRSA
 - *Pseudomonas aeruginosa*
 - *Acinetobacter* species
 - *Enterobacter* species
- Major risk factors for VAP include:
 - Age over 60 years
 - Male gender
 - Chronic lung disease
 - Acute respiratory distress syndrome
 - Aspiration
 - Sinusitis
 - Nasogastric tube
 - Transport in and out of the ICU
 - Failure to elevate the head of the bed
 - Endotracheal cuff pressures <20 cm of H₂O
 - Increased severity of illness
 - Delayed extubation
 - Continuous sedation
 - Cardiopulmonary resuscitation
 - Medications including H₂ blockers and paralytic agents
- Diagnosis of VAP:
 - VAP suspected when a patient on mechanical ventilation develops a new infiltrate on a chest radiograph (CXR) along with:
 - Leukocytosis
 - Fever
 - Purulent tracheobronchial secretions
 - Presence of new infiltrate on CXR, together with two of above-cited clinical findings:
 - Has sensitivity of 69% with a specificity of 75% for diagnosis of VAP
 - Decision to treat a suspected VAP on clinical grounds alone will frequently overdiagnose the condition and lead to treatment that fails to cover the correct pathogen in patients with true VAP
 - Quantitative cultures of secretions obtained from lower respiratory tract can facilitate making VAP diagnosis.
 - Two most common techniques include:
 - Protected specimen brush (PSB) sampling
 - Bronchoalveolar lavage (BAL)

Ventilator-Associated Pneumonia (VAP)

- Common source of fever in intubated patient
- Intubation increases the risk of developing pneumonia from 6- to 21-fold

- These techniques can be performed bronchoscopically or blindly
 - Blind bronchial suctioning and mini-bronchoalveolar lavage are gaining popularity
 - Shown to be as effective as a protected specimen brush
- These are generally safe, inexpensive tests that can be performed by respiratory therapists without a physician present
 - We are aware of significant complications caused by mini-BAL and recommend great care and thought before initiating its use
 - The threshold for positivity is 1,000 CFU/mL for PSB
 - 10,000 CFU/mL for BAL
 - A threshold of 500 and 5,000 CFU/mL, respectively, will increase the sensitivity of the tests, but this is controversial.
 - Microscopic examination of BAL fluid is used to facilitate the diagnosis of VAP.
 - With <50% neutrophils, pneumonia can be excluded.
 - Role of quantitative culture of tracheal aspirates (as opposed to lower respiratory tract sampling) is unclear at this time.
 - Effect of quantitative culture techniques on patient outcome is unclear.
 - However, these techniques result in a significant reduction in the use of antibiotics.

Urinary Tract Infection (UTI)

- Most ICU patients require an indwelling urinary catheter for monitoring fluid balance and renal function.
- UTIs are the third most common infection found in the ICU.
 - In patients admitted to the ICU for at least 48 hours:
 - 6.5% developed a UTI
 - Overall incidence of 9.6 cases per 1,000 ICU days
 - Incidence of bacteremia and fungemia was only 0.1 case per 1,000 catheter-days
 - UTIs more common in medical ICU and least likely in cardiothoracic patients
 - Reported risk factors for UTIs include:
 - Female gender
 - Age over 60 years
 - Antimicrobial therapy use
 - Severity of illness
 - Duration of urinary catheterization
 - Presence of urinary catheter for longer than 4 to 5 days increases risk of UTI
 - Gram-negative bacteria, especially *Escherichia coli* and *Pseudomonas aeruginosa*, account for more than half of pathogens
 - Gram-positive organisms, especially *Enterococcus* and *Candida*, account for remaining cases
 - Risk factors for funguria include:
 - Immunosuppression
 - Diabetes
 - Renal failure
 - Structural or functional abnormalities of the urinary tract
 - Recent surgery
 - Chronic illness
 - Broad-spectrum antibiotics
 - Examination of the urine with “dipsticks” for leukocyte esterase and nitrate is insensitive and not a substitute for quantitative culture.
- Significance of UTIs in catheterized ICU patients unclear
 - Appear unlikely to lead to increased morbidity or mortality
 - Most patients have asymptomatic bacteriuria rather than true infections of the urinary tract.
 - Treatment of patients with asymptomatic bacteriuria is based on a single study performed in the early 1980s that may not be applicable today.
 - In hospitalized patients, bacteriuria $\geq 10^5$ CFU of bacteria per mL urine during bladder catheterization was associated with a 2.8-fold increase in mortality.
 - Based on this study, thousands of ICU patients with urinary tract colonization have been, and continue to be, treated with antibiotics. Recent studies suggest that this approach may not be optimal.
 - In patients with indwelling urinary catheters, colonic flora rapidly colonizes the urinary tract.
 - In catheterized patients, bacteria rapidly proliferate in the urinary system to exceed 10^5 CFU/mL over a short period of time
 - Bacteriuria-quantitative culture $\geq 10^5$ CFU/mL reported in up to 30% of catheterized hospitalized patients
 - Bacteriuria implies colonization of the urinary tract without bacterial invasion and an acute inflammatory response
 - Urinary tract infection implies an infection of the urinary tract
 - Criteria have not been developed for differentiating asymptomatic colonization of the urinary tract from symptomatic infection.
 - Presence of white cells in urine is useful for differentiating colonization from infection
 - Most catheter-associated bacteriuria have accompanying pyuria
 - Unclear how many catheterized patients with $\geq 10^5$ CFU/mL actually have UTI
 - Catheter-associated bacteriuria common in ICU patients
 - Less than 3% of catheter-associated bacteriuric patients will develop bacteremia caused by organisms in the urine
 - Surveillance for, and treatment of, isolated bacteriuria in most ICU patients is currently not recommended.
 - Bacteriuria should be treated following:
 - Urinary tract manipulation
 - Surgery in patients with kidney stones
 - Urinary tract obstruction
 - With systemic signs of infection together with bacteriuria and no other obvious source of infection:
 - Prudent to treat this patient with a short course of antibiotics
 - Ultrasonography to exclude urinary tract obstruction and repeat urine culture is recommended
 - Treatment clearly indicated in patients with bacteriuria who develop bloodstream infection
 - Isolated *Candida* lower UTI exceedingly uncommon
 - When diagnosis entertained, *Candida* infection of kidney should be excluded

Sinusitis

- An underappreciated cause of fever in the ICU
 - Diagnosis is usually not considered or made until other, more common infectious causes of fever excluded
 - If not diagnosed and treated in a timely fashion, can lead to nosocomial pneumonia and severe sepsis

- Risk factors of acquiring nosocomial sinusitis:
 - Nasal colonization with enteric Gram-negative rods
 - Nasoenteric tubes
 - Glasgow Coma Scale score <7
 - Patients who are orally intubated are less prone to develop sinusitis than those who are nasotracheally intubated
 - Up to 85% of nasally intubated patients will develop sinusitis within a week
- In patients with radiologic evidence of sinusitis:
 - Aspiration of the sinuses is required to confirm the diagnosis and to identify the causative pathogen.
 - Radiologic tests employed to identify problem
 - Computed tomography (CT) scan of sinuses is considered gold standard study
 - If patient too ill to be transported from ICU, plain films of sinuses may be obtained
 - To maximize chances of making diagnosis, multiple views required
 - Bedside ultrasound gaining popularity in European countries over the past decade
 - May be at least equivalent to CT scanning
- Once sinusitis diagnosed:
 - All nasal tubes should immediately removed
 - Early sinus drainage performed
 - Broad-spectrum antibiotics should be commenced
 - Coverage will include *Pseudomonas* and MRSA
 - Antibiotics should then be deescalated once culture data are available
 - Topical decongestants and vasoconstrictors, alone or combined with systemic decongestants and antihistamines, are also recommended

Clostridium Difficile Colitis

- See above
- Crucial to diagnose this disease early, as it can lead to severe sepsis, multiorgan system failure, and death
- Often present with a leukemoid reaction, with white blood cell (WBC) counts reaching >35,000 cells/ μ L
 - Leukemoid reaction or unexplained leukocytosis may be presenting sign of *C. difficile*
 - Even in the absence of diarrheal symptoms
 - *C. difficile* presenting with a leukemoid reaction associated with worse prognosis and higher mortality
- Concurrent or prior antibiotic use a strong risk factor
 - Clindamycin
 - β -lactams (especially cephalosporins)
 - Quinolones
- Proton pump Inhibitors associated with a higher risk of *C. difficile* infection
- Epidemics of extremely virulent strain of *C. difficile* reported in United States and Canada
 - Suggested that increasing use of fluoroquinolones has played a role
 - Strain associated with higher morbidity and mortality
 - Produces significantly more toxins than do the other strains
- The diagnosis of *C. difficile* colitis:
 - Usually made by immunoassays of stool against both toxin A and toxin B
 - Presence of *C. difficile* antigen in absence of toxin suggests colonization
- Low sensitivity of the toxin assay results in two stool specimens being examined
- Cytotoxic assay more sensitive and specific but not readily available and takes longer to perform
- Where diagnosis is in doubt, colonoscopy performed to look for pseudomembranes
- CT scan may be helpful
 - 50% of patients will have changes that can be seen on imaging
 - Positive CT scans are associated with leukocytosis, abdominal pain, and diarrhea
- If *C. difficile* colitis is suspected:
 - Empiric treatment should be started until diagnosis excluded
 - Alcohol-based hand hygiene does not kill spore-forming organisms such as *C. difficile*
 - Should not replace handwashing with soap

Skin Infections

- Especially infected pressure ulcers, may be a source of infection in ICU patients
- Several factors increase the risk of ICU patients developing pressure ulcers, including:
 - Emergent admissions
 - Severity of illness
 - Extended ICU length of stay
 - Malnutrition
 - Age
 - Diabetes
 - Infusion of vasopressor agents
 - Anemia
 - Fecal incontinence
- Protocols for prevention of pressure ulcers should be routine in ICU
 - Physicians and nurses should routinely examine their patient's skin
 - Particularly high-pressure areas such as sacrum and heels to detect early signs of skin breakdown

Other Infections

- Nosocomial meningitis exceedingly uncommon in hospitalized patients who have not undergone a neurosurgical procedure
 - Lumbar puncture does not need to be performed routinely in nonneurosurgical ICU patients who develop a fever
 - Unless they have meningeal signs or contiguous infection
- Patients who have undergone abdominal surgery and develop a fever, intra-abdominal infection must always be excluded
 - Evaluation includes CT scanning of the abdomen
- In patients who have undergone other operative procedures, wound infection must be excluded

Noninfectious Causes of Fever in the Intensive Care Unit

- Many noninfectious conditions result in tissue injury with inflammation and fever Table 69.2.
- Most noninfectious disorders usually do not lead to a fever in excess of 38.9°C (102°F)
 - Reason is unclear

TABLE 69.2**NONINFECTIOUS CAUSES OF FEVER IN THE INTENSIVE CARE UNIT****Drug-related**

Drug fever
 Neuroleptic malignant syndrome
 Malignant hyperthermia
 Serotonin syndrome
 Drug withdrawal (including alcohol and recreational drugs)
 Intravenous contrast reaction

Posttransfusion Fever**Neurologic**

Intracranial hemorrhage
 Cerebral infarction
 Subarachnoid hemorrhage
 Seizures

Endocrine

Hyperthyroidism
 Pheochromocytoma
 Adrenal insufficiency

Rheumatologic

Crystal arthropathies
 Vasculitis
 Collagen vascular diseases

Hematologic

Phlebitis
 Hematoma

Gastrointestinal/Hepatic

Acalculous cholecystitis
 Ischemic bowel
 Cirrhosis
 Hepatitis
 Gastrointestinal bleed
 Pancreatitis

Pulmonary

Aspiration pneumonitis
 Acute respiratory distress syndrome
 Thromboembolic disease
 Fat embolism syndrome

Cardiac

Myocardial infarction
 Dressler syndrome
 Pericarditis

Oncologic

Neoplastic syndromes

- Generally, if the temperature increases above this threshold, the patient should be considered to have an infectious etiology
 - Patients with drug fever may have a temperature $>102^{\circ}\text{F}$
 - Fever secondary to blood transfusion may exceed 102°F
 - With a temperature $>40^{\circ}\text{C}$ (104°F), must consider:
 - Neuroleptic malignant syndrome
 - Malignant hyperthermia
 - “Serotonin syndrome”
 - Subarachnoid hemorrhage

Drug-Induced Fever

- Estimated that about 10% of inpatients develop drug fever during their hospital stay
 - Patients with human immunodeficiency syndrome (HIV) at a particularly high risk of developing a drug fever

- Diagnosis of drug fever in ICU patients is challenging
 - Onset of fever can occur immediately after administration of the drug or it can occur days, weeks, months, or even years after the patient has been on the offending medication.
 - Once implicated medication is discontinued, fever can take 3 to 4 days to resolve.
 - Associated rashes and leukocytosis occur in $<20\%$ of cases.
 - Penicillins, cephalosporins, anticonvulsants, heparin, and H_2 blockers commonly used medications in ICU associated with drug fevers
- Five mechanisms have been described that give rise to drug fevers:
 - Most common mechanism is a hypersensitivity reaction to the drug
 - Medications can cause fever by disrupting normal thermoregulatory mechanisms of the body
 - Drugs can cause fever directly related to administration of the drug
 - From contamination of the solution with endotoxin or other exogenous pyrogens
 - Can also cause a chemical phlebitis or inflammation at the site of injection
 - Due to the direct extension of the pharmacologic action of the drug
 - Chemotherapy with cell necrosis, lysis, and the release of various pyrogenic substances
 - Antimicrobial therapy with the release of bacterial products into the circulation, known as the Jarisch-Herxheimer reaction
 - Idiosyncratic reactions including:
 - Malignant hyperthermia
 - Neuroleptic malignant syndrome
 - Serotonin syndrome
 - Glucose-6-phosphate dehydrogenase deficiency
 - **Malignant Hyperthermia.** A rare genetic disorder of the muscle membrane causing an increase of calcium ions in the muscle cells
 - Can cause a variety of clinical problems, most commonly a dangerous hypermetabolic state after the use of agents such as succinylcholine and the potent inhaled anesthetic agents
 - Typically occurs within 1 hour of anesthesia but can be delayed for up to 10 hours
 - Patients present with continually increasing fevers, muscle stiffness, and tachycardia.
 - Can rapidly develop hemodynamic instability with progression to multiorgan failure
 - With dantrolene, mortality of malignant hyperthermia has decreased from 80% in the 1960s to $<10\%$
 - **Neuroleptic Malignant Syndrome.** Characterized by high fevers, a change in mental status, muscle rigidity, extrapyramidal symptoms, autonomic nervous system disturbances, and altered levels of consciousness
 - Symptoms usually begin within days to weeks of starting the offending drug
 - Typically see very high creatinine kinase levels
 - Caused by excessive dopaminergic blockade causing CNS dopamine deficiency
 - Agents most commonly implicated include:
 - Neuroleptic medications
 - Certain antiemetics

- Treatment includes discontinuing the offending drug, aggressive supportive care, and close hemodynamic monitoring
- Drug treatment controversial
 - Case control analysis and a retrospective analysis of published cases suggested that dantrolene, bromocriptine, and amantadine may be beneficial.
- **Serotonin Syndrome.** Shares many of the clinical features found in neuroleptic malignant syndrome
 - Typically have lower fevers than those with neuroleptic malignant syndrome, but have more gastrointestinal dysfunction
 - Neuromuscular findings are more consistent with hyper-reactivity
 - Tremors
 - Clonus
 - Muscular hypertonicity
 - Presentation is much more rapid than that of neuroleptic malignant syndrome
 - 74.3% of patients presented within 24 hours of medication initiation, overdose, or change in dosage
 - 61.5% presented within the first 6 hours
 - Hunter Serotonin Toxicity Criteria commonly used to evaluate likelihood of serotonin syndrome
 - Criteria include the following features in a patient recently administered a serotonergic agent:
 - Spontaneous clonus
 - Inducible clonus
 - Ocular clonus
 - Agitation or diaphoresis
 - Tremor and hyperreflexia
 - Hypertonicity
 - Fever >38°C
 - Benzodiazepines used for control of agitation
 - Physical restraints should be avoided
 - Cyproheptadine, an H₁-receptor antagonist with non-specific 5-HT_{1A} and 5-HT_{2A} antagonistic properties, has been used in patients who respond poorly to benzodiazepines alone.
 - Paralysis with nondepolarizing agents, endotracheal intubation, and mechanical ventilation may be needed in severely agitated and hyperthermic patients

Alcohol and Drug Withdrawal

- Withdrawal from alcohol and medications is a common cause of noninfectious fever in hospitalized patients.
- Usually presents within the first few days of hospital admission
- Can present in a variety of ways including:
 - Fever alone
 - Neuroleptic malignant-like syndromes
 - Fever with hemodynamic instability
- Important to get an accurate list of current medications at the time of admission
- Drug withdrawal syndromes have been described with the use of:
 - Baclofen
 - Selective serotonin reuptake inhibitors (SSRI)
 - Antidepressants
 - Levodopa
 - Narcotics

- Certain street drugs
- Some herbal remedies

Crystal-Associated Arthritis

- Patients in the ICU at increased risk of developing gout or pseudogout
- Thorough physical examination focusing on joints and an arthrocentesis to examine the synovial fluid are essential in making this diagnosis
- Gout will typically present as a monoarthritis
 - Patients at increased risk for gout have:
 - Increased body mass index
 - Hypertension
 - Alcohol consumption
 - Renal disease
 - Trauma, surgery, and severe infection are associated with an abrupt drop in uric acid level, which can trigger acute gout.
 - Loop diuretics, iodinated contrast dye, and total parenteral nutrition may also precipitate gout.
- Calcium pyrophosphate dehydrate crystal deposition disease (pseudogout)
 - Most commonly affects the knee
 - Can be triggered by trauma, surgery, or severe medical illness
 - Increased risk with electrolyte disorders:
 - Hypomagnesemia
 - Hypophosphatemia
 - Also associated with endocrine and metabolic disorders:
 - Hyperparathyroidism
 - Hemochromatosis
 - Wilson disease
 - Hypothyroidism

Acalculous Cholecystitis

- Condition of inflammation of the gallbladder in the absence of calculi
- Carries significant morbidity and mortality
 - Can lead to:
 - Empyema
 - Gallbladder gangrene
 - Gallbladder perforation
- High index of suspicion required as a difficult diagnosis to make
 - Especially in intubated and sedated patient
 - Initially patients present with very few symptoms
 - Clinical features include:
 - Fever
 - Leukocytosis
 - Abnormal liver function tests
 - Palpable right upper quadrant mass
 - Vague abdominal discomfort
 - Jaundice
 - Untreated, bacterial superinfection may occur
 - Can progress to empyema, peritonitis, and septic shock
- Pathophysiology complex and involves hypoperfusion and biliary stasis
 - Risk factors include everything seen in the ICU:
 - Trauma
 - Surgery
 - Intermittent positive pressure ventilation
 - Coronary heart disease

- Cholesterol emboli
- Fasting
- Total parental nutrition
- Immunosuppression
- Transfusions of blood products
- Hypotension
- Multiorgan dysfunction
- Sedation/opiates
- Diabetes
- Infections
- Childbirth
- Renal failure
- Ultrasound usually first diagnostic test performed, as it may be performed at bedside
 - Ultrasound inferior to morphine cholescintigraphy and CT
 - Ultrasound has sensitivity of 29% to 50% compared to 67% to 90% for morphine cholescintigraphy with specificity of 94% and 100%, respectively
 - Abnormal ultrasound can be seen in 50% of ICU patients, even if they are not suspected of having acalculous cholecystitis
 - As soon as the diagnosis is suspected:
 - Blood cultures should be drawn
 - Broad-spectrum antibiotics initiated
 - Surgical consult requested
 - Percutaneous drainage preferable to surgical intervention in unstable patient

Postoperative Fever

- Surgery alone can cause self-limited fever
 - Early postoperative period patient's temperature may increase up to 1.4°C
 - Peak occurs approximately 11 hours after surgery
 - 50% of postoperative patients develop a fever $\geq 38^{\circ}\text{C}$
 - 25% reaching 38.5°C or higher
 - Fever typically lasts for 2 to 3 days
- Postoperative fever believed to be caused by tissue injury and inflammation with associated cytokine release
 - Invasiveness of procedure and genetic factors influences degree of cytokine release and febrile response
 - Physical examination, history of timing, and sequence of events crucial to help differentiate this from other causes of infectious and noninfectious fever
 - Reactions to medications, especially anesthesia, blood products, and infections that might have existed prior to the surgery, should be considered during early postoperative course.
 - Nosocomial and surgical site infections usually develop 3 to 5 days postoperatively.

Atelectasis

- Commonly implicated as a cause of fever even in standard ICU texts
 - No primary reference source to support this assertion
 - Medical students and house-staff have been taught that atelectasis is one of the five main causes of postoperative fever
 - Little data to support this widely held belief
 - In 100 postoperative cardiac surgery patients no relationship between atelectasis and fever
 - Atelectasis induced in experimental animals by ligation of a main stem bronchus shows no fever

- IL-1 and TNF- α levels in macrophage cultures from atelectatic lungs were significantly increased compared with control lungs.
- Thus, atelectasis probably does not cause fever absent pulmonary infection.

Blood Transfusions

- Many patients in the ICU will receive transfusions of blood products.
 - 44% of 4,892 ICU patients received blood transfusion
 - 85% of patients in ICU for longer than 1 week reported to receive a blood transfusion
- Febrile, nonhemolytic transfusion reactions exceedingly common following transfusion
 - Likely mediated by the transfusion of cytokines such as IL-1, IL-6, IL-8, and TNF- α , which accumulate with increasing length of blood storage
 - Normally manifest within first 6 hours after transfusion
 - Are self-limiting
 - Can present with chills and rigors in addition to fever
 - Crucial to differentiate from febrile acute hemolytic transfusion reactions
 - These can be life threatening
 - Leukoreduction shown to reduce risk of febrile non-hemolytic transfusion reactions

Thromboembolic Disease

- Fever reported in 14% to 18% of patients with thromboembolic disease
 - Generally uncommon cause of fever in hospitalized patients
 - If present, the fever is typically low grade (37.5°C – 38°C)

AN APPROACH TO THE CRITICALLY ILL PATIENT WITH FEVER

- Following approach is suggested in ICU patients who develop a fever (Fig. 69.1)
- Due to frequency, excess morbidity and mortality associated with bacteremia:
 - Blood cultures are recommended in all ICU patients who develop fever
 - Comprehensive physical examination and review of chest radiograph essential
 - Noninfectious causes of fever should be excluded
 - With an obvious focus of infection:
 - Purulent nasal discharge
 - Abdominal tenderness
 - Profuse green diarrhea
 - Focused diagnostic workup is required
 - If no clinically obvious source of infection:
 - Unless the patient is clinically deteriorating
 - Falling blood pressure
 - Decreased urine output
 - Increasing confusion
 - Rising serum lactate concentration
 - Falling platelet count
 - Worsening coagulopathy
 - Temperature in excess of 39°C (102°F)

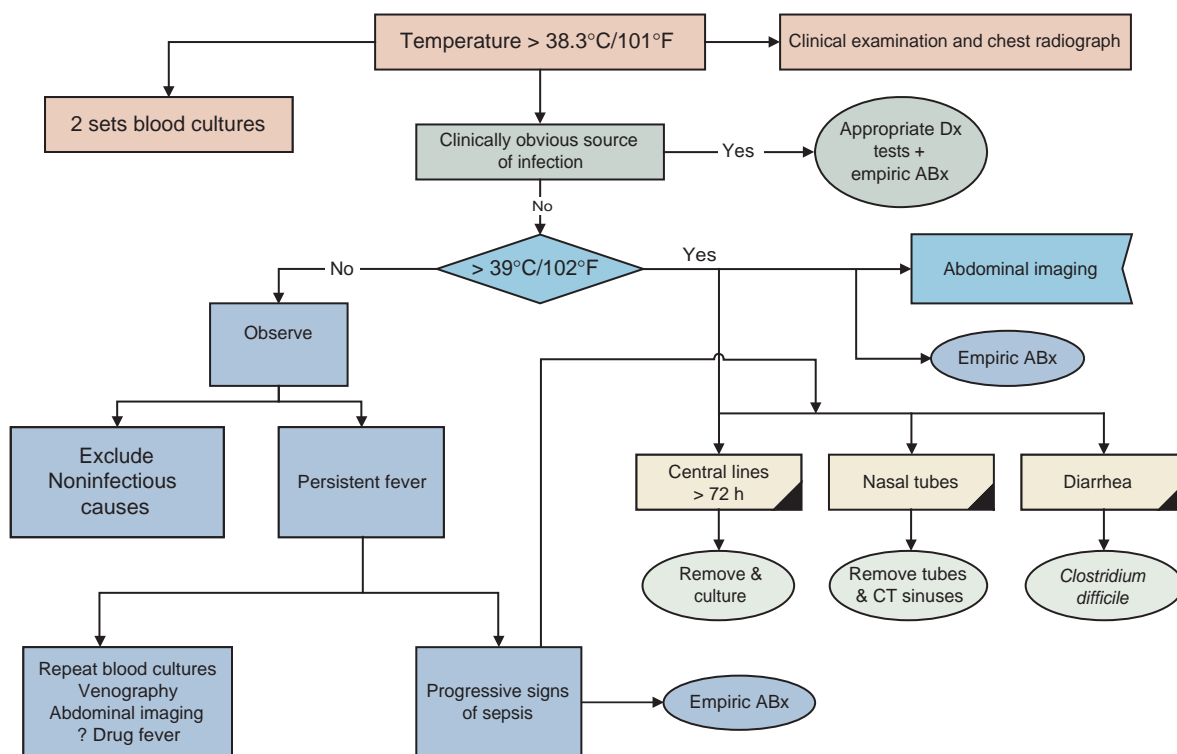

FIGURE 69.1. Suggested diagnostic algorithm for intensive care unit patients who develop a fever. ABx, antibiotics; CT, computed tomography; Dx, diagnostic.

- May be prudent to perform blood cultures and observe before embarking on the further diagnostic tests and commencing empiric antibiotics
 - ALL neutropenic patients with fever and patients with severe or progressive signs of sepsis:
 - Should be started on broad-spectrum antimicrobial therapy immediately after obtaining appropriate cultures
- In clinical picture consistent with infection
 - With no clinically obvious source documented
 - Removal of all central catheters more than 48 hours old recommended
 - With semiquantitative or quantitative cultures performed on the intracutaneous segments
 - Stool culture for *C. difficile* toxin in those patients with loose stools
 - CT scan of sinuses with removal of all nasal tubes
 - Urine culture is indicated only in patients with abnormalities of the renal system or following urinary tract manipulation.
 - Bacteriuria common
- If patient at risk of abdominal sepsis or has abdominal signs:
 - Tenderness
 - Distention
 - Inability to tolerate enteral feeds
 - CT scan of the abdomen is indicated
 - Patients with right upper quadrant tenderness require an abdominal ultrasound or CT examination.
 - Reevaluation of status after 48 hours essential:
 - Using all available results
 - Evolution of the patient's clinical condition
 - If fever persists despite empiric antibiotics and no source of infection has been identified
 - Empiric antifungal therapy may be indicated in patients with risk factors
 - Additional diagnostic tests may be appropriate at this time, including:
 - Venography
 - Differential blood count for eosinophils to assist in the diagnosis of drug fever
 - Abdominal imaging

CHAPTER 70 ■ THE ROLE OF ANTIBIOTICS IN THE MANAGEMENT OF SERIOUS HOSPITAL-ACQUIRED INFECTIONS

- ICUs are an important area for emergence of antimicrobial resistance due to:
 - Frequent use of broad-spectrum agents
 - Physical crowding of patients with high-acuity diseases within relatively small specialized areas
 - Reductions in nursing and other support staff due to economic pressures, which increase the likelihood of person-to-person transmission of microorganisms
 - Presence of more chronically and acutely ill patients who require prolonged hospitalizations and often harbor antibiotic-resistant bacteria
- Treatment strategy described is the approach of antibiotic de-escalation
 - Strategy attempts to provide appropriate initial antimicrobial therapy to optimize patient outcomes
 - While avoiding consequences of excessive or unnecessary antibiotic administration

ESSENTIAL DIAGNOSTIC TESTS AND PROCEDURES

- For patients with septic shock:
 - Establish adequate intravenous access and assess intravascular volume status (e.g., measure central venous pressure).
 - Perform a directed medical history and physical examination to identify potential sources and sites of infection.
 - Obtain specimens for microbiologic testing including blood, urine, and lower respiratory tract secretions.
 - Other specimens should be directed by initial history/physical examination (e.g., ascites, pleural fluid, cerebral spinal fluid).
 - Perform radiographic evaluation to identify infection sites requiring expeditious surgical or percutaneous drainage (intra-abdominal abscess, thoracic empyema, necrotizing skin, or visceral infection)

INITIAL THERAPY

- Administer intravenous fluids to patient with septic shock to achieve predetermined goals:
 - Ventral venous pressure >8 mm Hg
 - Oxygen saturation of central venous blood (S_{scvO_2}) >70%
- Initial appropriate antibiotic regimen should be prescribed with adequate activity against all pathogens likely to be responsible for the infection

- Dosing and interval of administration should be pharmacokinetically based to ensure that drug concentrations at site of infection are adequate to achieve therapeutic drug levels.
- Antibiotic treatment should be reassessed as soon as microbiologic test results become available.
- Failure of initial antimicrobial therapy should prompt a thorough re-evaluation to identify the reason for failure.
 - Inadequate fluid resuscitation
 - Inappropriate initial antimicrobial therapy
 - Unidentified collection of infected fluid needing drainage
- Drainage of amenable infection sites should occur once the patient has received adequate intravascular fluid replacement and appropriate initial antibiotic therapy.

ANTIMICROBIAL RESISTANCE

Risk Factors and Influence on Outcome

- Antimicrobial use is the key driver for the emergence of antibiotic resistance.
- Close association between the prior use of antibiotics and the emergence of subsequent antibiotic resistance in both gram-negative and gram-positive bacteria.
- Other factors promoting antimicrobial resistance include:
 - Prolonged hospitalization
 - Presence of invasive devices such as endotracheal tubes and intravascular catheters (possibly due to the formation of biofilms on the surfaces of these devices)
 - Residence in long-term treatment facilities
 - Inadequate infection control practices
- Antimicrobial regimens that lack action against identified microorganisms causing serious infections (i.e., inappropriate initial antimicrobial therapy) are associated with greater hospital mortality.
- Changing antibiotic therapy to an appropriate regimen after antimicrobial susceptibility data become available is not demonstrated to improve clinical outcomes.
- Infectious Disease Society of America/American Thoracic Society (IDSA/ATS) guidelines for the treatment of nosocomial pneumonia emphasize the importance of inappropriate initial antimicrobial therapy as a determinant of hospital mortality.
 - Guideline also stresses importance of maintaining local, frequently updated antibiograms within individual hospitals and ICUs.

- Antimicrobial resistance is associated with excess costs.
 - Most of these costs are simply associated with the acquisition of a nosocomial infection.
 - Presence of antibiotic resistance may also confer added morbidity and costs.

CLINICAL FACTORS THAT AFFECT INITIAL ANTIMICROBIAL SELECTION

- To provide empirical antimicrobial regimen with appropriate spectrum of activity, one must appreciate:
 - Likely pathogens causing various infections
 - Local pathogen distribution and resistance patterns
 - Patient-specific risk factors for resistance
- Recent publication of the NNIS data reported pathogen distribution by site of infection and compared data from 1975 and 2003 as demonstrated in Table 70.1.
 - Occurrence of hospital-acquired infections attributed to potentially antibiotic-resistant bacteria—*Staphylococcus aureus*, *Pseudomonas aeruginosa*—is increasing
 - Gram-negative aerobes remain the most frequently reported pathogen associated with pneumonia (65.9%).
 - *Staphylococcus aureus* (27.8%) is the most frequently reported single species.
 - In patients with primary bloodstream infections:
 - Coagulase-negative staphylococci (42.9%) is the most common pathogen.
 - *Staphylococcus aureus* (14.3%) has been reported as frequently as enterococci (14.5%).
 - In patients with urinary tract infections:
 - *Escherichia coli* (26%) is the most frequently reported isolate.
 - *Pseudomonas aeruginosa* constituted 16.3%.
 - Surgical site infections:
 - Proportion of gram-negative isolates decreased significantly during past two decades.
 - Gram-positive pathogens are now more commonly associated with both bloodstream infections and skin and skin structure infections.
- Gram-negative aerobes predominate in pneumonia and urinary tract infections.
- Concerning trend reported in NNIS data is increasing isolation of *Acinetobacter* species in urinary tract infections, pneumonia, and surgical site infections.
 - Overall numbers of isolates of *Acinetobacter* are still relatively small (approximately 2.0%); percentage increase is significant.
 - More concerning is community-acquired pneumonia attributed to *Acinetobacter* species, suggesting that this pathogen is extending its area of influence outside of the health care setting.
- For each antibiotic–pathogen combinations tested:
 - Significant increase in resistance between study periods
 - Most impressive were trends in carbapenem- and cephalosporin-resistant *Pseudomonas aeruginosa* and *Acinetobacter* species.
 - Rates of imipenem- and amikacin-resistant *Acinetobacter* isolates are approaching 20%.
 - Organism is intrinsically multidrug-resistant (MDR), which makes these trends particularly worrisome.
 - Many isolates lack effective treatment options and represent a serious public health concern.
 - 2003 rates of third-generation cephalosporin-resistance in *Escherichia coli* (6.4%) and *Klebsiella pneumoniae* (14.2%) provide estimates of presence of extended-spectrum β -lactamase (ESBL) producing often MDR bacteria, again with very limited treatment options.
- Prevalence of MDR pathogens varies by patient population, hospital, and type of floor or unit in which the patient resides (Table 70.2).

ANTIBIOTICS, THEIR MODE OF ACTION, CLINICAL INDICATIONS FOR THEIR USE, AND ASSOCIATED TOXICITIES

- Most antimicrobial agents used for treatment of infections are categorized according to principal mechanism of action.

TABLE 70.1

RELATIVE PERCENTAGE BY SITE OF INFECTION OF PATHOGENS ASSOCIATED WITH NOSOCOMIAL INFECTION

TABLE 70.2

DEFINITIONS OF INFECTION CATEGORIES (WITH FOCUS ON BACTERIAL PATHOGENS)

Infection category	Definition
Community-acquired infection	Patients with a first positive bacterial culture obtained within 48 hours of hospital admission lacking risk factors for health care-associated infection
Hospital-acquired infection	Patients with a first positive bacterial culture >48 hours after hospital admission
Health care-associated infection	Patients with a first positive bacterial culture within 48 hours of admission and any of the following: <ul style="list-style-type: none"> • Admission source indicates a transfer from another health care facility (e.g., hospital, nursing home) • Receiving hemodialysis, wound, or infusion therapy as an outpatient • Prior hospitalization for ≥ 3 days within 90 days • Immunocompromised state due to underlying disease or therapy (human immunodeficiency virus, chemotherapy)

- For antibacterial agents, the major modes of action include the following:
 - Interference with cell wall synthesis
 - Disruption of the bacterial cell membrane
 - Inhibition of protein synthesis
 - Interference with nucleic acid synthesis
 - Inhibition of a metabolic pathway
- Tables 70.3 through 70.5 review major pathogens, antimicrobials of choice by pathogen, and major toxicities of specific agents.

Cell Wall Active Antibiotics

- Antibacterial drugs that work by inhibiting bacterial cell wall synthesis include:
 - β -lactams, such as the penicillins, cephalosporins, carbapenems, and monobactams
 - Inhibit the synthesis of bacterial cell wall by interfering with enzymes required for the synthesis of peptidoglycan layer
 - Glycopeptides, including vancomycin and teicoplanin
 - Vancomycin and teicoplanin interfere with cell wall synthesis by preventing the cross-linking steps required for stable cell wall synthesis.

Disruption of Bacterial Cell Membrane

- Disruption of the bacterial membrane a less well characterized mechanism of action
 - Polymyxin antibiotics appear to exert their inhibitory effects by increasing bacterial membrane permeability, causing leakage of bacterial contents.
 - Cyclic lipopeptide, daptomycin, appears to insert its lipid tail into the bacterial cell membrane, causing membrane depolarization and eventual death of the bacterium.

Inhibition of Bacterial Protein Synthesis

- Inhibiting protein synthesis:
 - Macrolides
 - Aminoglycosides

- Tetracyclines
- Chloramphenicol
- Streptogramins
- Oxazolidinones
- Mechanism
 - Macrolides, aminoglycosides, and tetracyclines bind to the 30S subunit of ribosome.
 - Chloramphenicol binds to the 50S subunit.
 - Linezolid is a gram-positive antibacterial oxazolidinone.
 - Binds to the 50S ribosome subunit on a site not shown to interact with other classes of antibiotics.

Inhibition of Nucleic Acid Synthesis

- Fluoroquinolones
 - Disrupt DNA synthesis and cause lethal double-strand DNA breaks during DNA replication

Inhibition of a Metabolic Pathway

- Sulfonamides and trimethoprim block pathway for folic acid synthesis
 - Ultimately inhibits DNA synthesis
 - Antibacterial drug combination of trimethoprim, a folic acid analogue, plus sulfamethoxazole (a sulfonamide) inhibits two steps in the enzymatic pathway for bacterial folate synthesis.

Mechanisms of Resistance to Antibacterial Agents

- Most antimicrobial agents exert their effect by influencing a single step in bacterial reproduction or bacterial cell function.
 - Resistance can emerge with a single point mutation aimed at bypassing or eliminating the action of the antibiotic.
- Some species of bacteria are innately resistant to at least one class of antimicrobial agents.
 - With resulting resistance to all the members of those antibacterial classes
- Several mechanisms of antimicrobial resistance are readily transferred to various bacteria.

TABLE 70.3

MOST COMMON PATHOGENS ASSOCIATED WITH SITES OF SERIOUS INFECTION COMMONLY SEEN IN THE ADULT INTENSIVE CARE UNIT SETTING

Infection site	Pathogens	
I. Pneumonia		
1. Community-acquired pneumonia (non-immunocompromised host)	<i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i> <i>Moraxella catarrhalis</i> <i>Mycoplasma pneumoniae</i> <i>Legionella pneumophila</i> <i>Chlamydia pneumoniae</i> Methicillin-resistant <i>Staphylococcus aureus</i> (MRSA) Influenza virus	
2. Health care-associated pneumonia	MRSA <i>Pseudomonas aeruginosa</i> <i>Klebsiella pneumoniae</i> <i>Acinetobacter</i> species <i>Stenotrophomonas</i> species <i>Legionella pneumophila</i>	
3. Pneumonia (immunocompromised host)		
a. Neutropenia	Any pathogen listed above <i>Aspergillus</i> species <i>Candida</i> species	
b. Human immunodeficiency virus	Any pathogen listed above <i>Pneumocystis carinii</i> <i>Mycobacterium tuberculosis</i> <i>Histoplasma capsulatum</i> Other fungi	
c. Solid organ transplant or bone marrow transplant	Cytomegalovirus Any pathogen listed above (Can vary depending on timing of infection to transplant)	
d. Cystic fibrosis	<i>Haemophilus influenzae</i> (early) <i>Staphylococcus aureus</i> <i>Pseudomonas aeruginosa</i> <i>Burkholderia cepacia</i>	
4. Lung abscess	<i>Bacteroides</i> species <i>Peptostreptococcus</i> species <i>Fusobacterium</i> species <i>Nocardia</i> (in immunocompromised patients)	
5. Empyema	Amebic (when suggestive by exposure) <i>Staphylococcus aureus</i> <i>Streptococcus pneumoniae</i> Group A <i>Streptococci</i> <i>Haemophilus influenzae</i> Anaerobic bacteria <i>Enterobacteriaceae</i> <i>Mycobacterium tuberculosis</i>	Usually acute Usually subacute or chronic
II. Meningitis	<i>Streptococcus pneumoniae</i> <i>Neisseria meningitidis</i> <i>Listeria monocytogenes</i> <i>Haemophilus influenzae</i> <i>Escherichia coli</i> Group B streptococci <i>Staphylococcus aureus</i> <i>Enterobacteriaceae</i> <i>Pseudomonas aeruginosa</i>	Neonates Postsurgical or post-trauma
III. Brain abscess	<i>Streptococci</i> <i>Bacteroides</i> species <i>Enterobacteriaceae</i> <i>Staphylococcus aureus</i> <i>Nocardia</i> <i>Toxoplasma gondii</i>	Postsurgical or posttrauma Immunocompromised or HIV infected

Infection site	Pathogens	
IV. Encephalitis	West Nile Herpes simplex Arbovirus Rabies Catscratch disease	
V. Endocarditis	<i>Streptococcus viridans</i> <i>Enterococcus</i> species <i>Staphylococcus aureus</i> <i>Streptococcus bovis</i> MRSA	Intravenous drug user, prosthetic valve Prosthetic valve
VI. Catheter-associated bacteremia	<i>Candida</i> species <i>Candida</i> species <i>Staphylococcus aureus</i> <i>Enterococcus</i> species <i>Enterobacteriaceae</i> <i>Pseudomonas aeruginosa</i>	
VII. Pyelonephritis	<i>Enterobacteriaceae</i> <i>Escherichia coli</i> <i>Enterococcus</i> species <i>Pseudomonas aeruginosa</i> <i>Acinetobacter</i> species	Catheter-associated, postsurgical
VIII. Peritonitis		
1. Primary or spontaneous	<i>Enterobacteriaceae</i> <i>Streptococcus pneumoniae</i> <i>Enterococcus</i> species Anaerobic bacteria (rare)	
2. Secondary (bowel perforation)	<i>Enterobacteriaceae</i> <i>Bacteroides</i> species <i>Enterococcus</i> species <i>Pseudomonas aeruginosa</i> (uncommon)	
3. Tertiary (bowel surgery, hospitalized on antibiotics)	<i>Pseudomonas aeruginosa</i> MRSA <i>Acinetobacter</i> species <i>Candida</i> species	
IX. Skin structure infections		
1. Cellulitis	Group A streptococci <i>Staphylococcus aureus</i> <i>Enterobacteriaceae</i>	Diabetics
2. Decubitus ulcer	Polymicrobial <i>Streptococcus pyogenes</i> <i>Enterococcus</i> species <i>Enterobacteriaceae</i> Anaerobic streptococci <i>Pseudomonas aeruginosa</i> <i>Staphylococcus aureus</i> <i>Bacteroides</i> species	
3. Necrotizing fasciitis	<i>Streptococcus</i> species <i>Clostridia</i> species Mixed aerobic/anaerobic bacteria	
X. Muscle infection		
1. Myonecrosis (gas gangrene)	<i>Clostridium perfringens</i> Other <i>Clostridia</i> species	
2. Pyomyositis	<i>Staphylococcus aureus</i> Group A streptococci Anaerobic bacteria Gram-negative bacteria (rare)

Infection site	Pathogens
XI. Septic shock	
1. Community-acquired	<i>Streptococcus pneumoniae</i> <i>Neisseria meningitidis</i> <i>Haemophilus influenzae</i> <i>Escherichia coli</i> <i>Capnocytophaga</i> (DF-2 with splenectomy)
2. Health care-associated	MRSA <i>Pseudomonas aeruginosa</i> <i>Acinetobacter</i> species <i>Candida</i> species
3. Toxic shock syndrome	<i>Staphylococcus aureus</i> Streptococci species
4. Regional illness or special circumstances	Rickettsial species Ehrlichiosis Babesiosis Cat scratch disease (immunocompromised hosts) <i>Yersinia pestis</i> <i>Francisella tularensis</i> <i>Leptospira</i> <i>Salmonella enteritidis</i> <i>Salmonella typhi</i>

- Organism may acquire genes encoding enzymes, such as β -lactamases, that destroy the antibacterial agent before it can have an effect.
- Bacteria may acquire efflux pumps that extrude the antibacterial agent from the cell before it can reach its target site and exert its effect.
- Bacteria may acquire several genes for a metabolic pathway.
 - Ultimately produces altered bacterial cell walls that no longer contain binding site of antimicrobial agent
- Bacteria may acquire mutations that limit access of antimicrobial agents to intracellular target site by down-regulation of porin genes.
- Susceptible bacteria can also acquire resistance to an antimicrobial agent by new mutations such as those noted above.

- Possibly as a result of promoting antimicrobial heterogeneity and specific end points for antibiotic discontinuation
- Automated and nonautomated antimicrobial guidelines:
 - Also employed to reduce overall use of antibiotics and limit use of inappropriate antimicrobial treatment
 - Both of which could affect the development of antibiotic resistance
 - Limit unnecessary use of antimicrobial agents by:
 - Therapy modification when initial empiric broad-spectrum antibiotics are prescribed
 - Culture results reveal that narrow-spectrum antibiotics can be used

STRATEGIES THAT OPTIMIZE THE EFFICACY OF ANTIBIOTICS WHILE MINIMIZING ANTIBIOTIC RESISTANCE

Formal Protocols and Guidelines

- Antibiotic practice guidelines or protocols:
 - Emerged as potentially effective means of avoiding unnecessary antibiotic administration and increasing effectiveness of prescribed antibiotics
- Automated antimicrobial utilization guidelines:
 - Successfully used to identify and minimize the occurrence of adverse drug effects due to antibiotic administration and to improve antibiotic selection
 - Use also associated with stable antibiotic susceptibility patterns for both gram-positive and gram-negative bacteria

Hospital Formulary Restrictions

- Restricted use of specific antibiotics or antibiotic classes from hospital formulary used:
 - Strategy to reduce occurrence of antibiotic resistance and antimicrobial costs
 - Approach shown to achieve reductions in pharmacy expenses and adverse drug reactions from restricted drugs
 - Not all experiences uniformly successful
 - Homogenous use of a single or limited number of drug classes may actually promote the emergence of resistance.
 - Restricted use of specific antibiotics has generally been applied to those drugs with:
 - Broad spectrum of action (e.g., carbapenems)
 - Rapid emergence of antibiotic resistance (e.g., cephalosporins)
 - Readily identified toxicity (e.g., aminoglycosides)
 - Difficult to demonstrate that restricted hospital formularies effective in curbing overall emergence of antibiotic resistance among bacterial species

TABLE 70.4

DRUGS OF CHOICE IN SERIOUS INFECTIONS^a

Organism	Drug of choice	Alternative drugs
GRAM-POSITIVE COCCI		
<i>Staphylococcus aureus</i> ^b or <i>Staphylococcus epidermidis</i>		
Penicillin-sensitive	Penicillin G	Cephalosporin, vancomycin, or clindamycin ^c
Penicillinase-producing ^d	Oxacillin or nafcillin	Cephalosporin, vancomycin, or clindamycin
Methicillin-resistant ^e	Vancomycin (linezolid for pneumonia)	Quinolone, TMP/SMX, minocycline, clindamycin
Non-enterococcal streptococci	Penicillin G	Cephalosporin, vancomycin, or clindamycin
<i>Enterococcus</i>	Penicillin or ampicillin + gentamicin	Vancomycin + gentamicin
<i>Streptococcus pneumoniae</i> ^f	Penicillin G	Cephalosporin, vancomycin, macrolide, or clindamycin
GRAM-POSITIVE BACILLI		
<i>Actinomyces israelii</i>	Penicillin G	Tetracycline
<i>Bacillus anthracis</i>	Penicillin G	Tetracycline, macrolide
<i>Clostridium difficile</i>	Metronidazole	Oral vancomycin
<i>Clostridium perfringens</i>	Penicillin ^g	Clindamycin, metronidazole, tetracycline, imipenem
<i>Clostridium tetani</i>	Penicillin ^b	Tetracycline
<i>Corynebacterium diphtheriae</i>	Macrolide ^g	Penicillin
<i>Corynebacterium JK</i>	Vancomycin	Penicillin G + gentamicin, erythromycin
<i>Listeria monocytogenes</i>	Ampicillin gentamicin	TMP/SMX
<i>Nocardia asteroides</i>	TMP/SMX	carbapenem + amikacin
<i>Propionibacterium</i> spp.	Penicillin	Clindamycin, erythromycin
GRAM-NEGATIVE COCCI		
<i>Moraxella catarrhalis</i>	TMP/SMX	Amoxicillin-clavulanic acid, ceftriaxone, macrolide, tetracycline
<i>Neisseria gonorrhea</i>	Ceftriaxone	Penicillin G, quinolones
<i>Neisseria meningitidis</i>	Penicillin G	Ceftriaxone
ENTERIC GRAM-NEGATIVE BACILLI		
<i>Bacteroides</i>		
Oral source	Penicillin	Clindamycin, cefoxitin, metronidazole, cefotetan
Bowel source	Metronidazole	Cefoxitin, cefotetan, imipenem, ampicillin-sulbactam, ticar-clavulanate, pip-tazobactam, clindamycin
<i>Citrobacter</i>	Cefepime or imipenem/meropenem	Aminoglycoside, quinolone, piperacillin, aztreonam
<i>Enterobacter</i> spp. ⁱ	Cefepime or imipenem/meropenem	Ciprofloxacin, aminoglycoside, aztreonam
<i>Escherichia coli</i> ^j	Third-generation cephalosporin	Aminoglycoside, carbapenem, cefepime, β -lactam/ β -lactamase inhibitor, ciprofloxacin, TMP/SMX
<i>Klebsiella</i> ^l	Third-generation cephalosporin	As for <i>E. coli</i>
<i>Proteus mirabilis</i>	Ampicillin	Aminoglycoside, quinolone, cephalosporin, piperacillin, ticarcillin, TMP/SMX
<i>Proteus</i> , non-mirabilis	Third-generation cephalosporin	Aminoglycoside, quinolone, piperacillin, aztreonam, imipenem
<i>Providencia</i>	Second- or third-generation cephalosporin	Gentamicin, amikacin, piperacillin, aztreonam, imipenem, ticarcillin, mezlocillin, TMP/SMX
<i>Salmonella typhi</i>	Ceftriaxone or quinolone	Ampicillin, TMP/SMX
<i>Salmonella</i> , non-typhi ^k	Cefotaxime, ceftriaxone, or quinolone	Ampicillin, TMP/SMX
<i>Serratia</i>	Cefepime or imipenem/meropenem	Aminoglycoside, aztreonam, piperacillin, TMP/SMX, quinolone
<i>Shigella</i>	Quinolone	Ampicillin, TMP/SMX, ceftriaxone, cefixime
<i>Yersinia enterocolitica</i>	TMP/SMX	Aminoglycoside, tetracycline, 3rd-generation cephalosporin, quinolone
OTHER GRAM-NEGATIVE BACILLI		
<i>Acinetobacter</i>	Imipenem	Cefepime, aminoglycoside, TMP/SMX, colistin, sulbactam
<i>Eikenella corrodens</i>	Ampicillin	Penicillin G, erythromycin, tetracycline, ceftriaxone
<i>Francisella tularensis</i>	Streptomycin, gentamicin	Tetracycline
<i>Fusobacterium</i>	Penicillin	Clindamycin, metronidazole, cefoxitin
<i>Haemophilus influenzae</i>	3rd-generation cephalosporin	Ampicillin, imipenem, quinolone, cefuroxime ^l , quinolone, macrolide, TMP/SMX

Organism	Drug of choice	Alternative drugs
<i>Legionella</i>	Erythromycin (1 g q6h) + rifampin	
<i>Pasteurella multocida</i>	Penicillin G	Tetracycline, cephalosporin, amps-sulbactam
<i>Pseudomonas aeruginosa</i>	Antipseudomonal penicillin ^m + aminoglycoside	Aztreonam, cefepime, imipenem, quinolone
<i>Pseudomonas cepacia</i>	TMP/SMX	Ceftazidime
<i>Spirillum minus</i>	Penicillin G	Tetracycline, streptomycin
<i>Streptobacillus moniliformis</i>	Penicillin G	Tetracycline, streptomycin
<i>Vibrio cholerae</i> ⁿ	Tetracycline	TMP/SMX, quinolone
<i>Vibrio vulnificus</i>	Tetracycline	Cefotaxime
<i>Xanthomonas maltophilia</i>	TMP/SMX	Quinolone, minocycline, ceftazidime
<i>Yersinia pestis</i>	Streptomycin	Tetracycline, gentamicin
CHLAMYDIAE		
<i>Chlamydia pneumoniae</i> (TWAR)	Macrolide	Tetracycline
<i>Chlamydia psittaci</i>	Tetracycline	Chloramphenicol
<i>Chlamydia trachomatis</i>	Macrolide	Sulfonamide, tetracycline
MYCOPLASMA sp.	Macrolide	Tetracycline
	Tetracycline	Quinolone
SPIROCHETES		
<i>Borrelia burgdorferi</i>	Doxycycline, amoxicillin	Penicillin G, macrolide, cefuroxime, ceftriaxone, cefotaxime
<i>Borrelia spp.</i>	Tetracycline	Penicillin G
<i>Treponema pallidum</i>	Penicillin	Tetracycline, ceftriaxone
VIRUSES		
Cytomegalovirus	Ganciclovir ^o	Foscarnet, cidofovir
Herpes simplex	Acyclovir	Foscarnet, ganciclovir
HIV	See Centers for Disease Control Web site	
Influenza	Amantadine	Rimantadine, oseltamivir, zanamivir
Respiratory syncytial	Ribavirin	
Varicella zoster	Acyclovir	Famciclovir ^p
FUNGI		
<i>Aspergillus</i>	Voriconazole	Amphotericin B, echinocandin, Itraconazole
<i>Blastomyces</i>	Amphotericin B or itraconazole	Ketoconazole
<i>Candida</i> ^q		
Mucosal	Fluconazole, echinocandin ^r	Ketoconazole, itraconazole
Systemic	Fluconazole, echinocandin	Amphotericin B
<i>Coccidioides</i>	Amphotericin B or fluconazole	Itraconazole, ketoconazole
<i>Cryptococcus</i>	Amphotericin	Fluconazole, itraconazole
<i>Histoplasma</i>	Itraconazole or Amphotericin B	
<i>Pseudallescheria</i>	Ketoconazole or itraconazole	
Zygomycosis ("mucor")	Amphotericin B	Posaconazole

^aThis table does not consider minor infections that may be treated with oral agents, single-agent therapy, or less toxic drugs. Sensitivity testing must be done on bacterial isolates to confirm the sensitivity pattern.

^bSome authorities recommend clindamycin as the first choice for susceptible toxin-producing staphylococci, streptococci, or clostridia.

^cFirst-generation cephalosporins are most active. If endocarditis is suspected, do not use clindamycin. Some authorities recommend the addition of gentamicin for endocarditis caused by non-enterococcal streptococci or tolerant staphylococci.

^dPenicillinase-producing staphylococci are also resistant to ampicillin, amoxicillin, carbenicillin, ticarcillin, mezlocillin, and piperacillin.

^eMethicillin-resistant staphylococci should be assumed to be resistant to all cephalosporins and penicillins, even if disk testing suggests sensitivity.

^fTigecycline, ceftobiprole, daptomycin, telavancin, and dalbavancin may be alternatives for specific types of methicillin-resistant infection pending future studies and indications.

^gSome stains show intermediate- or high-level penicillin resistance. Highly resistant strains are treated with vancomycin, or rifampin, or both. In regions with high prevalence of resistant pneumococcus, ceftriaxone or vancomycin should be considered until sensitivity is known.

^hUse as an adjunct to debridement of infected tissues.

ⁱUse as an adjunct to active and passive immunization.

^jBecause of rapid development of resistance, cephalosporins not recommended even if initial tests indicate susceptibility.

^k*Klebsiella spp.* and *E. coli* producing extended-spectrum beta-lactamase (ESBL) should be preferentially managed with a carbapenem.

^lUncomplicated *Salmonella* enteritis should not be treated with antibiotics.

^mShould not be used in meningitis because of poor CNS penetration.

ⁿAntipseudomonal penicillins include ticarcillin, mezlocillin, and piperacillin.

^oPrimary therapy is fluid and electrolyte repletion.

^pOral form should be used only in maintenance therapy of retinal cytomegalovirus.

^qApproved only for mild herpes zoster in immunocompetent hosts.

^r*Candida krusei* and *Torulopsis glabrata* may be resistant to azole therapy, *Candida parapsilosis* may be resistant to echinocandins.

^sEchinocandins include caspofungin, micafungin, and anidulafungin.

TABLE 70.5

TOXICITIES ASSOCIATED WITH ANTIMICROBIALS

Antimicrobial	Serious toxicities, uncommon	Common toxicities ^a
Penicillins	Anaphylaxis, seizures, hemolytic anemia, neutropenia, thrombocytopenia, drug fever	Diarrhea, nausea, vomiting, rash
Ampicillin		
Penicillin		
Antistaphylococcal penicillins	Anaphylaxis, neutropenia, thrombocytopenia, acute interstitial nephritis, hepatotoxicity	Diarrhea, nausea, vomiting, rash
Nafcillin		
Oxacillin		
B-lactam/B-lactamase inhibitors	Anaphylaxis, seizures, hemolytic anemia, neutropenia, thrombocytopenia	Diarrhea, nausea, vomiting, rash
Amoxicillin/clavulanate		
Ampicillin/sulbactam	<i>C. difficile</i> colitis, cholestatic jaundice,* drug fever	
Piperacillin/tazobactam*		
Ticarcillin/clavulanate		
Cephalosporins	Anaphylaxis, seizures, neutropenia, thrombocytopenia, drug fever	Diarrhea, nausea, vomiting, rash
Carbapenems	Anaphylaxis, seizures (imipenem > meropenem, ertapenem)	Diarrhea, nausea, vomiting
Imipenem		
Meropenem	<i>C. difficile</i> colitis, drug fever	
Ertapenem		
Glycopeptides	Ototoxicity, nephrotoxicity (unlikely without concomitant nephrotoxins), thrombocytopenia	Red-man syndrome
Vancomycin		
Oxazolidinones	<i>More common with long-term use:</i> Peripheral and optic neuropathy, myelosuppression	Diarrhea
Linezolid	<i>Possible with short-term use:</i> Lactic acidosis, myopathy anemia	
Lipopeptides		
Daptomycin		Diarrhea, constipation, vomiting
Streptogramin		Arthralgia, myalgia, inflammation, pain, edema at infusion site, hyperbilirubinemia
Quinupristin/dalfopristin		Nephrotoxicity, ototoxicity
Aminoglycosides		
Amikacin		
Gentamicin		
Tobramycin		
Fluoroquinolones	Anaphylaxis, dysglycemia* QTc prolongation, joint toxicity in children, tendon rupture	Nausea, vomiting, diarrhea, photosensitivity, rash
Second generation		
Ciprofloxacin		CNS stimulation, dizziness, somnolence
Third generation		
Levofloxacin		
Fourth generation		
Gatifloxacin*		
Moxifloxacin		
Gemifloxacin		
Macrolides	QTc prolongation (erythromycin > clarithromycin > azithromycin), cholestasis*	Nausea, vomiting, diarrhea, abnormal taste
Erythromycin*		
Azithromycin		
Clarithromycin		
Ketolides	Acute hepatic failure	Nausea, vomiting, diarrhea
Telithromycin	QTc prolongation	
Clindamycin	<i>C. difficile</i> colitis	Nausea, vomiting, diarrhea, abdominal pain, rash
Tetracyclines	Tooth discoloration and retardation of bone growth (in children), renal tubular necrosis,* dizziness, vertigo,†	Photosensitivity, diarrhea
Tetracycline*		
Doxycycline		
Minocycline† pseudotumor cerebri		
Glycylcyclines		Nausea, vomiting, diarrhea

(continued)

TABLE 70.5

CONTINUED

Antimicrobial	Serious toxicities, uncommon	Common toxicities ^a
Tigecycline	Myelosuppression	Rash, nausea, vomiting, diarrhea
Trimethoprim/sulfamethoxazole	Stevens–Johnson syndrome, hyperkalemia, aseptic meningitis, hepatic necrosis	
Metronidazole	Seizures, peripheral neuropathy	Nausea, vomiting, metallic taste, disulfiram-like reaction
Nitrofurantoin	Pulmonary toxicity, peripheral neuropathy	Urine discoloration, photosensitivity
Antifungal Agents		
Azoles	Hepatic failure, increased AST/ALT, cardiovascular toxicity, hypertension, edema	Nausea, vomiting, diarrhea, rash, visual disturbances, phototoxicity
Fluconazole		
Itraconazole		
Voriconazole		
Amphotericin B products	Acute liver failure, myelosuppression	Nephrotoxicity (less common with lipid formulations), acute infusion-related reactions, hypokalemia, hypomagnesemia
Amphotericin B deoxycholate		
ABLC		
ABCD		
Liposomal amphotericin B		
Echinocandins	Hepatotoxicity, infusion-related rash, flushing, itching	
Caspofungin		
Micafungin		
Anidulafungin		
Flucytosine	Myelosuppression, hepatotoxicity, confusion, hallucinations, sedation	Nausea, vomiting, diarrhea, rash
Antiviral Agents		
Nucleoside analogues	Nephrotoxicity, rash, encephalopathy, inflammation at injection site, phlebitis	Bone marrow suppression, headache, nausea, vomiting, diarrhea (with oral forms)
Acyclovir		
Valacyclovir		
Ganciclovir		
Valganciclovir		
Amantadine	CNS disturbances (amantadine > rimantadine)	Nausea, vomiting, anorexia, xerostomia
Rimantadine		
Neuraminidase inhibitors		
Oseltamivir	Anaphylaxis, bronchospasm	Nausea, vomiting, cough, local discomfort
Zanamivir		
Cidofovir	Anemia, neutropenia, fever, rash	Nephrotoxicity, uveitis/iritis, nausea, vomiting
Foscarnet	Seizures, anemia, fever	Nephrotoxicity, electrolyte abnormalities (hypocalcemia, hypomagnesemia, hypokalemia, hypophosphatemia), nausea, vomiting, diarrhea, headache

^aToxicities were classified as “common” relative to the other toxicities that agent is known to cause. Because toxicities are classified as “common”, it does not imply they are not serious.

- However, use has been successful in specific outbreaks of infection with antibiotic-resistant bacteria, particularly in conjunction with infection control practices and antibiotic educational activities.

Use of Narrow-Spectrum Antibiotics

- Another proposed strategy to curtail development of antimicrobial resistance
 - In addition to the judicious overall use of antibiotics
- Use drugs with a narrow antimicrobial spectrum
- Several lines of evidence suggest infections such as community-acquired pneumonia can be successfully treated with narrow-spectrum antibiotic agents.
 - Especially if infections are not life-threatening.
- Avoidance of broad-spectrum antibiotics. . .
 - Especially those associated with rapid emergence of resistance (cephalosporins, quinolones)
 - Reintroduction of narrow-spectrum agents (penicillin, trimethoprim, gentamicin)
 - Infection control practices

- Successful in reducing the occurrence of specific infections in hospital setting

Quantitative Cultures and Assessment of Infection Risk

- Pneumonia is the most common hospital-acquired infection in mechanically ventilated patients.
- Use of quantitative bacterial cultures obtained from the lower respiratory tract may facilitate de-escalation of empiric broad-spectrum antibiotics and reduce drug-specific antibiotic days of treatment
- Patients with a clinical suspicion for VAP and culture-negative bronchoalveolar lavage (BAL) results for a major pathogen can have antimicrobial therapy safely discontinued within 72 hours.
- Regardless of whether quantitative culture methods are used
 - Results of microbiologic testing should be used to routinely modify or discontinue antibiotic treatment in the appropriate clinical setting.

Combination Antibiotic Therapy

- No definitive evidence that emergence of antibiotic resistance is reduced by the use of combination antimicrobial therapy.
- Empiric combination therapy directed against high-risk pathogens:
 - Such as *Pseudomonas aeruginosa*
 - Should be encouraged until the results of antimicrobial susceptibility become available
 - Approach to empiric treatment can increase the likelihood of providing appropriate initial antimicrobial therapy with improved outcomes.

Antibiotic Cycling and Scheduled Antibiotic Changes

- Concept of antibiotic class cycling suggested as strategy for reducing emergence of antimicrobial resistance
- Class of antibiotics or a specific antibiotic drug:
 - Withdrawn from use for a defined time period
 - Reintroduced at a later time in attempt to limit bacterial resistance to cycled antimicrobial agents
- Mathematical modeling suggests that use of antibiotic cycling inferior to “mixing” of antibiotics as a strategy to reduce emergence of antimicrobial resistance
 - Beneficial outcomes in terms of antibiotic resistance, with benefits extending outside of the ICU setting, have not been confirmed.
 - Antimicrobial heterogeneity or mixing seems to be a logical policy.
- Simple cycling of antibiotics combined with prolonged treatment exposures:
 - A strategy that will only promote further antibiotic resistance

Antimicrobial Decolonization Strategies

- Topical antibiotic administration (i.e., selective digestive decontamination), with or without concomitant parenteral antibiotics
 - Shown to be effective at reducing nosocomial infections
 - Routine use of selective digestive decontamination linked to emergence of antimicrobial resistance
- Antimicrobial and nonantimicrobial agents should be considered for oral decontamination only in *appropriate high-risk ICU* patients.
 - Or to assist in the containment of outbreaks of MDR bacterial infections in conjunction with established infection control practices

Shorter Courses of Antibiotic Treatment

- Prolonged administration of antibiotics to hospitalized patients is an important risk factor for the emergence of colonization and infection with antibiotic-resistant bacteria.
 - 7 to 8 days of antibiotic treatment (short course):
 - Acceptable for most *nonbacteremic* patients with VAP
 - Successfully used in patients at low risk for VAP with pyelonephritis
 - For community-acquired pneumonia
 - Associated with a significantly lower risk for the emergence of antimicrobial resistance compared to more traditional durations of antibiotic treatment ranging from 14 to 21 days
- More specific markers for the presence of bacterial infection:
 - Procalcitonin
 - Soluble triggering receptor on myeloid cells (sTREM1)
 - May allow shorter courses of empiric antibiotic administration in patients without identified bacterial infection
 - Published guidelines for the antibiotic management of nosocomial pneumonia and severe sepsis currently recommend discontinuation of empiric antibiotic therapy after 48 to 72 hours if cultures negative or signs of infection resolved.

Optimizing Pharmacokinetic/Pharmacodynamic (Pk/Pd) Principles

- Antibiotic concentrations that are sublethal:
 - Can promote the emergence of resistant pathogens
 - Duration of time the serum drug concentration remains above minimum inhibitory concentration of the antibiotic ($T > MIC$) enhances bacterial eradication with β -lactams, carbapenems, monobactams, glycopeptides, and oxazolidinones.
- See increased $T > MIC$ and improve clinical and microbiologic cure rates with:
 - Frequent dosing
 - Prolonged infusion times
 - Continuous infusions
- To maximize the bactericidal effects of aminoglycosides:
 - Must optimize maximum drug concentration (C_{max})-to-MIC ratio

- C_{\max} :MIC ratio of $\geq 10:1$ using once-daily aminoglycoside dosing (5–7 mg/kg) associated with:
 - Preventing emergence of resistant organisms
 - Improving clinical response to treatment
 - Avoiding toxicity
- 24-hour area under antibiotic concentration curve-to-MIC ratio (AUC) is correlated with fluoroquinolone efficacy and prevention of resistance development
- AUC value of > 100 associated with significant reduction in risk of resistance development while on therapy
- Generally, should use the *maximum approved dose* of an antibiotic for a potentially life-threatening infection to optimize tissue concentrations of the drug and killing of pathogens

New Antimicrobial Agents

- In 1996, the first clinical isolate of *Staphylococcus aureus* with reduced susceptibility to vancomycin (vancomycin-intermediate *Staphylococcus aureus*, or VISA) was reported in Japan.
 - Similar cases have been reported around the world.
 - Now clinical isolates of *Staphylococcus aureus* that are fully resistant to vancomycin have been reported in South Africa and Michigan.
 - Emergence of methicillin-resistant *Staphylococcus aureus* (MRSA) strains with reduced vancomycin susceptibility has limited the treatment options and increased the incidence of treatment failure.
 - Infection with one of these strains may be an independent predictor of mortality.
 - More concerning are observations that upward drift in the minimum inhibitory concentrations for vancomycin in MRSA are associated with an increased risk of clinical treatment failures.

Linezolid

- First licensed member of a new class of antibiotics
 - Oxazolidinones
 - Binds to the ribosome and inhibits microbial protein synthesis
 - Novel mechanism of action provides an antimicrobial activity independent of resistance status toward other antibiotics
 - Linezolid may be associated with improved survival and clinical cure rates compared to vancomycin in patients with nosocomial pneumonia.
 - Linezolid a suitable alternative to vancomycin in nosocomial infections caused by MRSA, particularly in pneumonia
 - General agreement on the superiority of linezolid to vancomycin and teicoplanin is lacking
 - Does not require adjustment for renal function at a dosage of 600 mg every 12 hours.
 - Close monitoring of blood cell count should be done in case of pre-existing myelosuppression and during prolonged treatment.

Daptomycin

- A cyclic lipopeptide active only against gram-positive organisms

- Recently approved for the treatment of complicated skin and soft tissue infections
- Activity against resistant and susceptible isolates of *Staphylococcus aureus*
- Once-daily dosing (4 mg/kg IV) and safety profile (except for some concerns for rhabdomyolysis) make daptomycin an attractive option for the treatment of staphylococcal infections
 - May not be a useful agent for deep-seated tissue infections
 - In 740 patients with pneumonia, treatment terminated early due to a lower level of efficacy compared to ceftriaxone
 - May be related to:
 - Molecular size of this drug
 - Protein-binding characteristics
 - Inhibition by pulmonary surfactant
- Current use limited to skin infections and bacteremia and/or endocarditis

Quinupristin-Dalfopristin

- A semisynthetic, parenteral streptogramin
 - Activity against most of the gram-positive pathogens
 - Comparing quinupristin-dalfopristin and vancomycin in treatment of nosocomial pneumonia by gram-positive pathogens, similar clinical success rates were observed, including in MRSA subgroup.
 - Quinupristin-dalfopristin probably not a better option than vancomycin
 - Side effect profile of quinupristin-dalfopristin (myalgia, arthralgia, and thrombophlebitis) and its lack of proven efficacy over vancomycin have limited its overall use

Tigecycline

- The first glycylcycline to be launched
 - One of the very few antimicrobials with activity against gram-negative bacteria and MRSA
 - In contrast to classic tetracyclines, tigecycline can be administered only parenterally.
 - Major side effect appears to be dose-related nausea and emesis
 - Dosing regimen for tigecycline has been validated in clinical trials that involved a 100-mg loading dose
 - Followed by 50 mg twice daily in patients with complicated infections of the skin and skin structure, as well as intra-abdominal infections
 - Evades acquired efflux and target-mediated resistance to classical tetracyclines but not chromosomal efflux
 - C_{\max} is low, but tissue penetration is excellent.
 - Compound has shown equivalence to imipenem/cilastatin in intra-abdominal infection and to vancomycin plus aztreonam in skin and skin structure infection.
 - Tigecycline may prove particularly useful for the treatment of surgical wound infections, where both gram-negative bacteria and MRSA are likely pathogens.
 - May also have a role in the treatment of infections due to multiresistant pathogens, including *Acinetobacter* species and extended-spectrum β -lactamase producing gram-negatives

Ceftobiprole

- Ceftobiprole (BAL5788) is the water-soluble prodrug of BAL9141.
- Novel broad-spectrum cephalosporin
- Potent bactericidal activities against MRSA and penicillin-resistant *Streptococcus pneumoniae*
- BAL9141, a novel pyrrolidinone-3-ylidenemethyl cephalosporin:
 - Specifically designed to have strong affinity for penicillin-binding protein (PBP) 2a
 - Known to confer resistance in staphylococci and pneumococci
 - BAL9141 also binds strongly to the relevant PBPs of most gram-positive and gram-negative pathogens and is resistant to many β -lactamases.
- Ceftobiprole is currently being investigated in patients with pneumonia and complicated skin infections.

Dalbavancin

- A lipoglycopeptide antimicrobial:
 - Studied in phase two trials for complicated skin and skin structure infections and catheter-related bloodstream infection
- A bactericidal agent
 - Long terminal plasma half-life (9–12 days)

- Allows for the unique dosing of 1,000 mg given on day 1 and 500 mg given on day 8

Telavancin

- Telavancin is another lipoglycopeptide in development.
 - Exerts concentration-dependent bactericidal activity against gram-positive bacteria, including MRSA
 - Rapid bactericidal activity arises from two mechanisms:
 - Inhibition of peptidoglycan synthesis
 - Interaction with bacterial membrane
- Effective for treatment of complicated skin and skin structure infections given as a once-daily dosing

Doripenem

- A novel broad-spectrum parenteral carbapenem antimicrobial
 - Chemical formula for doripenem confers β -lactamase stability
 - Resistance to inactivation by renal dehydropeptidases
- Doripenem has spectrum and potency against:
 - Gram-positive cocci most similar to imipenem or ertapenem
 - Gram-negative activity most like meropenem (twofold or fourfold superiority to imipenem)

CHAPTER 71 ■ SURGICAL INFECTIONS

- Surgical patients are at particular risk of infection for many reasons.
 - Surgery is inherently invasive.
 - Creates portals of entry in natural epithelial barriers for pathogens to invade the host
 - Surgical illness is immunosuppressive (e.g., trauma, burns, malignant tumors).
 - As is therapeutic immunosuppression following solid organ transplantation
 - General anesthesia almost always means a period of mechanical ventilation.
 - Period of reduced consciousness during emergence
 - Risk of pulmonary aspiration of gastric contents
 - Nosocomial pneumonia occurs more frequently among surgical patients than comparably ill medical patients.
 - Surgical patients are also uniquely afflicted by infections of incisions.
- Surgical infections traditionally considered to be infections that require surgical therapy
 - Complicated intra-abdominal and soft tissue infections
 - Surgical patients are especially vulnerable to nosocomial infection.
 - Definition includes any infection that affects surgical patients

RISK FACTORS FOR POSTOPERATIVE INFECTION

- General principles of surgical care, critical care, and infection control cannot be overemphasized
 - Resuscitation must be rapid, yet precise
 - Pathology must be identified and treated as soon as possible.
 - Infection control sometimes sacrificed under chaotic conditions of resuscitation
 - Central venous catheters inserted under suboptimal barrier precautions
 - Lack of cap, mask, sterile gown, and sterile gloves for the operator and a full-bed drape for the patient
 - These must be removed and replaced (if necessary) by a new puncture at a new site as soon as patient's condition permits

CONTROL OF BLOOD SUGAR

- Hyperglycemia is deleterious to host immune function.
- May also reflect catabolism and insulin resistance associated with surgical stress response

- Poor perioperative control of blood glucose increases the risk of infection and worsens outcome from sepsis.
- Diabetic patients undergoing cardiopulmonary bypass surgery have a higher risk of infection of both sternal incision and vein harvest incisions on lower extremities.
- Moderate hyperglycemia (>200 mg/dL) any time on first postoperative day:
 - Increases risk of surgical site infection (SSI) fourfold after cardiac and noncardiac surgery
- Insulin infusion to keep blood glucose concentrations <110 mg/dL associated with:
 - 40% decrease in mortality among critically ill postoperative patients
 - Fewer nosocomial infections and less organ dysfunction
 - Meta-analysis of 35 trials of control of blood glucose indicates:
 - Risk of mortality is decreased significantly (risk ratio [RR] 0.85, 95% confidence interval [CI] 0.75–0.97) by tight glucose control
 - Especially so for critically ill surgical patients (RR 0.58, 95% CI 0.22–0.62)
 - Regardless of whether the patients had diabetes mellitus (RR 0.71, 95% CI 0.54–0.93) or stress-induced hyperglycemia (RR 0.73, 95% CI 0.58–0.90)
- Nutritional support is crucial.
 - Surgical stress causes catabolism
 - Restoration of anabolism requires the provision of calories and nitrogen far in excess of basal requirements of 25 to 30 kcal and 1 g nitrogen/kg per day
 - Parenteral nutrition appears to convey no advantage over not feeding the patient at all
 - Perhaps because of inherent morbidity of central intravenous feeding
 - Risk of catheter-related bloodstream infection (CR-BSI)
 - Hyperglycemia
 - Early enteral feeding
 - Within the first 48 hours or immediately if the gut is functional
 - Clearly beneficial, with the possible exception of pneumonia prevention
 - Risk of infection was reduced by 55% (odds ratio [OR] 0.45, 95% CI 0.30–0.66) in a meta-analysis of 15 randomized trials of early enteral feeding following surgery, trauma, or burns

Blood Transfusion

- Blood transfusion can be life saving after trauma or hemorrhage.
- An increased risk of infection is the consequence.
- Transfusions exert immunosuppressive effects through:
 - Presentation of leukocyte antigens
 - Induction of shift to T-helper 2 (immunosuppressive) phenotype
 - Mechanism remains somewhat controversial
 - Transfusion of leukocyte-depleted red blood cell concentrates does not reduce the risk of infection
- Exponential relationship between transfusion risk and infection risk among trauma patients

- Detectable with even 1 unit of transfusion
- A virtual certainty after more than 15 units of transfused blood (RR 1.084, 95% CI 1.028–1.142)
- By meta-analysis risk of infection related to blood transfusion increased for trauma patients by more than fivefold (OR 5.26, 95% CI 5.03–5.43)
 - For surgical patients by more than threefold
 - Increased risk for infection by transfusion has also been identified for critically ill patients in general
 - For CR-BSI and ventilator-associated pneumonia (VAP) specifically
- Banked blood is affected by a “storage lesion” characterized by:
 - Loss of membrane 2-3-diphosphoglycerate and adenosine triphosphate
 - Leading to loss of membrane deformability
 - Erythrocytes cannot deform as they must transit to the microcirculation
 - Causing disruption of nutrient blood flow and impaired oxygen offloading
 - Thus, blood transfusion does not increase oxygen consumption for critically ill patients with sepsis
 - May actually increase the risk of organ dysfunction
 - Storage lesion becomes fully manifest after about 14 days of storage
 - Transfusion of older blood is an independent risk factor for the development of infection.
 - **It is safe to be conservative in the administration of red blood cell concentrates to stable patients in the intensive care unit (ICU).**

INFECTION CONTROL

- Infection control is an individual and collective responsibility of the critical care team and unit.
- Hand hygiene is most effective and underutilized means to reduce spread of infection
 - Hand cleansing with soap and water requires a minimum of 30 to 45 seconds to be effective.
 - Alcohol gel hand cleansers are equally effective.
 - Except against the spores of *Clostridium difficile*
 - Compliance with use is higher
 - When used prevalence of multidrug resistant (MDR) bacteria is reduced
 - Universal precautions must be observed whenever there is a risk of splashing of body fluids.
- Source of most bacterial pathogens is patient’s endogenous flora
 - Skin surfaces
 - Artificial airways
 - Gut lumen
 - Wounds
 - Catheters
 - Inanimate surfaces (e.g., bed rails, computer terminals) may become colonized
 - Any break in natural epithelial barriers
 - Incisions
 - Percutaneous catheters
 - Airway or urinary catheters
 - A portal of entry for invasion of pathogens

- Fecal–oral route the most common manner by which pathogens reach the portal
- But health care workers definitely facilitate the transmission of pathogens around a unit
- Contact isolation an important part of infection control
 - Should be used selectively to prevent the spread of pathogens:
 - Methicillin-resistant *Staphylococcus aureus* (MRSA)
 - Vancomycin-resistant enterococci (VRE)
 - MDR Gram-negative bacilli
 - Contact isolation may decrease the amount of direct patient contact.
 - Appropriate balance must be struck
 - Reduced nurse staffing of ICUs has been independently associated with an increased risk of a number of nosocomial infections.

CATHETER CARE

- Optimal catheter care includes:
 - Avoidance of use when unnecessary
 - Appropriate skin cleansing and barrier protection during insertion
 - Proper catheter selection
 - Proper dressing of indwelling catheters
 - Removal as soon as possible when no longer needed
 - Or after insertion under less than ideal circumstances (e.g., trauma bay, cardiac resuscitation)
- Benefit of information gained by catheterization must always be weighed against the risk of infection (Table 71.1)
- All indwelling catheters carry a risk of infection.
 - Nontunneled central venous catheters and pulmonary artery catheters highest risk
 - Including local site infections and CR-BSIs (see below)
 - Other catheters that pose increased infection risk include:
 - Intercostal thoracostomy catheters (if inserted as an emergency)
 - Ventriculostomy catheters for intracranial pressure monitoring
 - Urinary bladder catheters
 - Each day of endotracheal intubation and mechanical ventilation increases the risk of pneumonia by 1% to 3%.
 - Controversial whether tracheostomy decreases that risk
- Chlorhexidine (bactericidal, viricidal, and fungicidal)
 - Used preferentially for skin preparation for vascular catheter insertion
 - Shown to be superior to povidone-iodine solution
 - If povidone-iodine solution is used (of which use is discouraged), it must be allowed to dry, as it is not bactericidal when wet
- Full barrier precautions are mandatory for all bedside catheterization procedures
 - Except arterial and urinary bladder catheterization, for which sterile gloves and a sterile field suffice
 - A central venous line (CVL) inserted under suboptimal conditions must be removed (and replaced at a different site if still needed) as soon as permitted by patient's hemodynamic status, but no more than 24 hours after insertion.
 - Single dose of a first-generation cephalosporin (e.g., cefazolin) only may prevent some infections following emergency tube thoracostomy or ventriculostomy
 - Not indicated for vascular or bladder catheterizations
 - Topical antiseptics placed postprocedure at insertion site of no benefit for any type of indwelling catheter, and may actually increase the risk of infection
- Dressings must be maintained carefully
 - Challenging if the patient is agitated or the body surface is irregular
 - The neck (intra jugular vein catheterization) versus the chest wall (subclavian vein catheterization)
 - Importance is crucial
 - Marking the dressing clearly with the date and time of each change is a simple and effective way to manage dressing changes
 - Dressing carts or similar apparatus should not be brought from patient to patient; rather, sufficient supplies should be kept in each patient's room
 - Possibility for inanimate objects (e.g., scissors) to be transmission vectors if not cleansed thoroughly after contact with each patient
 - Dedicated catheter care teams reduce the risk of CR-BSI substantially
 - Choice of catheter may play a role in decreasing the risk of infection related to endotracheal tubes, central venous catheters, and urinary catheters

TABLE 71.1

RATES OF HEALTH CARE-ASSOCIATED PNEUMONIA AND CATHETER-RELATED BLOODSTREAM INFECTION AMONG VARIOUS ICU TYPES

ICU type	CVC use	CR-BSI rate mean/median	TT use	VAP rate mean/median
Medical	0.52	5.0/3.9	0.46	4.9/3.7
Pediatric	0.46	6.6/5.2	0.39	2.9/2.3
Surgical	0.61	4.6/3.4	0.44	9.3/8.3
Cardiovascular	0.79	2.7/1.8	0.43	7.2/6.3
Neurosurgical	0.48	4.6/3.1	0.39	11.2/6.2
Trauma	0.61	7.4/5.2	0.56	15.2/11.4

CVC use, number of days of catheter placement per 1,000 patient-days in ICU; CR-BSI, catheter-related bloodstream infection; TT use, number of days of indwelling endotracheal tube or tracheostomy per 1,000 patient-days in ICU; VAP, ventilator-associated pneumonia. Infection rates are indexed per 1,000 patient-days.

From the National Nosocomial Infection Surveillance System, U.S. Centers for Disease Control and Prevention. Data available at www.cdc.gov, and are in the public domain.

- Continuous aspiration of subglottic secretions (CASS), via an endotracheal tube with an extra lumen that opens to the airway just above the balloon, facilitates the removal of secretions that accumulate below the vocal cords but above the endotracheal tube balloon
 - Incidence of VAP is decreased by one-half by CASS
 - Silver-impregnated endotracheal tubes are effective in reducing airway colonization, but whether VAP incidence is reduced not yet known
- Antibiotic- (e.g., minocycline/rifampin) or antiseptic-coated central venous catheters (e.g., Chlorhexidine/silver sulfadiazine) can reduce the incidence of CR-BSI
 - Especially in high-prevalence units
 - Minocycline/rifampin-coated catheters may be more effective
- Urinary bladder catheters coated with ionic silver reduce the incidence of catheter-related bacterial cystitis by a similar amount
- Ventilator weaning by protocol, combined with daily sedation holidays and spontaneous breathing trials
 - Allows earlier endotracheal extubation and decreases the risk of VAP (see below)
 - Better strategy may be avoidance of endotracheal intubation entirely
 - Noninvasive positive pressure ventilation delivered by mask (e.g., continuous positive airway pressure [CPAP])
 - Improved resuscitation techniques and noninvasive monitoring techniques have decreased the utilization of pulmonary artery catheters, which pose a particularly high risk of infection
 - Most drains do not decrease the risk of infection
 - Risk is probably increased because the catheters hold a portal open for invasion by bacteria.

RISK FACTORS FOR SURGICAL SITE INFECTION

- Clean surgical procedures affect only integumentary and musculoskeletal soft tissues
- Clean-contaminated procedures open a hollow viscus (e.g., alimentary, biliary, genitourinary, respiratory tract) under controlled circumstances.
 - For example, elective colon surgery
- Contaminated procedures involve extensive introduction of bacteria into a normally sterile body cavity, but too briefly to allow infection to become established during surgery
 - For example, penetrating abdominal trauma, enterotomy during adhesiolysis for mechanical bowel obstruction
- Dirty procedures are performed to control established infection
 - For example, colon resection for perforated diverticulitis
- Numerous factors determine whether a patient will develop an SSI, including (Table 71.2):
 - Factors related to patient
 - Environment
 - Therapy
- Most recognized factors are:
 - The wound classification
 - American Society of Anesthesiologists class 3 or higher (class 3: chronic active medical illness)

TABLE 71.2

RISK FACTORS FOR THE DEVELOPMENT OF SURGICAL SITE INFECTIONS

Patient Factors

Ascites (for abdominal surgery)
 Chronic inflammation
 Corticosteroid therapy (controversial)
 Obesity
 Diabetes
 Extremes of age
 Hypcholesterolemia
 Hypoxemia
 Peripheral vascular disease (for lower extremity surgery)
 Postoperative anemia
 Prior site irradiation
 Recent operation
 Remote infection
 Skin carriage of staphylococci
 Skin disease in the area of infection (e.g., psoriasis)
 Undernutrition

Environmental Factors

Contaminated medications
 Inadequate disinfection/sterilization
 Inadequate skin antisepsis
 Inadequate ventilation

Treatment Factors

Drains
 Emergency procedure
 Hypothermia
 Inadequate antibiotic prophylaxis
 Oxygenation (controversial)
 Prolonged preoperative hospitalization
 Prolonged operative time

- Prolonged operative time, where time is longer than the 75th percentile for each such procedure
- Risk of SSI increases with an increasing number of risk factors present, irrespective of the type of operation
- Laparoscopic surgery decreases incidence of SSI under most circumstances
 - Reasons possibly several, including:
 - Decreased wound size
 - Limited use of cautery in the abdominal wall
 - Diminished stress response to tissue injury
- Host-derived factors contribute importantly to the risk of SSI, including:
 - Increased age
 - Obesity
 - Malnutrition
 - Diabetes mellitus
 - Hypcholesterolemia
- Numerous other factors that are not accounted for specifically by the National Nosocomial Infections Surveillance System (NNIS) system
 - In one 6-year study of 5,031 patients undergoing noncardiac surgery, the overall incidence of SSI was 3.2%.
 - In another prospective study of 9,016 patients, 12.5% of patients developed an infection of some type within 28 days after surgery.
- Lapses in the modern operating room can result in increased rates of SSI

- Proper sterilization
- Ventilation
- Skin preparation techniques
 - Operating team must be attentive to personal hygiene (e.g., hand scrubbing, hair)
 - Recent data indicate that a brief rinse with soap and water followed by use of an alcohol gel hand rub is equivalent to the prolonged (and ritualized) session at the scrub sink
- Hypothermia during surgery is common if patients are not warmed actively, owing to:
 - Evaporative water losses
 - Administration of room temperature fluids
- Maintenance of normal core body temperature is unequivocally important for decreasing the incidence of SSI.
 - Mild intraoperative hypothermia is associated with an increased rate of SSI following elective colon surgery and diverse operations.
- Intuitive that oxygen administration in postoperative period beneficial for wound healing
 - Ischemic milieu of the fresh surgical incision is vulnerable to bacterial invasion
 - Oxygen has been postulated to have a direct antibacterial effect
 - Clinical trials have had conflicting results
 - Supplemental oxygenation administration specifically to reduce the incidence of SSI remains plausible, and further studies are needed
- Closure of a contaminated or dirty incision is widely believed to increase the risk of SSI
 - Few good studies exist to help sort out the multiplicity of wound closure techniques available to surgeons
 - “Open abdomen” techniques of temporary abdominal closure for management of trauma or severe peritonitis are utilized increasingly.
 - Retrospective studies indicate that antibiotics are not indicated for prophylaxis of the open abdomen.
 - But infection of the abdominal wall is highly morbid
 - Inability to achieve primary abdominal closure is associated with infectious complications:
 - Pneumonia
 - Bloodstream infection
 - SSI
 - Infectious complications significantly increased costs from prolonged length of stay, but not mortality
- Drains placed in incisions probably cause more infections than they prevent
 - Epithelialization of the wound is prevented and the drain becomes a conduit, holding open a portal for invasion by pathogens colonizing the skin
 - Several studies of drains placed into clean or clean-contaminated incisions show that the rate of SSI is not reduced.
 - Rate is increased
 - Considering that drains pose a risk and accomplish little of what is expected of them, they should be used as little as possible and removed as soon as possible.
 - Under no circumstances should prolonged antibiotic prophylaxis be administered to “cover” indwelling drains.
- Wound irrigation is a controversial means to reduce the risk of SSI.

- Routine low-pressure saline irrigation of an incision does not reduce the risk of SSI.
- High pressure irrigation (i.e., pulse irrigation) may be beneficial.
- Intraoperative topical antibiotics can minimize the risk of SSI.
 - But use of antiseptics rather than antibiotics might minimize possibility of development of resistance

Risk Factors for Pneumonia

- Surgical patients susceptible to pneumonia, particularly if they require mechanical ventilation
- Ventilator-associated pneumonia, defined as pneumonia occurring 48 to 72 hours after endotracheal intubation, is the most common ICU infection among surgical and trauma patients.
 - VAP is partially iatrogenic
 - Nonspecific diagnostic criteria, indiscriminate antibiotic use, and unclear therapeutic end points have all contributed to increased episodes of VAP caused by MDR pathogens.
 - MDR pathogens increase the likelihood of inadequate initial antimicrobial therapy, which exerts further selection pressure for these pathogens and results in higher mortality.
 - Distinction is sometimes made between:
 - Early-onset VAP (occurring <5 days after intubation)
 - Late-onset VAP (occurring ≥5 days after intubation)
 - Early-onset VAP, to which trauma patients are particularly prone, is often a result of aspiration of gastric contents and is usually caused by antibiotic-sensitive bacteria such as methicillin-sensitive *S. aureus*, *Streptococcus pneumoniae*, and *Haemophilus influenzae*.
 - Late-onset VAP is at increased risk for infection with MDR pathogens (e.g., MRSA, *Pseudomonas aeruginosa*, or *Acinetobacter* spp.)
 - The incidence of VAP depends upon the diagnostic criteria utilized and thus varies in published reports
 - Clinical criteria alone overestimate the incidence of VAP as compared with either microbiologic or histologic data
 - Systematic review of 89 studies of VAP among mechanically ventilated patients reported a pooled incidence of VAP of 22.8% (95% CI 18.8–26.9).
 - NNIS system reported recently that VAP occurred at a rate of 4.9 cases per 1,000 ventilator-days in medical ICUs and 9.3 per 1,000 ventilator-days in surgical ICUs (see Table 71.1).
 - Risk for trauma patients, especially those with traumatic brain injury, is especially high.
 - Incidence of VAP increases with the duration of mechanical ventilation:
 - 3% per day during the first 5 days
 - 2% per day during days 5 to 10
 - 1% per day after that
 - Risk factors for VAP are summarized in Table 71.3.
 - Perhaps most important is airway intubation itself.
 - Risk of VAP increases six- to 20-fold in mechanically ventilated patients.
 - VAP is also especially common in patients with acute respiratory distress syndrome (ARDS), owing to prolonged mechanical ventilation and devastated local airway host defenses.

TABLE 71.3**RISK FACTORS FOR VENTILATOR-ASSOCIATED PNEUMONIA**

Age ≥ 60 years
 Acute respiratory distress syndrome
 Chronic obstructive pulmonary disease or other underlying pulmonary disease
 Coma or impaired consciousness
 Serum albumin <2.2 g/dL
 Burns, trauma
 Blood transfusion
 Organ failure
 Supine position
 Large-volume gastric aspiration
 Sinusitis
 Immunosuppression

- Several evidence-based strategies can prevent VAP, but to be used effectively a thorough understanding of modifiable risk factors is required (Table 71.4).
- Prevention of VAP begins with minimization of endotracheal intubation and the duration of mechanical ventilation.
- Noninvasive positive pressure ventilation (NIPPV) should be considered in lieu of intubation, as management of respiratory failure with NIPPV leads to a lower incidence of VAP.
- If endotracheal intubation is required:
 - Orotracheal route is preferred to nasotracheal intubation to decrease the risk of VAP by as much as one-half by decreasing the risk of nosocomial sinusitis.
 - Evidence-based strategies to decrease the duration of mechanical ventilation include:
 - Daily interruption of sedation

TABLE 71.4**STRATEGIES TO PREVENT VENTILATOR-ASSOCIATED PNEUMONIA**

Strategy	Recommended	Insufficient evidence
Universal infection control precautions	+	
Orotracheal intubation	+	
Maintenance of endotracheal cuff pressure >20 cm H ₂ O	+	
Continuous aspiration of subglottic secretions	+	
Semirecumbent positioning	+	
Postpyloric feeding		+
Postponement of enteral feeding for at least 48 hours following intubation	+	
Selective decontamination of the digestive tract		+
Topical chlorhexidine	+	
Transfusion restriction	+	
Antibiotic cycling		+

- Standardized weaning protocols
- Adequate ICU staffing
- Both maintenance of endotracheal cuff pressure >20 cm H₂O and continuous subglottic suction reduce the incidence of VAP significantly
- Semirecumbent positioning (30- to 45-degree head-up) is also protective as compared to supine positioning, especially during enteral feeding.
- Compared to postpyloric feeding, intragastric feeding increases both gastroesophageal reflux and aspiration.
 - A meta-analysis of 11 randomized trials reported a RR of 0.77 (95% CI 0.60–1.00, $p = 0.05$) for VAP with postpyloric as compared to gastric feedings.
 - Promotility agents such as erythromycin may facilitate safe intragastric feeding, should this route be used.
 - Early enteral feedings may increase the risk of VAP.
 - Enteral nutrition begun ≤ 48 hours after the initiation of mechanical ventilation was independently associated with the development of VAP (OR 2.65, 95% CI 1.93–3.63, $p < 0.0001$).
- Pharmacologic strategies to minimize the risk of aspiration include:
 - Minimization of stress ulcer prophylaxis
 - Use of self-decontamination of the digestive tract is currently not recommended for the routine prevention of VAP
 - Meta-analysis of studies of oropharyngeal decontamination with topical chlorhexidine provides sufficient evidence to recommend the practice especially for cardiac surgical patients.
 - Stress ulcer prophylaxis is a known risk factor for VAP.
 - Its use should be reserved for patients at high risk for gastrointestinal mucosal hemorrhage (e.g., mechanical ventilation more than 2 days, intracranial hemorrhage, coagulopathy, glucocorticoid therapy).
 - Results of randomized trials comparing histamine type 2 antagonists, sucralfate, and antacids are conflicting for prevention of VAP.
- Red blood cell transfusion can be an independent risk factor for VAP (OR 1.89, 95% CI 1.33–2.68, $p = 0.0004$).
- 90% decreased incidence of VAP in a surgical ICU following implementation of an anemia management protocol that resulted in fewer blood transfusions

Risk Factors for Catheter-Related Bloodstream Infection

- Critically ill patients often require reliable large-bore central venous access (e.g., femoral, internal jugular, or subclavian vein), but the catheters are highly prone to infection (see Table 71.1).
- Strict adherence to infection control and proper insertion technique crucial
- Under elective (controlled) circumstances, optimal insertion technique includes:
 - Chlorhexidine skin preparation (not povidone-iodine)
 - Draping the entire bed into the sterile field
 - Donning a cap, a mask, and sterile gown and gloves

- If technique is breached, the risk of infection increases exponentially, and the catheter should be removed and replaced (if still needed) at a different site using strict asepsis and antisepsis as soon as the patient's condition permits, but certainly within 24 hours.
- Infection risk for femoral vein catheters is highest, and is lowest for catheters placed via the subclavian route
- Peripheral vein catheters, peripherally inserted central catheters (PICCs), and tunneled central venous catheters (e.g., Hickman, Broviac) pose less risk of infection than percutaneous central venous catheters.

Risk Factors for Sinusitis

- Nosocomial sinusitis an uncommon closed-space infection that may be clinically occult but can have serious consequences
- Sinusitis often part of the differential diagnosis of fever
 - Incidence is low in comparison to other nosocomial infections in the ICU, and the diagnosis can be difficult to document convincingly
 - Likely pathogenesis of sinusitis is anatomic obstruction of the ostia draining the facial sinuses, especially the maxillary sinuses
 - Transnasal endotracheal intubation is the leading risk factor
 - Incidence of sinusitis estimated to be one-third after 7 days of intubation
 - Maxillofacial trauma, with obstruction of drainage by retained blood clots, is another clear risk factor.
 - Nasogastric intubation, nasal packing for epistaxis, and corticosteroid therapy have also been implicated, but the evidence is less convincing.

ANTIBIOTIC PROPHYLAXIS

- Prophylactic antibiotics are used most often to prevent infection of a surgical incision.

- Does not prevent postoperative nosocomial infections
- Actually occur at an increased rate after prolonged prophylaxis, selecting for more resistant pathogens when infection does develop
- Preoperative antibiotic prophylaxis has been proven to reduce the risk of postoperative SSI in many circumstances.
 - Only the incision is protected, but only while it is open and vulnerable to inoculation
 - Indicated for most clean-contaminated and contaminated (or potentially contaminated) operations
 - Current Surgical Care Improvement Project (SCIP) guidelines for antibiotic prophylaxis of elective colon surgery give equal weighting to oral prophylaxis alone, parenteral prophylaxis alone, or the combination (Table 71.5).
- Antibiotic prophylaxis of clean surgery is controversial.
 - Where bone is incised (e.g., craniotomy, sternotomy) or a prosthesis is inserted, antibiotic prophylaxis generally indicated
 - Meta-analysis of randomized controlled trials shows some benefit of antibiotic prophylaxis of breast cancer surgery without immediate reconstruction but no decrease of SSI rate for groin hernia surgery even when a nonabsorbable mesh prosthesis is implanted.
 - Arterial reconstruction with prosthetic graft material is an example of clean surgery where the susceptibility to infection is high, owing to the presence of ischemic tissue and the infrainguinal location of many such operations.
 - Meta-analysis identified 23 randomized, controlled trials of prophylactic systemic antibiotics for peripheral arterial reconstruction (Table 71.6).
 - Prophylactic systemic antibiotics reduced the risk of SSI by approximately 75%, and early graft infection by about 69%.
 - No benefit to prophylaxis for more than 24 hours, antibiotic bonding to the graft material itself, or preoperative bathing with an antiseptic agent compared with unmedicated bathing
- Four principles guide the administration of antimicrobial agents for prophylaxis:
 - Safety

TABLE 71.5

SURGICAL CARE IMPROVEMENT PROGRAM: APPROVED ANTIBIOTIC PROPHYLACTIC REGIMENS FOR ELECTIVE SURGERY

Type of operation	Antibiotic(s)
Cardiac (including CABG) ^a , vascular ^b	Cefazolin, cefuroxime, or vancomycin ^f
Hip/knee arthroplasty ^b	Cefazolin, cefuroxime, or vancomycin ^f
Colon ^{c,d}	Oral: Neomycin sulfate plus either erythromycin base or metronidazole, administered for 18 hours before surgery Parenteral: cefoxitin, cefotetan, or cefazolin plus metronidazole or ampicillin-sulbactam or ertapenem
Hysterectomy ^e	Cefazolin, cefoxitin, cefotetan, cefuroxime, or ampicillin-sulbactam

^aProphylaxis may be administered for up to 48 hours for cardiac surgery; for all other cases, the limit is 24 hours.

^bFor β -lactam allergy, clindamycin or vancomycin is an acceptable substitute for cardiac, vascular, and orthopedic surgery.

^cFor β -lactam allergy, clindamycin plus gentamicin, a fluoroquinolone, or aztreonam; or metronidazole plus gentamicin or a fluoroquinolone is an acceptable choice.

^dFor colon surgery, either oral or parenteral prophylaxis alone, or both combined, is acceptable.

^eFor β -lactam allergy, clindamycin plus gentamicin, a fluoroquinolone, or aztreonam; or metronidazole plus gentamicin or a fluoroquinolone or clindamycin monotherapy is an acceptable choice.

^fVancomycin is acceptable with a physician-documented justification for use in the patient's medical record.

TABLE 71.6

META-ANALYSIS OF MEASURES TO PREVENT INFECTION FOLLOWING ARTERIAL RECONSTRUCTION

Intervention	No. of trials	Odds ratio	95% CI
Systemic antibiotic prophylaxis			
<i>Surgical site infection</i>	10	0.25	0.17–0.38
>24 h prophylaxis	3	1.28	0.82–1.98
<i>Early graft infection</i>	5	0.31	0.11–0.85
Rifampicin bonding of polyester grafts			
<i>Graft infection—1 month</i>	3	0.63	0.27–1.49
<i>Graft infection—2 years</i>	2	1.05	0.46–2.40
Suction wound drainage—groin	2		
<i>Surgical site infection</i>	0.96	0.50–1.86	
Preoperative antiseptic bath	3		
<i>Surgical site infection</i>	0.97	0.70–1.36	
<i>In situ</i> surgical technique	2		
<i>Surgical site infection</i>	0.48	0.31–0.74	

Data from Stewart A, Evers PS, Earnshaw JJ. Prevention of infection in arterial reconstruction. *Cochrane Database Syst Rev.* 2006;3:CD003073.

- Appropriate narrow spectrum of coverage of relevant pathogens
- Little or no reliance upon the agent for therapy of infection (owing to the possible induction of resistance with heavy usage)
- Administration within 1 hour before surgery and for a defined, brief period of time thereafter (no more than 24 hours [48 hours for cardiac surgery]; ideally, a single dose)
 - According to these principles, quinolones or carbapenems are undesirable agents for surgical prophylaxis.
 - Ertapenem and quinolone prophylaxes have been endorsed by the SCIP for prophylaxis of colon surgery (the latter with metronidazole for penicillin-allergic patients) (see Table 71.5).
- Most SSIs are caused by Gram-positive cocci.
 - Prophylaxis should be directed primarily against staphylococci for clean cases and high-risk clean-contaminated elective biliary and gastric surgery.
 - First-generation cephalosporin is preferred in almost all circumstances (Table 71.7), with clindamycin used for penicillin-allergic patients.
 - If Gram-negative or anaerobic coverage is required, a second-generation cephalosporin or the combination of a first-generation agent plus metronidazole is most experts' regimens of first choice.
 - Vancomycin prophylaxis is generally appropriate only in institutions where the incidence of MRSA infection is high (>20% of all SSIs caused by MRSA).
- Optimal time to give parenteral antibiotic prophylaxis is within 1 hour prior to incision.
 - Given sooner they are ineffective, as are agents given after the incision is closed.
 - In 2001 only 56% of patients who received prophylactic antibiotics did so within 1 hour prior to the skin incision.
 - Timeliness was documented in only 76% of cases in a 2005 audit in Veterans Affairs hospitals
 - Most inappropriately timed first doses of prophylactic antibiotic occur too early
 - Antibiotics with short half-lives (<2 hours, e.g., cefazolin or cefoxitin) should be redosed every 3 to 4 hours during surgery if the operation is prolonged or bloody.
- SCIP specifies a 24-hour limit for prophylaxis (Table 71.8).
 - Excessively prolonged antibiotic prophylaxis is both pervasive and potentially harmful.
 - Recent U.S. data show that only 40% of patients who receive antibiotic prophylaxis do so for <24 hours.
 - As a result of ischemia caused by surgical hemostasis, antibiotic penetration into the incision immediately after surgery is questionable until neovascularization occurs (24–48 hours).
 - Antibiotics should not be given to “cover” indwelling drains or catheters, in lavage or irrigation fluid, or as a substitute for poor surgical technique.
- Prolongation of antibiotic prophylaxis beyond 24 hours is not only nonbeneficial, but also may be harmful.
 - *Clostridium difficile*-associated disease (CDAD) follows disruption of the normal balance of gut flora, resulting in overgrowth of the enterotoxin-producing *C. difficile*.
 - Virtually any antibiotic may cause CDAD (even a single dose).
 - Prolonged antibiotic prophylaxis increases risk.
 - Prolonged prophylaxis also increases the risk of nosocomial infections unrelated to the surgical site, and the emergence of MDR pathogens.
 - Pneumonia and vascular catheter-related infections have been associated with prolonged prophylaxis as has the emergence of SSI caused by MRSA.

EVALUATION OF POSSIBLE POSTOPERATIVE INFECTION

- Some infected patients do not become febrile and may even become hypothermic.

TABLE 71.7

APPROPRIATE CEPHALOSPORIN PROPHYLAXIS FOR SELECTED OPERATIONS^a

Operation	Alternative prophylaxis in serious penicillin allergy
First-generation cephalosporin (i.e., cefazolin, cefuroxime)	Clindamycin (for all cases herein except amputation) ^b
Cardiovascular and thoracic	
Median sternotomy	Vancomycin
Pacemaker insertion	
Vascular reconstruction involving the abdominal aorta, insertion of a prosthesis, or a groin incision (except carotid endarterectomy, which requires no prophylaxis)	
Implantable defibrillator	
Pulmonary resection	
Lower limb amputation	Gentamicin and metronidazole
General	
Cholecystectomy	Gentamicin
(High risk only)	
Gastrectomy	Gentamicin and metronidazole
(High risk only: Not uncomplicated chronic duodenal ulcer)	
Hepatobiliary	Gentamicin and metronidazole
Major debridement of traumatic wound	Gentamicin
Genitourinary	Ciprofloxacin
(Ampicillin plus gentamicin a reasonable alternative)	
Appendectomy	Metronidazole with/without gentamicin (all cases herein)
	Second generation (i.e., cefoxitin) ^c
Colon surgery	
Surgery for penetrating abdominal trauma	
Gynecologic	
Cesarean section (stat)	Metronidazole (after cord clamping)
Hysterectomy (cefoxitin a reasonable alternative)	Doxycycline
Head and neck/oral cavity	Gentamicin and clindamycin or metronidazole
Major procedures entering oral cavity or pharynx	
Neurosurgery	
Craniotomy	Clindamycin, vancomycin
Orthopedics	
Major joint arthroplasty	Vancomycin ^b
Open reduction of closed fracture	Vancomycin ^b

^aShould be given as a single intravenous dose just before the operation. Consider an additional dose if the operation is prolonged longer than 3–4 h.

^bPrimary prophylaxis with vancomycin (i.e., for the non-penicillin-allergic patient) may be appropriate for cardiac valve replacement, placement of a nontissue peripheral vascular prosthesis, or total joint replacement in institutions where a high rate of infections with methicillin-resistant *Staphylococcus aureus* or *Staphylococcus epidermidis* has occurred. The precise definition of “high rate” is debated. A single dose administered immediately before surgery is sufficient unless operation lasts for more than 6 h, in which case the dose should be repeated. Prophylaxis should be discontinued after a maximum of two doses, but may be continued for up to 48 h.

^cAn intraoperative dose should be given if cefoxitin is used and the duration of surgery exceeds 3–4 h, because of the short half-life of the drug. A postoperative dose is not necessary, but is permissible for up to 24 h.

TABLE 71.8

COMPARISON OF ANTIBIOTIC UTILIZATION (MEDIAN DEFINED DAILY DOSES) FOR SURGICAL INTENSIVE CARE UNITS (SICUs) AND INPATIENT UNITS, 1998–2002

Agent	Inpatient	SICU
First-generation cephalosporins	76	168
Third-generation cephalosporins	81	142
Vancomycin		104
Fluoroquinolones	62	87
Ampicillins	63	83
Second-generation cephalosporins	34	NR

NR, not reported.

From the National Nosocomial Infections Surveillance System, U.S. Centers for Disease Control and Prevention. Data abstracted from www.cdc.gov. Data are in the public domain.

- Elderly patients
- Those with open abdominal wounds or large burns
- Patients on extracorporeal support (e.g., continuous renal replacement therapy)
- Patients with end-stage liver disease or chronic renal failure
- Patients taking anti-inflammatory or antipyretic drugs
- Absent a fever, hypotension, tachycardia, tachypnea, confusion, rigors, skin lesions, respiratory manifestations, oliguria, lactic acidosis, leukocytosis, leukopenia, immature neutrophils (i.e., bands >10%), or thrombocytopenia may indicate a workup for infection and immediate empiric therapy.
- Definition of fever is arbitrary, and depends on how and when temperature was measured
- In addition to host biology, a variety of environmental forces in an ICU can also alter body temperature:
 - Specialized mattresses
 - Lighting, heating, or air conditioning
 - Peritoneal lavage

- Renal replacement therapy
- Thermoregulatory mechanisms can be disrupted by drugs or by injury to the central nervous system (CNS).
- Often difficult to determine if an abnormal temperature is a reflection of a physiologic process, a drug, or an environmental influence
- In surgical patients, the substantial possibility (~50%) that a fever is due to a noninfectious cause must be considered
- Many ICUs consider any patient with a core temperature $\geq 38.3^{\circ}\text{C}$ ($\geq 101^{\circ}\text{F}$) to be febrile and to warrant evaluation to determine if infection is present.
 - Lower threshold may be decided upon for immunocompromised patients
 - Laboratory tests or imaging studies to search for infection should be performed only after a clinical assessment (history and physical examination) indicates that infection might be present.

Blood Cultures

- Should be obtained with a new fever when clinical evaluation does not strongly suggest a noninfectious cause
 - Site of venipuncture should be cleaned with either 2% chlorhexidine gluconate in 70% isopropyl alcohol or 1% to 2% tincture of iodine
 - Povidone-iodine (10%), while acceptable, is not bactericidal until dry
 - One blood culture is defined as a 20- to 30-mL sample of blood drawn at a single time from a single site
 - Regardless of how many bottles or tubes are filled for processing
 - Sensitivity of blood culturing for detection of true bacteremia or fungemia is related to many factors:
 - Most importantly the volume of blood drawn
 - Obtaining the cultures before initiation of anti-infective therapy
 - Cumulative yield of pathogens is optimized when three blood cultures with adequate volume (20- to 30-mL each) are drawn.
 - Ideally drawn by separate venipuncture or through a separate intravascular device
 - Not through multiple ports of the same intravascular catheter
 - No evidence that the yield of cultures drawn from an artery or vein is different
 - Drawing two to three blood cultures with appropriate volume from separate sites of access at the onset of fever is the most effective way to discern whether an organism found in blood culture represents:
 - True pathogen (multiple cultures are often positive)
 - Contaminant (only one of multiple blood cultures is positive for an organism commonly found on skin and clinical correlation does not support infection)
 - Bacteremia/fungemia from an infected catheter (one culture from the source catheter is positive, often with a positive catheter tip, and other cultures are not)
- As part of a comprehensive physical examination
- To determine if they are still needed
- Whether signs of infection are present locally (e.g., inflammation or purulence at the exit site or along the tunnel) or systemically
- Contaminated catheter hubs are common portals of entry for organisms colonizing the catheter's endoluminal surface
- Infusate (i.e., parenteral fluid, blood products, or intravenous medications) can become contaminated and produce bacteremia or fungemia, which is especially likely to result in septic shock.
 - Abrupt onset of signs and symptoms of sepsis or shock in patients with an indwelling vascular catheter should prompt suspicion of infection of an intravascular device.
 - Recovery in multiple blood cultures of staphylococci or *Candida* spp. strongly suggests infection of an intravascular device.
- Removal and culture of the catheter historically the gold standard for diagnosis of CR-BSI particularly with short-term catheters
 - Demonstrated the reliability of semiquantitative or quantitative catheter tip culture methods for the diagnosis of CR-BSI
 - Confirmed when a colonized catheter is associated with concomitant bloodstream infection with the identical organism, with no other plausible source
 - Some ICU clinicians culture central venous catheters routinely on removal, regardless of whether infection is suspected
 - Approximately 20% of central venous catheters are colonized at removal, most unassociated with local or systemic infection, so this practice is expensive and can lead to unnecessary therapy.
 - Predictive value of a positive catheter culture is very low when there is a low pretest probability of line sepsis.
 - Catheters removed from ICU patients should only be cultured if there is strong clinical suspicion of CR-BSI.
- For patients with fever alone without systemic inflammatory response syndrome (SIRS):
 - Usually no need to remove or change all indwelling catheters immediately
 - Although such an approach would be prudent in a patient with a prosthetic heart valve or a fresh arterial graft
- If patients have severe sepsis or septic shock, peripheral embolization, disseminated intravascular coagulation, or ARDS:
 - Removal of all intravascular catheters is indicated, even if the catheters are cuffed or tunneled devices.
- Infected phlebitis (suppurative phlebitis) of central vein due to a CVL is unusual.
 - With suppurative phlebitis, bloodstream infection characteristically persists
 - Originates from a peripheral vein catheter site with infected intravascular thrombus
 - Producing a picture of overwhelming sepsis with high-grade bacteremia or fungemia
 - Syndrome is most often encountered in burn patients or other ICU patients who develop unrecognized catheter-related infection
- In patients with persistent *S. aureus* bacteremia or fungemia, echocardiography is appropriate to assess for endocarditis and guide further therapy.

Intravascular Devices

- All intravascular devices and insertion sites must be assessed daily:

INTRACRANIAL DEVICE-RELATED FEVER

- When a patient with an intracranial device such as an extraventricular drain (EVD) (ventriculostomy catheter) or a ventriculoperitoneal shunt becomes febrile, cerebrospinal fluid (CSF) should be analyzed.
 - Access to CSF in the patient with an EVD is straightforward.
 - Patient with a shunt or Ommaya reservoir should have the reservoir aspirated.
 - Patients with EVDs who develop stupor or signs of meningitis should have the catheter removed and the tip cultured.
- Basic tests of CSF for suspected CNS infection include:
 - Cell counts and differential
 - Glucose and protein concentrations
 - Gram stain
 - Bacterial cultures
- Patients with bacterial meningitis typically have:
 - CSF glucose concentration <35 mg/dL
 - CSF:blood glucose ratio <0.23
 - CSF protein concentration >220 mg/dL
 - $>2,000$ total white blood cells/ μ L, or $>1,180$ neutrophils/ μ L
 - Conversely, the presence of a normal opening pressure, <5 white blood cells/ μ L, and a normal CSF protein concentration essentially exclude meningitis.
 - Measurement of CSF lactate concentration may be useful in neurosurgical patients to distinguish infection from postoperative aseptic meningitis.

NONINFECTIOUS CAUSES OF FEVER IN THE INTENSIVE CARE UNIT

Postoperative Fever

- Fever is common during the initial 72 hours following surgery and is usually noninfectious in origin.
 - Presuming that unusual breaks in sterile technique or pulmonary aspiration did not occur
 - Once a patient is more than 96 hours postoperative, fever is more likely to represent infection.
- Chest radiograph:
 - Not mandatory for evaluation of postoperative fever unless:
 - Respiratory rate
 - Auscultation
 - Abnormal blood gases
 - Pulmonary secretions suggest a high yield
 - Atelectasis often considered to be a cause of postoperative fever, but is not
 - Patient could have aspirated during the perioperative period
 - Patient could have been incubating a community-acquired pneumonia prior to the operation caused, for example, by pneumococci or influenza A
- Urinary tract infection is common postoperatively in non-trauma patients because of the use of urinary drainage catheters.
 - Duration of catheterization increases the risk of bacteriuria by about 5% per day

- Increases the risk of nosocomial cystitis or pyelonephritis
- A urinalysis or culture is not mandatory to evaluate fever during the initial 3 days postoperatively unless there is reason by history or examination to suspect an infection at this site.
- After trauma, urinary tract infection is common only after injury to the urinary tract.
- Fever can be related to hematoma or infection of the surgical field.
 - Surgical site infection is rare in the first few days after operation, except for group A streptococcal infections and clostridial infections.
 - Can develop within hours to 1 to 3 days after surgery
 - These causes should be suspected on the basis of inspection of the incision
 - Many emergency abdominal operations are performed for control of an infection (e.g., perforated diverticulitis).
 - Even under optimal circumstances (definitive surgical source control and timely administration of appropriate broad-spectrum antibiotics), it may take ≥ 72 hours for such patients to defervesce.
 - New or persistent fever more than 4 days after surgery should raise suspicion of persistent pathology or a new complication.
 - Mandatory to remove the surgical dressing to inspect the incision
 - Swabbing an open wound or collecting fluid from drains (if present) for culture rarely helpful because the likelihood of colonization is high
 - **Muscle compression injury** (either direct trauma or as a result of compartment syndrome) and **tetanus** are two rare complications of traumatic wounds that may cause fever.
 - Toxic shock may accompany infection with group A streptococci or *S. aureus*.
 - Other potentially serious noninfectious causes of postoperative fever include:
 - Deep venous thrombosis or pulmonary embolus
 - Tissue ischemia or necrosis
 - Adrenal insufficiency
 - Drug-induced fever
 - Anesthesia-induced malignant hyperthermia
 - Acute allograft rejection

Drug-Related Fever

- “Drug fever” is decidedly unusual in surgical patients.
 - Must be considered a diagnosis of exclusion
 - Some drugs cause fever by producing local inflammation at the site of administration (phlebitis, sterile abscesses, or soft tissue reaction), such as:
 - Amphotericin B
 - Erythromycin
 - Potassium chloride
 - Drugs or their delivery systems (diluent, intravenous fluid, or intravascular delivery devices) may also contain pyrogens or, rarely, microbial contaminants
 - Some drugs may also stimulate heat production (e.g., thyroxine), limit heat dissipation (e.g., atropine or epinephrine), or alter thermoregulation (e.g., butyrophenone tranquilizers, phenothiazines, antihistamines, or antiparkinson drugs)

- Among drug categories, drug fever in surgical ICUs is most often attributed to antimicrobial agents (e.g., vancomycin, β -lactams) and anticonvulsants (especially phenytoin).
- Two important syndromes, malignant hyperthermia (MH) and neuroleptic malignant syndrome, deserve consideration when fever is especially high because the results can be devastating if left untreated:
 - MH more often identified in the operating room than the ICU, but onset can be delayed for as long as 24 hours, especially if the patient is on steroids.
 - MH believed to be genetically determined response mediated by a dysregulation of cytoplasmic calcium flux in skeletal muscle, resulting in intense muscle contraction, fever, and increased creatinine phosphokinase concentration.
 - Can be caused by succinylcholine and inhalational anesthetics
- The neuroleptic malignant syndrome is slightly more common and more often identified in the ICU than malignant hyperthermia.
 - Strongly associated with the neuroleptic medications:
 - Phenothiazines
 - Thioxanthenes
 - Butyrophenones
 - Most frequently haloperidol in the ICU
 - Also manifests as muscle rigidity, fever, and increasing creatinine phosphokinase concentration.
 - Unlike MH, the initiator of muscle contraction is central, the syndrome is often less intense, and mortality is less.
- Drug withdrawal from alcohol, opioids, barbiturates, and benzodiazepines may be associated with:
 - Fever
 - Tachycardia
 - Diaphoresis
 - Hyperreflexia
 - History of use of these drugs may not be available when the patient is admitted to the ICU.
 - Withdrawal and related fever may therefore occur several hours or days after admission.
- Other noninfectious causes of fever are listed in Table 71.9.

CLINICAL INFECTION SYNDROMES

Biliary Tract Infections

- Biliary tract infections remain an important cause of critical illness.
 - Difficult to diagnose in critically ill patients, owing to their relative rarity and the nonspecificity of symptoms noncommunicative patients may manifest
 - Unless diagnosed and treated aggressively, organ dysfunction and death may ensue rapidly.
 - Signs and symptoms of hepatobiliary infection commonly include:
 - Abdominal pain
 - Fever
 - Nausea and vomiting
 - Clinical presentation may range in severity from the appearance of a chronic disease state to overt septic shock.
 - Leukocytosis is common.

TABLE 71.9

CAUSES OF FEVER RELATED TO NONINFECTIOUS STATES

Acalculous cholecystitis
 Acute myocardial infarction
 Acute respiratory distress syndrome (fibroproliferative phase)
 Adrenal insufficiency
 Cytokine release syndrome
 Fat embolism
 Gout
 Hematoma
 Heterotopic ossification
 Immune reconstitution inflammatory syndrome (IRIS)
 Intracranial hemorrhage
 Pancreatitis
 Pericarditis
 Pulmonary infarction
 Thyroid storm
 Transfusion of blood or blood products
 Transplant rejection
 Tumor lysis syndrome
 Venous thromboembolic disease
 Withdrawal syndromes (drug, alcohol)

- Patterns of liver enzyme abnormalities overlap to such a degree that it may be difficult to make a definitive diagnosis based on history, physical examination, and laboratory values alone.
- May be difficult to distinguish liver dysfunction caused by primary infection from that caused by multiple organ dysfunction syndrome
- Imaging of the biliary tree is often of paramount importance.

Acute Cholecystitis

- In outpatients, acute cholecystitis usually occurs when gallstones migrate into the cystic duct, causing outflow obstruction.
- Obstruction causes sterile inflammation and edema of the gallbladder wall initially, followed by bacterial superinfection.
- Acute calculous cholecystitis presents with:
 - Fever
 - Right upper quadrant pain
 - Nausea and vomiting
- Physical examination may range from:
 - Arrest of inspiration due to tenderness on palpation in the right upper quadrant (Murphy sign)
 - To signs of peritonitis in advanced cases
 - Concomitant jaundice suggests the presence of choledocholithiasis
- Ultrasound highly sensitive and specific test (95% and 97%, respectively)
 - Diagnostic findings include:
 - Presence of stones in the gallbladder
 - Thickening of the gallbladder wall (>3.5 mm)
 - Pericholecystic fluid
 - Tenderness with application of the ultrasound probe (sonographic Murphy sign)

- Most cases (~80%) of acute calculous cholecystitis resolve with bowel rest, fluid resuscitation, and intravenous antibiotics and are treated ultimately by cholecystectomy.
 - Patients ill enough to require ICU care generally have gallbladder gangrene that progresses to perforation, resulting in either subhepatic abscess or free perforation with bile peritonitis.
 - Associated with a 30% mortality rate
 - Tends to occur in older patients
 - Emphysematous cholecystitis, a severe manifestation of acute cholecystitis with predilection for elderly patients and patients with diabetes mellitus
 - Defined by the presence of gas in the gallbladder wall as visualized on ultrasound or computed tomography (CT)
 - Characterized by polymicrobial infection including *Clostridium* spp., *Escherichia coli*, *Klebsiella* spp., and *Streptococcus* spp.
 - Roughly one-half of all cases of emphysematous cholecystitis are acalculous.
 - Reported mortality ranges from 15% to 25%
 - Acalculous cholecystitis has been reported in all age groups.
 - Most often occurs in the setting of severe illness or injury
 - May also occur in the postoperative setting, particularly in males after emergency surgery complicated by large-volume blood loss
 - Review of 31,710 cases of cardiac surgery found a 0.05% incidence
 - After open abdominal aortic aneurysm repair incidence has been reported to be between 0.7% and 0.9%
 - A grave condition of insidious onset in patients who are often already critically ill with mortality approaching 30%
 - Diagnosis of acalculous cholecystitis must always be entertained in a patient with sepsis for whom no clear source of infection can be determined.
 - Pathogenesis of acalculous cholecystitis most likely splanchnic ischemia-reperfusion injury
 - Alternatively, bile stasis associated with critical illness may lead to distention of the gallbladder, which, in combination with hypoperfusion, may cause ischemia and ultimately necrosis.
 - Factors such as mechanical ventilation, total parenteral nutrition, cytokine activation, and endotoxemia have also been implicated.
 - Diagnosis of acalculous cholecystitis difficult to make in the ICU
 - Patients who communicate may report abdominal pain localizing to the right upper quadrant or diffuse pain in the case of peritonitis
 - Fever usually present
 - Physical examination may reveal signs ranging from localized tenderness in the right upper quadrant to frank peritonitis.
 - Right upper quadrant abdominal phlegmon may be palpable.
 - Altered mental status that often accompanies critical illness may obscure any useful information that might be obtained from the history and physical examination.
 - Laboratory values are nonspecific but usually include:
 - Elevated liver enzymes, particularly of bilirubin, transaminases, and alkaline phosphatase
 - Hyperbilirubinemia is typical and occurs more often in acalculous than calculous cholecystitis
- Ultrasound is perhaps the ideal radiologic study to investigate the diagnosis of acalculous cholecystitis in the ICU.
 - May reveal hydrops of the gallbladder
 - Pericholecystic fluid
 - Gallbladder wall thickening
 - If thickness ≥ 3.5 mm, ultrasound is 98.5% sensitive and 80% specific for the diagnosis of acalculous cholecystitis
- Upon making diagnosis:
 - Decision about method of source control must be made
 - Empiric antibiotic therapy started:
 - Up to one-half of cases of acute acalculous cholecystitis are associated with culture-negative bile at least initially
 - Empiric antibiotics needed because distinguishing sterile from infected cases can be clinically impossible
 - Organisms most frequently cultured from the bile in acalculous cholecystitis are *E. coli*, *Klebsiella*, and *Enterococcus faecalis*
- Source control for cholecystitis, whether calculous or acalculous, traditionally cholecystectomy:
 - Percutaneous cholecystostomy tube placement is a minimally invasive alternative to cholecystectomy that is favored increasingly
 - Complications of percutaneous cholecystostomy include bacteremia, hemorrhage, bile peritonitis, and tube dislodgement
 - With uncomplicated cholecystitis should improve rapidly after gallbladder decompression
 - Failure to improve should raise suspicions of an incorrect diagnosis or inadequate source control and surgical exploration mandated

Cholangitis

- An acute infection of the main biliary ductal system
 - Pathogenesis of cholangitis requires both obstruction and bacterial superinfection
 - Most common cause of intrinsic obstruction in the Western world is choledocholithiasis
 - Both primary and metastatic malignant disease of the abdominal viscera may cause extrinsic obstruction, among other causes
 - Obstruction from calculi more likely to cause cholangitis than malignant obstruction
 - May also occur in the postoperative setting, particularly after a biliary-enteric anastomosis
- Bile is sterile in the normal biliary tree and naturally bacteriostatic
 - Antegrade flow of bile from liver to duodenum serves as a flushing mechanism
 - Sphincter of Oddi is an anatomic barrier, preventing reflux of enteric flora
 - Bile salts absorb intraluminal endotoxins and may also exhibit a trophic effect on small bowel mucosa
- Charcot triad of fever, right upper quadrant pain, and jaundice

- Observed in 50% to 70% of patients who present with cholangitis
- Fever present most consistently (90%)
- Hypotension and altered mental status (i.e., severe sepsis or septic shock) in addition constitute the Reynolds pentad
- Typically have leukocytosis, direct hyperbilirubinemia (88%–100%), and elevated alkaline phosphatase (80%)
- Transaminitis is usually mild
- Common duct bile cultures positive 80% to 100% of the time in cholangitis
 - Positive blood cultures found in up to two-thirds of patients
 - Concordance rate between bile and blood cultures is 33% to 84%
 - Bile cultures being polymicrobial in roughly one-half of cases
 - Typical flora are *Klebsiella*, *E. coli*, and *Enterococcus*
- Imaging of patients with cholangitis is possible using ultrasound, CT, or magnetic resonance imaging (MRI)
- Ultrasound detects cholelithiasis and bile duct dilation reliably, but is only 50% sensitive for detecting choledocholithiasis
- CT detects ductal dilation with 98% accuracy and is superior to ultrasound in defining the level of obstruction, but may fail to visualize the 85% of biliary calculi that are radiolucent
- Stones can be visualized on MRI
 - Magnetic resonance cholangiopancreatography (MRCP) provides the most complete imaging as to the etiology of biliary obstruction
- Endoscopic retrograde cholangiopancreatography (ERCP) and Percutaneous transhepatic cholangiopancreatography (PTC) are both 90% to 100% sensitive for defining the site and nature of biliary obstruction.
 - Either can be used diagnostically or therapeutically to decompress the biliary tree.
 - Both ERCP and PTC have rare potential complications (e.g., bile leak, bleeding) that may precipitate ICU admission.
- Treatment of cholangitis consists of:
 - Immediate fluid resuscitation and broad-spectrum antibiotics
 - Followed by urgent or emergent biliary decompression
 - Many authorities prefer a single broad-spectrum agent such as piperacillin/tazobactam or a carbapenem
 - 10% to 15% will require emergent decompression
 - ERCP is the safest and most efficacious treatment for acute cholangitis with a success rate of 90% and a mortality rate of 10%, considerably lower than that of emergency surgical decompression of the common bile duct.
 - Other complications of ERCP include pancreatitis, perforation, aspiration, systemic sepsis, and failure to decompress the bile duct.
 - Percutaneous transhepatic biliary drainage carries 30% morbidity.
 - Complications such as hemorrhage, pneumothorax, subphrenic abscess, and bile peritonitis
 - Mortality for PTC is estimated to be between 5% and 10%, similar to that seen with ERCP.
 - Surgery is now infrequent in the primary management of acute cholangitis

- In situations that require surgery (e.g., resectable malignant obstruction), patients may be temporized by ERCP or PTC
 - Also indicated in patients who fail less invasive treatment methods
 - Standard emergency surgical therapy includes cholecystectomy, choledochotomy, and T-tube placement

Liver Abscess

- Most common cause (50% to 65%) of liver abscesses is now ascending biliary tract infection (e.g., cholangitis, direct extension of acute suppurative cholecystitis).
- Seeding from the portal vein accounts for 10% to 25% of abscesses and is typically a result of intra-abdominal sources of infection such as diverticulitis.
- Systemic seeding via the hepatic artery occurs in 1% to 10% of cases from processes such as bacterial endocarditis, dental abscesses, or interventions such as hepatic artery chemoembolization, intraoperative cryoablation, or radiofrequency ablation.
- Liver abscess complicates fewer than 1% of blunt liver injuries managed nonoperatively and is more common in patients requiring damage-control laparotomy and perihepatic packing to control hemorrhage.
- Patients with pyogenic hepatic abscess usually present with fever and chills, abdominal pain, and weight loss.
 - Nonspecific abdominal complaints and constitutional symptoms are common, and presentation can range from the appearance of a chronic disease state to overt septic shock.
- Laboratory workup demonstrates leukocytosis in most patients, with liver enzymes being moderately abnormal as well.
- Due to the protean manifestations of liver abscess and the mimicry of a number of disease processes, radiographic imaging is crucial.
 - Ultrasound and CT both have >95% sensitivity for the diagnosis.
 - One-half of patients will present with more than one abscess, and approximately 75% of all liver abscesses will be found in the right lobe of the liver.
- Pyogenic liver abscesses are equally likely to be polymicrobial as monomicrobial.
 - Approximately 5% to 27% show no growth in culture.
 - Failure to speciate bacteria in culture may reflect prior antibiotic treatment.
 - Flora found in liver abscesses reflects the underlying source of the infection.
 - Overall the most common Gram-negative aerobes found in pyogenic liver abscesses are *E. coli* and *Klebsiella* spp.
 - Most common Gram-positive aerobes are *Enterococcus* spp., viridans streptococci, and *S. aureus*. Among cultured anaerobes, *Bacteroides* spp. predominate.
 - Medical management carried a mortality rate of 60% to 100%.
 - Recent case series demonstrate success rates for antibiotics alone of up to 80% when multiple (military) abscesses are too small or too numerous for percutaneous drainage.
 - Preferred method of treatment is broad-spectrum antibiotics in conjunction with drainage of all abscesses.

- Most can be drained successfully by image-guided percutaneous techniques, with a success rate of 70% to 93%.
- Surgical drainage is indicated in patients who:
 - Fail percutaneous drainage
 - Require surgical management of the underlying problem (e.g., diverticulitis)
 - Have abscesses that are not amenable to minimally invasive techniques because of their location
- Contemporary series quote a mortality rate for hepatic abscess between 6% and 31%.
- Factors associated with a worse prognosis include:
 - Underlying diagnosis of malignant disease
 - Multiple abscesses
 - High presenting APACHE II score

Postoperative Infections after Biliary Tract Operations

- Perihepatic infections may occur as a result of commonly performed hepatobiliary surgical procedures.
- Postoperative bile leaks may occur after any operation in which a bile duct is opened
 - Hepatectomy
 - Hepaticoenterostomy
 - Hepatic transplant
 - Cholecystectomy
- Leaking bile may induce chemical peritonitis or cause infection with microbial flora present in or introduced into tissue at the time of operation, or by translocation from the gut.
 - Leading to an infected intrahepatic or perihepatic collection, known as a biloma
- After cholecystectomy, bile leaks occur in up to 1% of patients.
 - Present with right upper quadrant pain, fever, nausea, vomiting, or jaundice
 - Discrimination between sterile bile peritonitis and infection may be difficult without culture of the collection
 - Postoperative fluid collections may be imaged with ultrasound, CT, or nuclear scintigraphy
- Diagnosis of bile leak can also be made by image-guided aspiration of the collection
- Treatment of postoperative bile leakage hinges first upon drainage and then definitive treatment of the underlying problem.
- Perihepatic or intra-abdominal abscess complicates 8% to 30% of major liver resections.
 - Associated with preoperative biliary stenting, hepaticoenterostomy, increased operative time, greater extent of resection, and the need for blood transfusion
- Preoperative hyperbilirubinemia as a result of biliary obstruction occurs frequently in patients with malignant biliary tract obstruction.
 - Such patients are at increased risk for complications of surgical resection.
 - Preoperative stent placement to alleviate biliary obstruction leads to increased rates of postoperative infectious complications.
- Resection of hepatic parenchyma leaves dead space in the abdomen that collects bile and blood and is in proximity to ischemic tissue at the resection margin.
 - Bacterial superinfection may occur, leading to the formation of an abscess
- Infected bilomas are heralded by fever, right upper quadrant pain, leukocytosis, and elevated liver enzymes.
- Imaging modalities for posthepatectomy abscesses include CT, ultrasound, and MRI
- Cultures reveal that 50% to 75% of postoperative perihepatic abscesses are polymicrobial.
 - Bacteria of enteric origin (e.g., *E. coli*, *Enterococcus*) predominate
 - Image-guided percutaneous drainage is the treatment of choice where feasible, with reoperation reserved for those patients in whom percutaneous drainage is not possible or unsuccessful.
- Liver transplantation is plagued by complication rates ranging from 24% to 64%.
- Incidence of bile leak after orthotopic liver transplantation is between 10% and 40%.
 - Leaks arise most commonly from hepatic resection lines, T-tube sites, and biliary anastomoses.
 - Patients may present up to 6 months after transplantation.
 - CT is used to image the collection, which may be intrahepatic in up to two-thirds of cases.
 - ERCP, PTC, or cholangiogram through a preexisting T tube may be used to delineate the origin of the leak.
 - Most collections can be drained percutaneously, and in the event of direct communication with the biliary tree, ERCP can be used to reestablish preferential enteric drainage.
 - Blood supply to the biliary tree is provided by the hepatic artery; anastomotic leaks after liver transplantation may occur as a result of ischemia from hepatic artery thrombosis.
 - Assessment of the patency of the graft hepatic artery must be determined.
 - Some cases of biloma associated with hepatic artery thrombosis may respond to conservative measures, up to two-thirds will require retransplantation.

SURGICAL SITE INFECTION

- SSIs among the most frequently encountered complications in surgical patients regardless of specialty
- Simply opening and draining the incision in cases of superficial incisional SSI
- Infections extending below the superficial fascia (deep incisional SSIs) invariably require formal surgical debridement and open wound care to resolve the infection.
- Vacuum-assisted closure (VAC) and antimicrobial therapy also improved outcomes.
 - MDR pathogens may complicate resolution of ostensibly simple infections in the postoperative period particularly if they required antimicrobial therapy
- Surgical site infection remains a clinical diagnosis
 - Presenting signs and symptoms depend on the depth of infection
 - Typically as early as postoperative day 4 or 5
 - Clinical signs range from local induration only to the hallmarks of infection (e.g., erythema, edema, tenderness, warm skin, and pain-related immobility).
 - May manifest before wound drainage

- In deep incisional SSIs, tenderness may extend beyond the margin of erythema, and crepitus, cutaneous vesicles, or bullae may be present.
- With ongoing infection, signs of SIRS herald the development of sepsis
- Cultures are not mandatory for management of superficial incisional SSIs.
 - In cases of deeper infection or infection that has arisen in the hospital, exudates or drainage specimens should be sent for analysis.
 - Culturing surgically opened wound (as opposed to the already opened wound, which becomes colonized) by the swab method shown experimentally to be reliable
 - CT and MRI are more sensitive in detecting small amounts of gas in soft tissues.
 - CT-guided aspiration or drainage often facilitates treatment and may serve as definitive source control for an organ/space SSI.
- More severe SSIs, especially the dangerous forms of necrotizing soft tissue infection (NSTI)
 - True emergencies that need immediate surgical attention
 - Even modest delays can increase patient mortality substantially
 - Mortality increased from 32% to 70% when therapy was delayed more than 24 hours.
 - With an established diagnosis of NSTI, immediate and widespread operative debridement is indicated without waiting for precise determination of the causative pathogen or the identification of a specific clinical symptom.
 - Often require planned, sequential, repetitive surgical debridement sessions to control the infection
- When faced with a potential SSI, the first steps in management are:
 - Remove the appropriate sutures
 - Open and examine the suspicious portion of the incision
 - Decide about further surgical treatment
 - If infection is not confined to the skin and superficial underlying subcutaneous tissue:
 - Urgent surgical exploration and debridement is essential to obtain local control of the infection, remove necrotic tissue, and restore aerobic conditions to prevent further spread of the infection.
 - Surgical site infection must also be considered the cause of delayed or failed wound healing and prompt the same decisions as described above.
- Superficial SSIs:
 - Functionally are subcutaneous abscesses, rarely lead to systemic infection
 - Usually do not make patients seriously ill
 - Antibiotic therapy is not indicated for patients who do not have systemic signs of infection
 - Formal surgical intervention is limited to complications such as loculated abscesses or necrosis of the skin or underlying tissue
- Deep incisional SSIs typically present with extensive discomfort in more seriously ill patients.
 - Extend to superficial fascia or beneath
 - May cause extensive tissue necrosis and liquefaction beyond the obvious limits of the cutaneous signs, making it necessary to explore the wound formally in the operating room

- Broad-spectrum antimicrobial therapy should be given empirically
- Organ or space SSIs occur within a body cavity
 - Directly related to a surgical procedure, and may manifest as intra-abdominal, intrapleural, or intracranial infections
 - May remain occult or present with few symptoms, mimicking incisional SSIs and leading to inadequate initial treatment, becoming apparent only when a major complication ensues
 - Diagnosis of organ or space SSI usually requires imaging to confirm the site and extent of infection.
 - Adequate source control requires a drainage procedure, whether open or percutaneous.
- VAC optimizes blood flow, decreases tissue edema, and removes fluid from the wound bed, thereby facilitating the removal of bacteria from the wound.
- Mechanical deformation of the wound promotes tissue expansion to cover the defect, and subatmospheric pressure in the milieu may trigger a cascade of intracellular signals that increases the rate of cell division and formation of granulation tissue.
- Clinical value of VAC systems has been described only in small case series and cohort studies, mostly for sternal infections following cardiac surgery, abdominal wall dehiscence, and the management of complex perineal wounds, or as a method to secure skin grafts.
- A lack of well-designed randomized, controlled trials precludes more specific recommendations.

PERITONITIS

- Only about 15% of patients with secondary peritonitis are ill enough to require ICU care.
- Severe secondary peritonitis may follow penetrating intestinal injury that is not recognized or treated promptly (>12-hour delay).
- Other causes include dehiscence of a bowel anastomosis with leakage and development of an intra-abdominal abscess.
- Secondary peritonitis is polymicrobial.
 - Anaerobic Gram-negative bacilli (e.g., *Bacteroides fragilis*) predominating
 - *E. coli* and *Klebsiella* spp. isolated commonly from community-onset infections
- When secondary peritonitis develops in a hospitalized patient as a complication of disease or therapy, the flora are more likely to reflect MDR pathogens encountered in the hospital.
 - Outcomes are worsened if empiric therapy is not appropriate.
- Failure of two source control procedures with persistent intra-abdominal collections is referred to as tertiary peritonitis.
 - Tertiary peritonitis is characterized by complete failure of intra-abdominal host defenses.
 - Controversy whether tertiary peritonitis is a true invasive infection, or rather peritoneal colonization with incompetent local host defenses, and thus, whether antibiotics should be prescribed and if so, for how long
 - Bacteria isolated in tertiary peritonitis are avirulent opportunists such as Methicillin-related *S. epidermidis* (MRSE),

enterococci, *Pseudomonas*, and *Candida albicans*, supporting the incompetent host defense hypothesis.

- Some authorities recommend management with an open-abdomen technique, so that peritoneal toilet can be provided manually.
- May be no alternative to open-abdomen management if the infection extends to involve the abdominal wall and extensive debridement is required

Empiric Antibiotic Therapy

- Strategies have been promulgated to optimize antibiotic administration, including:
 - Reliance upon physician prescribing patterns
 - Computerized decision support
 - Administration by protocol
 - Formulary restriction programs
- Crucial for initial empiric antibiotic therapy to be targeted appropriately, administered in sufficient dosage to ensure bacterial killing, narrowed in spectrum (*deescalation*) as soon as possible based on microbiology data and clinical response, and continued only as long as necessary

Choice of Antibiotic

- Antibiotic choice is based on several interrelated factors (Table 71.10).
- Paramount is activity against identified or likely (for empiric therapy) pathogens, presuming infecting and colonizing organisms can be distinguished, and that narrow-spectrum coverage is always desired
- Local knowledge of antimicrobial resistance patterns is essential, even at the unit-specific level
- Patient-specific factors of importance include:
 - Age
 - Debility
 - Immunosuppression
 - Intrinsic organ function
 - Prior allergy or other adverse reaction
 - Recent antibiotic therapy
- Institutional factors of importance include:
 - Guidelines that may specify a particular therapy
 - Formulary availability of specific agents
 - Outbreaks of infections caused by MDR pathogens
 - Antibiotic control programs

TABLE 71.10

FACTORS INFLUENCING ANTIBIOTIC CHOICE

Activity against known or suspected pathogens
 Disease believed responsible
 Distinguish infection from colonization
 Narrow-spectrum coverage most desirable
 Antimicrobial resistance patterns
 Patient-specific factors
 Severity of illness
 Age
 Immunosuppression
 Organ dysfunction
 Allergy
 Institutional guidelines or restrictions

TABLE 71.11

ANTIBACTERIAL AGENTS FOR EMPIRIC USE

ANTIPSEUDOMONAL

Piperacillin-tazobactam
 Cefepime, ceftazidime
 Imipenem, meropenem
 Ciprofloxacin, levofloxacin (depending on local susceptibility patterns)
 Aminoglycoside

TARGETED SPECTRUM

Gram positive

Glycopeptide
 Lipopeptide (not for known/suspected pneumonia)
 Oxazolidinone

Gram negative

Third-generation cephalosporin (not ceftriaxone)
 Monobactam
Antianaerobic
 Metronidazole

BROAD SPECTRUM

Piperacillin-tazobactam
 Carbapenems
 Fluoroquinolones
 Tigecycline (plus an antipseudomonal agent)

ANTIANAEROBIC

Metronidazole
 Carbapenems
 β -Lactam/ β -lactamase combination agents
 Tigecycline

- Numerous agents are available for therapy (Table 71.11).
 - Agents may be chosen based on spectrum, whether broad or targeted (e.g., antipseudomonal, antianaerobic), in addition to the above factors.
 - Nosocomial Gram-positive pathogen is suspected (e.g., wound or surgical site infection, CR-BSI, pneumonia) or MRSA is endemic, empiric vancomycin (or linezolid) is appropriate
 - Some authorities recommend dual-agent therapy for serious *Pseudomonas* infections (i.e., an antipseudomonal β -lactam drug plus an aminoglycoside), but evidence of efficacy is lacking.
 - It is important to use at least two antibiotics for empiric therapy of any infection that may be caused by either a Gram-positive or Gram-negative infection (e.g., nosocomial pneumonia).

Antifungal Prophylaxis and Therapy

- Incidence of invasive fungal infections is increasing among critically ill surgical patients
- Several conditions are predictors for invasive fungal infection complicating critical illness, including:
 - Intensive care unit length of stay
 - Altered immune responsiveness
 - Number of medical devices placed
 - Neutropenia, diabetes mellitus, new-onset hemodialysis, total parenteral nutrition, broad-spectrum antibiotic administration, bladder catheterization, azotemia, diarrhea, and corticosteroid therapy are also associated with invasive fungal infection.

Duration of Therapy

- End point of therapy is largely undefined, in part because quality data are few
- If cultures are negative, empiric antibiotic therapy should be stopped in most cases.
 - Unnecessary antibiotic therapy in the absence of infection clearly increases the risk of MDR infection.
- Therapy beyond 48 to 72 hours with negative cultures usually is unjustifiable.
- Morbidity of antibiotic therapy includes allergic reactions, development of nosocomial superinfections (e.g., fungal, enterococcal, and *C. difficile*-related infections), organ toxicity, promotion of antibiotic resistance, reduced yield from subsequent cultures, and induced vitamin K deficiency with coagulopathy or accentuation of warfarin effect.
- If *bona fide* evidence of infection is evident, then treatment is continued as indicated clinically.
 - Some infections can be treated with therapy lasting 5 days or less.
 - Every decision to start antibiotics must be accompanied by a decision regarding the duration of therapy.
 - A reason to continue therapy beyond the predetermined end point must be compelling. Bacterial killing is rapid in response to effective agents, but the host response may not subside immediately.
 - Seldom should antibacterial therapy continue for more than 7 to 10 days.
 - Examples of bacterial infections that require more than 14 days of therapy include:
 - Tuberculosis of any site
 - Endocarditis
 - Osteomyelitis
 - Selected cases of brain abscess, liver abscess, lung abscess, postoperative meningitis, and endophthalmitis

ABBREVIATIONS

ARDS	Acute respiratory distress syndrome
CASS	Continuous aspiration of subglottic secretions
CDAD	<i>Clostridium difficile</i> -associated disease
CI	Confidence interval
CNS	Central nervous system
CPAP	Continuous positive airway pressure
CR-BSI	Catheter-related bloodstream infection
CSF	Cerebrospinal fluid
CT	Computerized tomography
ERCP	Endoscopic retrograde cholangiopancreatography
EVD	Extraventricular drain
ICU	Intensive care unit
MDR	Multidrug resistant
MRCP	Magnetic resonance cholangiopancreatography
MRI	Magnetic resonance imaging
MRSA	Methicillin-resistant <i>Staphylococcus aureus</i>
MRSE	Methicillin-related <i>S. epidermis</i>
NIPPV	Noninvasive positive pressure ventilation
NNIS	National Nosocomial Infections Surveillance System
NSTI	Necrotizing soft tissue infection
OR	Odds ratio
PICC	Peripherally inserted central catheters
PTC	Percutaneous transhepatic cholangiopancreatography
RR	Relative risk
SCIP	Surgical Care Improvement Project
SIRS	Systemic inflammatory response syndrome
SSI	Surgical site infections
VAC	Vacuum-assisted closure
VAP	Ventilator-associated pneumonia
VRE	Vancomycin-resistant enterococci

CHAPTER 72 ■ SKIN WOUNDS AND MUSCULOSKELETAL INFECTION

WOUND CLASSIFICATION

Surgical Site Infections

- In the United States an estimated 27 million surgical procedures are performed annually.
- Surgical site infections (SSIs) are third most common nosocomial infection in most hospitalized patients, accounting for 14% to 16%
 - Among surgical patients, SSIs were most common nosocomial infection
 - Accounting for 38% of infections
 - 66% of SSIs remained confined to the incision site
 - Remainder involved organs or spaces accessed during the surgical procedure
 - 1980 estimated that SSI increased hospital stay by 10 days and cost an additional \$2,000 per patient
 - 1992 that number had decreased to 7.5 days' increased stay; however, the cost had increased to \$3,152 per patient

- SSI contribution to the cost of health care in United States is calculated at \$130 to \$180 million per year
- Effects of SSIs are not only felt locally, such as tissue destruction, pain, scar formation, septic thrombophlebitis
 - Extend systemically to septicemia, shock, organ dysfunction, and death

Center for Disease Control (CDC) Classification of Surgical Site Infections

- **Superficial Incisional SSIs:** Infection occurs within 30 days of surgery and involves only skin or subcutaneous tissue with the following:
 - Purulent drainage
 - Presence of organisms in drainage
 - Pain or tenderness, swelling, redness
- **Deep Incisional SSIs:** Infection within 30 days of surgery, or within 1 year if implant is present. Infection involves deep soft tissues with the following:
 - Purulence from deep incision, not the organ space of operation
 - Dehiscence of deep incision or opened wound by surgeon due to symptoms of fever, pain, tenderness
 - Abscess found on direct examination or reoperation
- **Organ/Space SSIs:** Infection within 30 days of surgery, or within 1 year if implant is present. Infection involves any part of the anatomy other than the incision opened during operation with the following:
 - Purulence from a surgically placed drain in the organ space
 - Positive cultures from that organ space
 - Abscess found on direct examination or reoperation
 - Purulence alone not hallmark of infected wound
 - If present, however, a wound can be considered infected, even if confirmatory cultures are negative.
 - Absence of confirmatory pathogens can be a result of inadequate techniques of culture, the patient's current antimicrobial therapy, or a particularly fastidious organism.
 - Patients with immunologic dysfunction or those who are granulocytopenic may not always produce purulent material.
- Surgical wounds are grouped into four classes, each with its infection risk (Table 72.1):
 - **Class I (clean):** Uninfected operative wound in which no inflammation is encountered and the respiratory, alimentary, genital, or uninfected urinary tract is not entered.
 - Clean wounds are primarily closed and, if necessary, drained with closed drainage.
 - Operative incisional wounds that follow nonpenetrating (blunt) trauma should be included in this category if they meet the criteria.

- **Class II (clean to contaminated):** Operative wound in which respiratory, alimentary, genital, or urinary tracts are entered under controlled conditions and without unusual contamination.
 - Operations involving the biliary tract, appendix, vagina, and oropharynx are included in this category, provided no evidence of infection or major break in technique is encountered.
- **Class III (contaminated):** Include open, fresh, accidental wounds
 - Operations with major breaks in sterile techniques (e.g., open cardiac massage) or gross spillage from the gastrointestinal tract, and incisions in which acute nonpurulent inflammation is encountered
- **Class IV (dirty to infected):** Old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera
 - Organisms causing postoperative infection were present in the operative field before the operation

Risk Factors

- All surgical wounds are at risk for infection.
- National Nosocomial Infection Surveillance (NNIS) system was developed in the early 1970s to monitor the incidence of health care-associated infections (HAIs) and their associated risk factors and pathogens. NNIS has identified wound infection risk factors as the following:
 - Wound classified as contaminated or dirty
 - A patient with an ASA (American Society of Anesthesiologists) score of 3, 4, or 5 prior to operation
 - A procedure lasting longer than T hours, where T represents the 75th percentile of duration of time expected for that surgery
- To identify a patient's risk index category (RIC), each factor, if present, receives a score of 1, with a range between 0 and 3
- NNIS also publishes recommendations for reducing the risk of SSIs. The weight of these recommendations is based on the scientific evidence used to support the conclusions:
 - Category IA recommendations for SSI prevention:
 - Treat remote infection before performing an elective operation
 - Do not remove hair from operative sites unless it interferes with surgery and then only use electric clippers just prior to surgery
 - Select an agent with efficacy against the suspected organism, making sure the therapeutic serum levels exist from the beginning of the operation
 - Mechanical preparation of the colon with enemas and cathartics before elective colorectal operations and the use of nonabsorbable oral antimicrobials the day before operation have been beneficial
 - Category IB recommendations for SSI prevention:
 - Control serum glucose prior to operation
 - Cease tobacco use 30 days prior to operation
 - Shower night before surgery
 - Prepare operative site with an antiseptic skin agent
 - Do not routinely use vancomycin for antimicrobial prophylaxis

TABLE 72.1

SURGICAL WOUND CLASSIFICATION AND RISK OF INFECTION (IF NO ANTIBIOTICS USED)

Classification	Description	Infection risk (%)
Class I	Clean	<2
Class II	Clean to contaminated	<10
Class III	Contaminated	20
Class IV	Dirty	40

- The operative team should keep nails short and not wear artificial nails
- A 2- to 5-minute preoperative surgical scrub for the surgical team should occur
- Category II recommendations for SSI prevention:
 - Prepare skin in concentric circles from the incision site outward
 - Keep preoperative stay in the hospital as short as possible
 - Clean underneath each fingernail prior to performing first scrub of the day
 - Do not wear hand or arm jewelry
 - Limit the number of personnel entering the operating room
- No recommendation or unresolved issue:
 - Restriction of scrub suits to the operating suite, or coverage of scrub suits outside of theater

Pressure/Decubitus Ulcers

- Term *decubitus* has been applied to any area that develops an ulcer secondary to prolonged pressure between a bony prominence and an unyielding surface.
- Term *pressure ulcer* is a more accurate description.
- To overcome arterial and capillary hydrostatic pressure and develop subsequent tissue necrosis with ulceration, an individual must be subjected to 32 mm Hg pressure at the level of the ischium, sacrum, or heels for a prolonged period of time, usually exceeding 2 hours.
 - Points of greatest pressure with a supine patient are seen over the sacrum, heel, and occiput at 40 to 60 mm Hg.
 - In a prone position, the chest and knees absorb the greatest pressure, which may be 50 mm Hg.
 - When the patient is sitting, the ischial tuberosities are under the most pressure, measured at near 100 mm Hg.
 - If sensation is intact, ulceration usually will not occur as the incipient pain would lead to a change in position.
 - This occurs during the sleep cycle
- Risk factors associated with pressure ulcer development can be divided into external and internal causes.
 - Externally, the patient might be subjected to a constant pressure for a period of time, or friction exists between exposed skin and a surface that remains static, or a region remains moist and may have desquamation, leading to a loss of the epithelial protective mechanism.
 - Placement of splints can also alter a patient's ability to change position.
 - Administration of sedatives or paralytics can also remove the normal feedback pathways that exist to prevent pressure ulcer formation.
- Internally, factors responsible for pressure ulceration include:
 - Malnutrition (serum albumin levels <3.0 g/dL preoperatively)
 - Anemia
 - Endothelial dysfunction
 - Diabetes, peripheral vascular disease, and episodes of hypotension also increase the risk as do sensory deficits in patients with plegia or paresis
 - Patients with dementia may also not be sensitive to the importance of changing position frequently and may also be more prone to pressure ulceration.
- Most patients with pressure ulcers (66%) are older than 70 years old, with a prevalence rate in nursing homes of 17% to 28%.
- In contrast, patients admitted with an acute illness have an incidence rate of 3% to 11%.
- In both subsets of patients, recurrence rates as high as 90% may be seen.
- In the operating room, where patients are immobile, there is a report that up to 25% of all pressure ulcers are instigated there.
- Anatomic sites affected are:
 - Hip and buttocks (67% of the cases involve ischial, trochanteric, and sacral tuberosity)
 - 25% in malleolar, heel, patellar, or pretibial area
 - Remainder occurring on the nose, chin, occiput, chest, back, or elbow
- In paraplegic patients, pressure ulcers are a leading cause of death, responsible for an 8% mortality rate.
- Overall an estimated 60,000 people die each year from a pressure ulcer complication.
- The health care cost in the United States alone per year is in excess of \$1 billion.
- Several scoring systems are used to grade the risk for ulceration:
 - Braden scale is a summation rating scale made up of six subscores consisting of sensory perception, moisture, activity, mobility, nutrition, and friction/shear, each ranging from 1 to 3 or 4 points, with total scores ranging from 6 to 23.
 - Subscores measure functional capabilities of patient that contribute to either higher intensity and duration of pressure or lower tissue tolerance for pressure.
 - Lower Braden score indicates lower levels of functioning with a higher risk for pressure ulcer development.
 - Daniels classification looks at muscle and subcutaneous tissue breakdown, which occurs before dermal and epidermal changes are observed.
 - Epidermal necrosis occurs later because epidermal cells are able to better withstand prolonged absence of oxygen than cells in the deeper tissues both *in vivo* and *in vitro*.
 - Once skin damage is visible, irreversible internal damage may have already occurred.
- Shea staging describes ulcers that start superficially and progress to deeper structures:
 - Grade I: Limited to superficial epidermis and dermis
 - Grade II: Involving the epidermis and dermis and extending to the adipose tissue
 - Grade III: Extending through the superficial structures and adipose tissue down to muscle
 - Grade IV: Complete soft tissue destruction down to bone
- Currently the most widely accepted classification system for pressure ulcers is that produced by the National Pressure Ulcer Advisory Panel (NPUAP).
 - Considered to be a modification of the Shea system, it is used only to determine initial depth and is not a system to follow the natural history of the ulcer.
 - Limited by the presence of eschar, which will mask the underlying damage
 - Stage I represents intact skin with signs of impending ulceration

- Clinically, this may consist of blanchable erythema from reactive hyperemia that should resolve within 24 hours of relief of pressure
- Warmth and induration may also be present
- Continued pressure creates erythema that does not blanch
- Skin may appear white from ischemia. With proper treatment, resolution should be expected in 5 to 10 days.
- Stage II represents a partial-thickness loss of skin involving epidermis and possibly dermis. This lesion may present as an abrasion, blister, or superficial ulceration, with pigmentation changes. These too represent a reversible condition.
- Stage III represents a full-thickness loss of skin with extension into subcutaneous tissue but not through the underlying fascia.
 - Lesion presents as a crater with or without undermining of adjacent tissue.
 - On examination this will appear as a necrotic, foul-smelling crater with altered light and dark pigmentation.
- Stage IV represents full-thickness loss of skin and subcutaneous tissue and extension into muscle, bone, tendon, or joint capsule.
 - Osteomyelitis with bone destruction, dislocations, or pathologic fractures may be present.
 - Sinus tracts and severe undermining commonly are present.

Treatment

- All modalities of care for pressure ulcers fall along four paths:
 - Pressure reduction:
 - Frequent turning and repositioning the patient at least every 2 hours
 - Adopted because of nursing issues (it took 2 hours for the nurse to rotate all ward patients)
 - Debate in the literature as to this being an adequate amount of time
 - Mattresses that reduce pressure, such as low-air-loss and air-fluidized beds should be used for patients with stage III and IV ulcers.
 - For stage I and II ulcers, the use of static mattresses such as air, foam, or water overlays are the most beneficial.
 - Wound management:
 - Removal of dead tissue and debris, drainage, and protecting the surrounding healthy tissue are the goals.
 - Pressure needed to clean wounds with no necrotic material is 2 to 5 psi
 - If necrotic debris is present, the pressure required increases by a factor of 2 to 3
 - The old wound dictum—if it is dry, wet it; if it is wet, dry it—has some validity.
 - A draining wound needs either a hydrocolloid or alginate
 - A wound without drainage will respond to simple moist gauze; the surrounding skin of both need to be kept lubricated, but not wet, to reduce friction.
 - Negative pressure therapy enhances wound healing by reducing edema, increasing the rate of granulation tissue formation, and stimulating circulation.

TABLE 72.2

DRESSING CATEGORIES

Category	Properties/Uses
Alginates	Absorption of drainage, dead space obliteration, autolysis of necrotic material
Foams	Absorption of drainage, dead space obliteration, mechanical debridement, moisture retention
Gauzes	Absorption of drainage, dead space obliteration, mechanical debridement, moisture retention
Hydrocolloids	Dead space obliteration, autolysis of necrotic material, moisture retention
Vacuum-assisted closure	Dead space obliteration, induction of granulation
Ostomy appliances	Drainage diversion

- Increased blood flow translates into a reduction in the bacterial load and delivery of infection-fighting leukocytes.
- Significant contraindications for the use of vacuum-assisted or negative pressure therapy include:
 - Malignancy of the wound
 - Untreated osteomyelitis
 - Nonenteric fistulas
 - Exposed vessels, organs, or nerves
- Various dressing categories are presented in Table 72.2.
- Surgical intervention:
 - Debridement is the process of removing devitalized tissue.
 - Stages III and IV ulcers will require some form of debridement, whether it is from surgical, autolytic, mechanical, or via enzymatic means
 - The patient's wound and overall status will dictate the means of debridement, a more stable patient receiving a more aggressive means of removing the necrotic material.
 - Larger wounds may respond only to the placement of flaps, either fasciocutaneous or musculocutaneous.
 - Flap failure can be seen after insufficient excision of soft tissue and bone and if systemic factors such as nutritional status are suboptimal.
- Nutritional support:
 - Malnourished patients have a higher susceptibility for ulcer formation
 - Once formed these patients also have a diminished ability to heal or to prevent further ulcer formation in other sites.
 - Serum albumin levels <3 mg/dL may be candidates for supplemental feedings via enteral or parenteral routes.

PRIMARY BACTERIOLOGIC INFECTIONS

- Skin and soft tissue infections are usually easily treated but have the potential of being lethal.
- Tender, firm, painful, and rapidly expanding area of redness on the skin surrounding violation of the skin barrier should be a cause for concern.
- Red streaks between lymph node-bearing areas may be visible, and this is indicative of a potentially spreading infection.

- Certain areas are more prone in becoming infected depending on age group:
 - Facial cellulitis occurring more commonly in adults older than 50 years and in children 6 months to 3 years of age
- Most common causative organisms in skin infections are:
 - Group A β -hemolytic streptococci
 - *Staphylococcus aureus*
- Depending on the source of contamination and whether the patient is immunocompromised, Gram-negative rods and fungus can be seen.
- If the insult occurs during exposure to fresh water, the causative organism may be *Aeromonas*, a Gram-negative rod.
- Predisposing states where minor break in the skin barrier leads to significant infection include:
 - Diabetes
 - Immunodeficiency
 - Varicella
 - Venous, arterial, or lymphatic insufficiency, such as that seen after lymphatic removal during mastectomy
 - Vein stripping for varicosities
- Treatment of uncomplicated cellulitis:
 - Begins with removing the nidus of infection
 - Cleansing the wound with an antiseptic agent
 - Dressing wound with an antiseptic ointment if indicated
 - Considering a course of oral antibiotics
 - Dicloxacillin, 500 mg orally four times a day for 7 days
 - Cephalexin, 500 mg orally four times a day for 7 days
 - With a suspected or known penicillin allergy, clindamycin, 400 mg, is given orally four times a day

Erysipelas

- A form of cellulitis that affects the epidermis primarily extending into cutaneous lymphatics
 - During Middle Ages referred to as St. Anthony's fire after Egyptian healer who was successful in treating condition
- Shares the same underlying cause as cellulitis with bacterial inoculation into an area of skin violation
- More commonly seen in children and elderly
- Differs from cellulitis in that inflamed area is distinct from surrounding skin, being raised and demarcated
- Often found on face; however, it can also develop on the arms and legs
 - Sometimes skin will have what is called a *peau d'orange*, or orange peel, look to it
- As with cellulitis, streptococcus is the primary organism identified with its toxin responsible for the brisk inflammation associated with this condition.
- Treatment:
 - Elevation of affected extremity
 - Penicillin, 250 to 500 mg orally or 0.6 to 1.2 million units intramuscularly, given every 4 to 6 hours for a 10- to 20-day course
 - In penicillin allergy, a macrolide or cephalosporin usually suffices
 - If the area affected becomes ulcerated, saline dressings changed every 12 hours will assist with wound closure

Impetigo

- Also known as pyoderma, it is the most common bacterial infection of the skin seen.
 - Contagious and occurs at any age, but is more common in young children
- Patients report skin lesions, often with associated adenopathy, with minimal systemic signs and symptoms
- Presents in two forms:
 - Small vesicles with a honey-colored crust known as *impetigo contagiosa*
 - Purulent-appearing bullae, known as *bullous impetigo*
- Most commonly caused by *S. aureus*
- Group A beta-hemolytic strep is also commonly seen in the over-2-year-old population.
- Warm temperatures, humidity, poor hygiene, and crowded living conditions exacerbate spread.
- When associated with lymphadenitis in deeper infections, the term *ecthyma* is given
- Topical mupirocin (Bactroban) applied three times a day for 5 days is successful in treating >90% of cases
 - More effective than oral erythromycin
 - Lesions usually resolve completely within 7 to 10 days

CUTANEOUS FUNGAL INFECTIONS

- The most common important fungal infections that occur in the intensive care unit (ICU) setting are for the most part due to *Candida*, especially *albicans*, *glabrata*, and *tropicalis*.
 - In immunocompromised or morbidly obese patients
 - Usually manifests itself as cutaneous moniliasis
 - Can be treated with topical powders or ointments
 - Vaginitis treated with suppositories
 - Funguria is addressed by removing or replacing the urinary catheter, which will be successful in about one-third of patients.

MUSCULOSKELETAL INFECTIONS

- First described in 1848
- Deep soft tissue infection a disease of unknown cause until 1920 when Meleney identified 20 patients in China in whom a hemolytic streptococcus was identified in the wounds
- In Meleney gangrene, there is extensive necrosis of the skin and subcutaneous tissue caused by synergistic infection between microaerobic staphylococcal and hemolytic streptococcal infection.
- Term *necrotizing fasciitis* (NF) first coined in 1952 and involves the underlying fascia and subcutaneous tissue and spares muscle
- Myositis results in muscle involvement, which becomes exquisitely tender and indurated
 - Muscle involvement leads to elevation of the creatine phosphokinase and can spread over several hours to contiguous muscle groups, thus heightening the need for early diagnosis and treatment.
- Fournier's gangrene listed as a separate entity due to its predilection for the perineum

- All subgroups have common pathogenicity with organisms spreading from subcutaneous tissues to both superficial and deep fascial planes
- Local effect is vascular occlusion, ischemia, and necrosis
- Systemic effect is sepsis, end organ dysfunction with mortality rate as high as 75% with Fournier's gangrene and up to 100% in patients with multiple organ failure
- Mortality rate varies with age and extent of involvement
 - Survivors younger
 - Male:female ratio of affliction ranges 2 to 3:1

Types of Necrotizing Fasciitis

- See Table 72.3 for types of necrotizing fasciitis.
- Type I (polymicrobial):
 - Usually seen after injury or surgery
 - Can be misdiagnosed as a simple cellulitis
 - As tissue necrosis and hypoxia continue, pain and systemic symptoms of fever, chills, and malaise increase as underlying tissue liquefies while overlying skin may show minimal changes
 - In the late stages, extension into the muscle itself occurs
 - Over 2 to 3 days erythema increases, with occasional bullae formation
 - Cultures may show combination of aerobic and anaerobic organisms
 - Deep soft tissue infection of perineum termed *Fournier's gangrene*
 - Many of these patients have predisposing systemic issues:
 - Diabetes
 - Immunosuppressed states
 - Histologically, thrombosis of blood vessels and abundant bacteria with many polymorphonuclear cells are typically seen
 - Type II (group A streptococcal):
 - Also known familiarly as *flesh-eating bacteria* or as Meleney's synergistic gangrene
 - Nearly normal appearing overlying skin may result in a delay in diagnosing underlying ongoing necrosis
 - A simple incision into the region affected can demonstrate drainage or even gas in advanced cases
 - Other predisposing factors include:
 - Varicella infection
 - Use of nonsteroidal anti-inflammatory drugs (NSAIDs)
 - NSAID use an immunomodulator, which may predispose to this condition
- Type III (gas gangrene or clostridial myonecrosis):
 - Rapidly progressive infection coined *necrotizing fasciitis*
 - Most commonly caused by *Clostridium perfringens* and less frequently by *C. septicum*
 - Most cases arise in setting of recent surgery or trauma
 - Less commonly spontaneous as in types I and II
 - *C. perfringens* (formally *C. welchii*) an anaerobic Gram-positive spore-forming organism that produces at least 10 distinct exotoxins
 - Most important exotoxin leading to human pathogenesis is the α -toxin, which hemolyzes red blood cells, hydrolyzes cell membranes, and exerts a direct cardiodepressive effect
 - Within 12 to 24 hours, crepitation of soft tissues may be detected by palpation
 - Variant of type III, known as *anaerobic streptococcal myonecrosis*, has a slower progression and less gas production.
 - *Aeromonas hydrophilia*, a facultatively anaerobic, Gram-negative bacillus most commonly encountered in freshwater, can also yield a type III-like syndrome
 - Fournier's gangrene (idiopathic gangrene of the penis and scrotum):
 - First described in 1764 by Baurienne, entity received its name from a French venereologist, Jean-Alfred Fournier
 - In 1883 he presented a case of gangrene of the perineum in an otherwise healthy young man.
 - 95% of cases, an identifiable cause can be found, with the disease process originating from the anorectum, the urogenital tract, or the skin of the genitalia
 - Anorectum causes include:
 - Malignancy
 - Diverticulitis
 - Appendicitis
 - Urethral injury, urethral stricture, urogenital manipulation, or infection can initiate Fournier's gangrene
 - Cutaneous conditions like hidradenitis suppurativa or trauma can be precursors
 - Systemic factors may predispose, such as:
 - Leukemia

TABLE 72.3

SUBTYPES OF NECROTIZING FASCIITIS (NF)

Subtype	Organisms present	Treatment	Mortality
Type I	Gram-negative, Gram-positive, aerobes and anaerobes	Antibiotics, penicillin, clindamycin, debridement	Without organ dysfunction, 25%; with organ dysfunction, 75%; dependent on age
Type II	Streptococcus	Antibiotic, cessation of non-steroidal anti-inflammatory drug use, debridement	Same as above
Type III	<i>Clostridium perfringens</i> , <i>Clostridium septicum</i>	Wide local debridement, hyperbaric oxygen, immunoglobulin, antibiotics	75%
Fournier's	Polymicrobial, same as type III	Wide local debridement, hyperbaric oxygen, antibiotics	75%

- Systemic lupus erythematosus
- Crohn disease
- Human immunodeficiency virus (HIV) or other conditions of immunodeficiency
- Other predisposing comorbidities associated with Fournier's include:
 - Obesity
 - Cirrhosis
 - Vasculitides of the perineum
 - Steroid use
 - Diabetes
- On examination the typical Fournier's patient will be an elderly male in his sixth or seventh decade of life with one or more of the above comorbidities.
- Clinically, patient may have a history of fever and lethargy for approximately 1 week.
 - Pain, tenderness, and erythema of the genitalia and overlying skin will progress to a dusky appearance, ultimately with purulent-appearing drainage.
- No predictive tests as to when a superficial infection will develop into a deep infection nor is there a chemistry test for identifying a soft tissue infection
- Investigation has focused on polymerase chain reaction tests specific for streptococcal pyrogenic exotoxin (SPE) genes, variants A, B, and C along with streptococcal superantigens
 - Superantigens cause the release of cytokines through binding to a specific segment of the T-cell receptor, resulting in an overwhelming production of tumor necrosis factor- α (TNF- α), interleukin-1 (IL-1), and IL-6 with subsequent systemic effects of sepsis and septic shock.
 - Work has also centered on the filamentous M protein, which is anchored to the cell membrane and has antiphagocytic properties.

Imaging Studies for Necrotizing Fasciitis

- Summary of different imaging studies is presented in Table 72.4
- Computerized tomography shown with great sensitivity the presence and extent of gas or subcutaneous air
- Magnetic resonance imaging (MRI) T2-weighted images can show well-defined areas of high signal intensity significant for tissue necrosis, and absence of gadolinium contrast enhancement on T1 images reliably detects fascial necrosis in those who might require operative debridement.

- Ultrasound, although able to detect fluid or gas within soft tissues, requires the probe to be applied directly on the involved tissues.
 - Patients with NF, especially those with Fournier's, may not tolerate this, plus there may be a limitation of the anatomic site, causing difficulty in visualizing deep tissues.
 - Ultrasound has a sensitivity of 88% and a specificity of 93% (positive predictive value of 83%)
 - Diagnostic criteria include diffuse thickening of the subcutaneous tissue accompanied by fluid accumulation more than 4 mm in depth along the fascial layer.
- Additionally diagnosis can be made with culture and biopsy of the affected tissue
 - Gram stain to identify single or multiple organisms would be helpful in distinguishing type I from type II NF.
 - Once diagnosis is made, either on physical examination or through other diagnostic means, including culture, biopsy, or excision, multimodality therapy should be used early due to the rapidity of progression.

Therapy

- Until the organism is identified, broad-spectrum antibiotics should be administered.
 - For aerobic organisms, one regimen might be ampicillin, 8 to 14 g per day intravenous (IV) administered every 6 hours in divided dosages, and gentamicin, 3 mg/kg per day IV divided every 8 hours
 - Penicillin G, 8 to 24 million units per day IV in divided dosages every 4 to 6 hours should be given for presumed necrotizing fasciitis
 - If concern of anaerobic organisms clindamycin, 600 mg IV every 6 hours, or metronidazole, not to exceed 4 g per day, can be given
 - In the presence of group A streptococcal infection, use of clindamycin may be advantageous as it is not affected by inoculum size or stage of growth.
 - Clindamycin suppresses toxin production, facilitates phagocytosis of streptococcus pyogenes by inhibiting M-protein synthesis, and suppresses production of regulatory elements controlling cell wall synthesis.
- Other nonsurgical modalities include hyperbaric oxygen (HBO).
 - No prospective study exists to justify its value.
 - HBO can increase the oxygen saturation in infected wounds by a thousandfold, is bacteriocidal, improves

TABLE 72.4

IMAGING STUDIES

Type	Role of study	Limitations	Advantages
Ultrasound	Detection of fluid and gas within soft tissues	Requires direct contact, painful	Fast, reproducible, portable to bedside
Magnetic resonance imaging	T2-weighted images. T1-weighted images	Unstable patients unable to tolerate time required for study	High sensitivity for extent of involvement
Plain radiographs	Identification of air in subcutaneous location	Seen in <50% of cases	Fast, reproducible
Computerized tomography	Detection of extent of fluid/gas in soft tissues	Requires transport, dye is nephrotoxic	High sensitivity for extent of involvement

TABLE 72.5**CLINICAL INDICATORS PROMPTING WIDE SURGICAL INTERVENTION IN NECROTIZING FASCIITIS**

Indicator	Remarks
Failure of improvement	After hours of parenteral antibiotics for presumed cellulitis, no decrease in signs and symptoms is detected or if there is progression
Profound toxic effects occurring at the onset of infection	These include malaise, weakness, generalized aching, loss of appetite/concentration
Extensive necrosis	Necrosis or gas is noted in the wound or is evident on radiographs
Compartment syndrome suspected	Edema within muscle group resulting in ischemic injury

polymorphonuclear leukocytes (PMN) function, and enhances wound healing.

- There may be higher oxygenation and saturation in infected necrotic tissue secondary to HBO-induced vasodilation.
- HBO has been reported by some to improve patient survival by as much as 50% and decrease number of debridements required to achieve wound control, whereas others have failed to show any beneficial effect.
- Typical treatment protocol involves HBO given aggressively after first surgical debridement.
 - Three treatment sessions, in a multiplace chamber at 3 atmospheres absolute (ATA) at 100% oxygen for 90 minutes each, can be given in the first 24 hours; in a monoplace chamber, 2.5 to 2.8 ATA, 100% oxygen for 90 minutes per session can be given.
 - Beginning the second day, twice-daily treatments are given until granulation tissue is seen, usually requiring a total of 10 to 15 treatments.
 - Since clostridial myonecrosis is a monobacterial anaerobic infection, HBO therapy has a greater logistic role in inhibiting clostridial growth and alpha toxin production.
- IV immunoglobulin (IVIG) has also been used with necrotizing soft tissue infections, although there are no prospective randomized trials to support its use,
 - 21 consecutive patients with group A streptococcal toxic shock syndrome were administered IVIG and had a survival benefit rate of 33%
 - Several adverse side effects occurred in <5% of patients, which can mimic a worsening course of NF.
 - Adverse effects include pallor, flushing, fever, muscle aches, hypotension, anaphylaxis, erythema multiforme, and blood-borne pathogen transmission
- Wide local debridement is the classical therapy for cases of necrotizing soft tissue infections (Table 72.5).
- Series of small incisions under local anesthesia can be performed to delineate the extent and presence of muscle or facial necrosis.
- Frozen sections of tissue specimens obtained can establish diagnosis
- Once diagnosis confirmed no role for conservative debridement or incision and drainage
 - Two most common pitfalls with a necrotizing soft tissue infection are diagnostic delay and inadequate debridement
 - Excision of nonviable areas should be early and aggressive
 - Repeat debridements performed until the local process has been controlled
 - Use of electrocautery will aid in reducing the considerable operative blood loss if area of involvement is extensive
 - With perineal involvement, fecal diversion via colostomy allows for less contamination of wound site
 - With urogenital involvement, continued use of a urethral catheter is safe
 - Occasionally suprapubic cystostomy necessary
 - In Fournier's gangrene testicles are usually spared
 - To prevent desiccation usually placed in surgically made subcutaneous pocket
 - If not viable, orchiectomy performed
 - In all cases of NF, vacuum-assisted closure devices have shown great promise in decreasing time to grafting and closure of the debrided area

Factors Associated with Poor Outcome

- Factors associated with poor outcome are:
 - Older age
 - Female gender
 - Elevated creatinine and lactate
 - Extent of tissue involved
 - Inadequate debridement
 - Truncal involvement
 - Chest wall involvement
 - Presence of diabetes when in conjunction with renal dysfunction or peripheral vascular disease

CHAPTER 73 ■ NEUROLOGIC INFECTIONS

- Central nervous system (CNS) infections often rapidly progressive and fatal if left undiagnosed and/or treatment delayed
 - Prompt diagnosis and treatment crucial to decreasing morbidity and mortality
- Patients with CNS infections commonly require intensive care unit (ICU) support, particularly for airway protection and mechanical ventilation in the presence of an altered mental status
- Patients with undiagnosed CNS infections may be admitted to ICU, offering intensivists opportunity to make challenging diagnoses and alter patient outcomes with early and effective therapy
- Presence or absence of focal neurologic findings the most important distinction to be made in patients with suspected neurologic infections
 - Helps to focus differential diagnosis and identifies patients in whom lumbar puncture may be contraindicated—at least until neuroimaging is completed
 - Major neurologic infections encountered in critically ill include:
 - Acute bacterial meningitis
 - Encephalitis
 - Brain abscess
 - Subdural empyema
 - Epidural abscess
 - Suppurative intracranial thrombophlebitis
- CNS normally protected by various host defenses
 - Most important is blood–brain barrier
 - Once micro-organisms gain entry, they are able to proliferate rapidly due to low concentration of immunoglobulins and leukocytes in CNS.
- CNS infections can be caused by:
 - Viral
 - Bacterial
 - Mycobacterial
 - Fungal
 - Parasitic agents
- Important risk factors for acquiring specific types of infections or pathogens:
 - Patient age
 - Underlying host factors
 - Epidemiologic exposures including:
 - Travel
 - Animal or vector exposures
 - Contacts with infectious cases
- Prompt physical examination to identify patients in need of urgent interventions—including endotracheal intubation—needed, followed by lumbar puncture and/or imaging

MENINGITIS

Key Points

- Untreated acute bacterial meningitis universally fatal
 - Early recognition, rapid diagnostic testing, and emergent administration of antimicrobials crucial
- Classic triad of fever, nuchal rigidity, and change in mental status occurs in <66% of patients with bacterial meningitis
 - Absence of all three findings excludes diagnosis with 99% to 100% sensitivity
- Lumbar puncture (LP) should be performed urgently in all patients with suspected meningitis.
- Neuroimaging with computed tomography (CT) or magnetic resonance imaging (MRI) to rule out mass lesions should precede LP in those with:
 - Abnormal level of consciousness
 - Focal neurologic deficits
 - Papilledema
 - History of CNS disease
 - Immune compromise
 - Seizure within 1 week of presentation
- Empiric antimicrobial agents administered as soon as possible after blood cultures collected if neuroimaging to be performed prior to LP or immediately following CSF collection
- Specific microbiology and choice of empiric therapy depend on:
 - Patient risk factors, especially age
 - Underlying host immune status
 - History of preceding infections or neurosurgical procedures
- Dexamethasone shown to decrease mortality in adults with *Streptococcus pneumoniae* meningitis and children with *Haemophilus influenzae*
 - Should be administered before or concomitant with first dose of antimicrobial in all cases pending Gram stain and culture results
- Neurologic complications of bacterial meningitis include:
 - Seizure
 - Cerebral edema
 - Cerebral infarction
 - Cranial nerve involvement
 - Venous sinus thrombosis
 - Brain abscess
 - Subdural empyema
 - Coma
- Intracranial pressure monitoring and/or other surgical interventions may be required.

TABLE 73.1

CAUSES OF ACUTE MENINGITIS

	Common	Uncommon
Viruses	Enteroviruses nonpolio Human immunodeficiency virus (HIV) Arboviruses (including West Nile virus, St. Louis encephalitis virus) Herpes simplex virus types 1 and 2 (HSV-2)	Influenza Parainfluenza Lymphocytic choriomeningitis virus (LCM) Varicella-zoster virus (VZV) Polio Mumps Cytomegalovirus (CMV) Epstein-Barr virus (EBV) Adenovirus
Bacteria	<i>Streptococcus pneumoniae</i> <i>Neisseria meningitidis</i> <i>Haemophilus influenzae</i> <i>Listeria monocytogenes</i> Enterobacteriaceae <i>Staphylococcus aureus</i> <i>Mycobacterium tuberculosis</i> <i>Borrelia burgdorferi</i> (Lyme disease) <i>Streptococcus agalactiae</i>	<i>Treponema pallidum</i> (syphilis) <i>Rickettsiae</i> <i>Mycoplasma</i> <i>Brucella</i> <i>Chlamydia</i> <i>Leptospira</i>
Fungi	<i>Cryptococcus neoformans</i> <i>Histoplasma capsulatum</i> <i>Coccidioides immitis</i>	<i>Candida</i> <i>Aspergillus</i> <i>Blastomyces dermatitidis</i> <i>Sporothrix schenckii</i>
Parasites		<i>Toxoplasma gondii</i> <i>Naegleria fowleri</i> (free-living amoeba) <i>Angiostrongylus cantonensis</i> (eosinophilic meningitis) <i>Strongyloides stercoralis</i> (hyperinfection syndrome)
Other infectious syndromes	Parameningeal focus (brain abscess, subdural empyema, epidural abscess) Infective endocarditis	
Noninfectious causes	Medications Intracranial tumor Stroke Lymphoma/leukemia Meningeal carcinomatosis Post procedure (neurosurgery) Seizure	Autoimmune diseases (SLE, sarcoid, Behçet) Migraine syndromes

SLE, systemic lupus erythematosus.

- Chemoprophylaxis and/or immunoprophylaxis are available for *Neisseria meningitidis*, *Haemophilus influenzae*, and infections in specific circumstances.
 - In suspected meningococcal or *Haemophilus influenzae* meningitis, droplet isolation should be strictly enforced **until 24 hours of effective antimicrobial therapy** has been completed or alternate diagnosis reached.
 - Isolation in other cases of meningitis, including pneumococcal meningitis, not required
- Aseptic meningitis refers to inflammation of meninges not attributed to bacterial infection.
 - Cerebrospinal fluid (CSF) analysis usually reveals:
 - Normal glucose
 - Elevated protein
 - Elevated white blood cell (WBC) count with lymphocytic predominance
 - Negative Gram stain and bacterial cultures
- Differential diagnosis of aseptic meningitis includes:
 - Viral infection
 - Mycobacterial infection
 - Syphilitic infection
 - Fungal infection
 - Amoebic infection
 - Parameningeal infection
- Meningitis, or inflammation of the meninges, may be caused by a wide variety of micro-organisms (Table 73.1).
 - Infectious agents gain entry to CSF via hematogenous, transdural, or transparenchymal routes.
 - Important to consider noninfectious syndromes in the differential diagnosis of meningitis, including:
 - Meningeal carcinomatosis
 - Vasculitic syndromes

- Drug effect (e.g., nonsteroidal anti-inflammatories, antimicrobials, immunosuppressants, anticonvulsants)
 - Identification of such noninfectious conditions is essential, as therapies differ from those used in the treatment of infectious syndromes.
 - Specifically, high dose corticosteroid therapy may be indicated in some of these cases.
- Aseptic meningitis, inflammation of meninges not attributed to bacterial infection
- Critically ill patients, however, present much more commonly with bacterial meningitis by virtue of the more rapid and fulminant presentation of bacterial as opposed to aseptic meningitis.

Bacterial Meningitis

- Acute bacterial meningitis (ABM) accounts for approximately 1.2 million cases annually worldwide.
 - Most common meningeal pathogens include *Streptococcus pneumoniae* and *Neisseria meningitidis*
 - Specific etiologic agents and frequencies vary with underlying host factors such as age, immune status, and route of acquisition.
 - Case fatality rate for adults with ABM approximately 25%
 - Transient or permanent neurologic sequelae in 21% to 28% of survivors
- ABM develops as a result of several mechanisms:
 - Micro-organisms colonizing nasopharynx may invade local tissues and spread to bloodstream and CNS
 - Bacteremia and subsequent CNS invasion may also develop from localized sources such as pneumonia or urinary tract infection
 - Direct entry from contiguous infection (such as via the sinuses or mastoids), trauma, neurosurgery, or prosthetic devices such as CSF shunts or cochlear implants also occurs
- Host factors predispose to bacterial meningitis (Table 73.2)
 - Other risk factors for development of meningitis include:
 - Recent exposure to a patient with ABM
 - Recent travel to areas with endemic meningococcal disease
 - Injection drug use
 - Recent neurotrauma or CSF leak, and otorrhea
- Median duration of symptoms prior to admission in ABM averages approximately 24 hours
- Classic triad of fever, nuchal rigidity, and change in mental status occurs in <66% of cases
 - Almost all patients have at least one of these findings
 - Absence of these findings excludes diagnosis with 99% to 100% sensitivity
- Nuchal rigidity can be detected with passive or active flexion of the neck
 - Kernig and Brudzinski signs are well-described physical examination techniques but are neither sensitive nor specific
- In addition to severe headache, patients often note:
 - Photophobia
 - Seizures
- Focal neurologic deficits and papilledema may be seen on physical examination
- Some patients may not manifest classic signs and symptoms of ABM particularly:
 - Neonates
 - Those with underlying immunosuppressive conditions including:
 - Diabetes
 - Chronic organ failure
 - Neutropenia
 - Chronic corticosteroid use
 - Transplantation
 - Human immunodeficiency virus (HIV) infection
- Certain micro-organisms may present with specific physical findings:
 - Meningococcal meningitis may present with characteristic skin manifestations consisting of diffuse petechiae and purpura on distal extremities
 - Skin findings occur in approximately one-fourth of bacterial meningitis cases, over 90% of which are due to *Neisseria meningitidis* infection
 - Resultant to widespread use of conjugate vaccine for *H. influenzae* type b in infants, *Streptococcus pneumoniae* the most frequently observed cause of ABM
 - Accounts for 47% of total cases
 - *S. pneumoniae* serotypes causing bacteremic disease those commonly responsible for meningitis
 - Focal infection common with contiguous or distant sites, including sinusitis, mastoiditis, pneumonia, otitis media, and endocarditis
 - Major risk factors for pneumococcal meningitis include:
 - Asplenia
 - Hypogammaglobulinemia
 - Alcoholism
 - Chronic renal or hepatic disease
 - Malignancy
 - Diabetes mellitus
 - Basal skull fracture with CSF leak
 - Presence of a cochlear implant
 - Mortality rate range from 19% to 30%
 - *Neisseria meningitidis* commonly causes meningitis in children and young adults.
 - Serogroups B, C, and Y responsible for most endemic disease in North America, accounting for 32%, 35%, and 26% of cases, respectively.
 - Epidemic disease most commonly caused by serogroup C, with fewer outbreaks due to serogroup A.

TABLE 73.2

PREDISPOSING HOST FACTORS TO SPECIFIC ETIOLOGIC AGENTS OF MENINGITIS

Immunoglobulin deficiency	<i>S. pneumoniae</i>
Asplenia	<i>S. pneumoniae</i>
Complement deficiency	<i>N. meningitidis</i>
Corticosteroid excess	<i>L. monocytogenes</i> , <i>Cryptococcus</i>
HIV infection	<i>Cryptococcus</i> , <i>L. monocytogenes</i> , <i>S. pneumoniae</i>
Bacteremia	<i>S. aureus</i> , Enterobacteriaceae
Fracture of cribriform plate	<i>S. pneumoniae</i>
Basal skull fracture	<i>S. pneumoniae</i> , <i>H. influenzae</i> , <i>S. pyogenes</i>
Neurotrauma, postneurosurgery	<i>S. aureus</i> , <i>S. epidermidis</i> , Gram-negative bacilli including <i>P. aeruginosa</i>

HIV, human immunodeficiency virus.

TABLE 73.3**INCIDENCE BY CAUSE OF BACTERIAL MENINGITIS IN THE UNITED STATES, 1995**

Micro-organism	Rate per 100,000
<i>Streptococcus pneumoniae</i>	1.1
<i>Neisseria meningitidis</i>	0.6
<i>Streptococcus agalactiae</i> (group B streptococcus)	0.3
<i>Listeria monocytogenes</i>	0.2
<i>Haemophilus influenzae</i> type b	0.2

From Schuchat A, Robinson K, Wenger JD, et al. Bacterial meningitis in the United States in 1995. Active Surveillance Team. *N Engl J Med.* 1997;337(14):970–976, with permission.

- Risk factors for invasive meningococcal disease include:
 - Nasopharyngeal carriage
 - Terminal complement deficiency
 - Properdin deficiency
- Characteristic rapidly evolving petechial or purpuric rash strongly suggests *N. meningitidis*
 - Similar rash may be seen in splenectomized patients with overwhelming *S. pneumoniae* or *H. influenzae* type b infection
- *H. influenzae* previously accounted for a large proportion of cases of bacterial meningitis
 - Widespread vaccination against *H. influenzae* type b has markedly decreased incidence (Table 73.3)
 - Isolation of *H. influenzae* type b in adults suggests presence of an underlying condition such as:
 - Sinusitis
 - Otitis media
 - Pneumonia
 - Diabetes mellitus
 - Alcoholism
 - CSF leak
 - Asplenia
 - Immune deficiency
- *Listeria monocytogenes* meningitis:
 - Carries a mortality rate of 15% to 29%
 - Occurs in neonates, adults older than 50 years of age, and in those with risk factors including:
 - Alcoholism
 - Malignancy
 - Pregnancy
 - Immune suppression secondary to corticosteroid therapy or transplantation
 - Infection seen infrequently in HIV-infected patients for unknown reasons
 - Pregnant women may be asymptomatic carriers and transmit infection to infants
 - *L. monocytogenes* commonly makes up part of the fecal flora of farm animals and can be isolated from soil, water, or contaminated vegetables
 - Outbreaks associated with unpasteurized dairy products such as milk and cheeses, vegetables, and processed meats
- Aerobic Gram-negative bacilli can cause meningitis in specific groups of patients
 - Predisposing risk factors include:
 - Neurosurgical procedures
 - Neonatal status
 - Advanced age
 - Immune suppression
 - Gram-negative bacteremia
 - Disseminated *Strongyloides stercoralis* infection with hyperinfection syndrome
 - *Escherichia coli* a common cause of meningitis in neonates
 - *Staphylococcus aureus* or *Staphylococcus epidermidis* can both cause meningitis
 - Less common than previously described micro-organisms
 - Both staphylococcal species exist as part of normal skin flora
 - Predominantly causing infections following neurosurgery or neurotrauma or when prosthetic material is present
 - Particularly external ventricular drains or ventriculoperitoneal shunts
 - Some patients with staphylococcal bacterial meningitis have underlying infective endocarditis, paraspinal or epidural infection, sinusitis, osteomyelitis, or pneumonia
- Other less common causes of bacterial meningitis include:
 - Enterococci
 - Viridans group streptococci
 - Beta-hemolytic streptococci
 - Diphtheroids
 - *Propionibacterium acne*
 - Generally only in the setting of prosthetic material
 - Anaerobic species

Viral Meningitis

- The most commonly isolated pathogens in aseptic meningitis
 - Nonpolio enteroviruses, especially Coxsackie viruses A and B, and echoviruses common
 - Account for 85% to 95% of cases with identified pathogen
 - Enteroviruses:
 - Occur worldwide
 - Transmitted by fecal–oral or respiratory droplet spread
 - Exhibit summer and fall seasonality in temperate climates
 - Infants, children, and young adults commonly affected
 - Clinical manifestations depend on host age and immune status but generally include:
 - Abrupt onset of severe headache, fever, nausea, vomiting, photophobia, nuchal rigidity, and malaise
 - Rash and upper respiratory symptoms common
 - Only rarely is illness severe enough to require critical care
 - Arboviruses more commonly cause encephalitis but also isolated in cases of aseptic meningitis
 - Arboviruses endemic to North America include:
 - The flaviviruses
 - St. Louis encephalitis virus
 - Colorado tick fever
 - Japanese encephalitis virus
 - West Nile virus
 - California encephalitis viruses
 - Arboviruses occur predominantly in summer and early fall when vector exposure most likely
 - St. Louis encephalitis virus is mosquito borne and causes epidemic disease in the Mississippi River area

- Japanese encephalitis virus less commonly causes meningitis, is endemic in Asia, and requires prolonged stays in rural settings for acquisition so is uncommon even in returned travelers
- West Nile virus (WNV) came to widespread attention in 1999 when first North American cases identified
 - Virus has spread extensively across North America and should be considered in all patients with meningitis
 - Particularly in late summer or early fall
 - Infection asymptomatic in 80% of cases
 - Remaining patients present with:
 - West Nile nonneurologic syndrome (approximately 20%; formerly named West Nile fever)
 - West Nile neurologic syndrome (WNNS; <1%)
 - West Nile nonneurologic syndrome is a self-limited febrile illness characterized by:
 - Fever
 - Headache
 - Malaise
 - Myalgias
 - Often a rash (50%)
 - WNNS may present as encephalitis, meningitis, or flaccid paralysis
 - Meningitis the least common presentation of WNNS
- Lymphocytic choriomeningitis (LCM) virus:
 - A zoonotic disease
 - Transmitted by contact with infected rodents or their feces
 - House mice
 - Rats
 - Hamsters
 - Now rare, LCM virus was one of first viruses associated with aseptic meningitis
 - Infection more common in winter months
 - Presenting manifestations include an influenza-like syndrome and meningismus, with occasional rash, orchitis, arthritis, myopericarditis, and transient alopecia
- Six of the eight recognized human herpesviruses can cause meningitis
 - Herpes simplex viruses (HSV) most commonly associated with aseptic meningitis during primary genital infection
 - Affects 36% of women and 13% of men with primary genital herpes
 - HSV-2 infection responsible for most infections
 - HSV-1 genital infection and concomitant meningitis can also occur
 - Meningitis much less likely in setting of genital herpes recurrences
 - Presenting symptoms:
 - Headache
 - Photophobia
 - Meningismus
 - Genital lesions are present in 85% of patients with primary HSV-2 meningitis and generally precede meningeal symptoms by several days.
- Herpes zoster aseptic meningitis, with or without typical skin lesions also reported
 - Particularly in older patients
- Cytomegalovirus (CMV), Epstein-Barr virus (EBV), and human herpes virus 6 (HHV-6) all capable of causing aseptic meningitis
 - Occur very rarely, predominantly in immune-suppressed populations

- HIV-associated aseptic meningitis can occur with primary infection in approximately 5% to 10% of patients
 - Cranial neuropathies may be present along with headache, fever, and meningismus
 - Symptoms usually self-limited
- Mumps, now rare as a result of universal vaccination programs, once relatively common cause of aseptic meningitis
 - Clinical manifestations include fever, vomiting, headache, and parotitis in approximately 50% of patients
 - Meningismus, lethargy, and abdominal pain may also be present.

Other Less Common Infectious Causes

- Spirochetal meningitis may be caused by *Treponema pallidum* or *Borrelia burgdorferi*
 - *T. pallidum*, etiologic agent of syphilis, is acquired by:
 - Sexual contact
 - Placental transfer
 - Direct contact with active lesions
 - These include condyloma lata, mucous patches, or the rash of secondary syphilis
 - Syphilitic meningitis usually occurs during primary or secondary infection, complicating 0.3% to 2.4% of untreated infections during the first 2 years
 - *B. burgdorferi* is transmitted by the *Ixodes* tick and causes Lyme disease
 - The most common vector-borne disease in the United States
 - Meningitis can occur during the first stage of disease
 - Concurrently with erythema migrans at tick bite site
 - Dissemination of the micro-organism in second stage of disease, 2 to 10 weeks following exposure, may also result in aseptic meningitis
 - Late or chronic disease may include subacute encephalopathy but not meningitis
- *Mycobacterium tuberculosis* may cause a subacute or chronic form of meningitis.
 - Infection of meninges results from rupture of a tuberculous focus into subarachnoid space
 - In very young patients, concomitant disseminated systemic infection is common.
 - Epidemiologic risk factors include:
 - Known prior history of tuberculosis (TB) exposure
 - Residence in an endemic area
 - Contact with an active case
 - Incarceration
 - Homelessness
 - HIV infection
 - Tuberculin skin testing is negative in over half of patients with tuberculous meningitis
 - Negative skin test cannot be used to exclude tuberculous meningitis
 - Newer tests, such as the QuantiFERON-TB Gold test, may be available in some centers
- Fungal meningitis, although uncommon, should be considered, particularly given the high mortality associated with untreated infection.
 - *Cryptococcus neoformans* predominantly affects immunocompromised hosts but can also infect the immunocompetent.
 - Encapsulated yeast distributed worldwide
 - Prefers wet forested regions with decaying wood

- Found in particularly high concentrations in pigeon guano
- Risk factors for cryptococcal infection include:
 - HIV/acquired immunodeficiency syndrome (AIDS)
 - Prolonged corticosteroid therapy
 - Immunosuppression posttransplantation
 - Malignancy
 - Sarcoidosis
- Clinical presentation is typically indolent, occurring over 1 to 2 weeks
 - Characterized by fever, malaise, and headache
 - Meningismus, photophobia, and vomiting occur in <33% of patients.
- *Cryptococcus gattii*, a serotype usually restricted to tropical climates, emerged on Vancouver Island, British Columbia (BC), Canada in 1999.
 - Since been responsible for numerous cases of CNS infection in predominantly immunocompetent hosts in BC and the U.S. Pacific Northwest
- *Coccidioides immitis*, a dimorphic fungus, is found in soil in the dry desert regions of the southwest United States, Mexico, and Central and South America
 - Infection results after inhalation of arthroconidia, usually following a dust storm or during building construction.
 - Infection usually confined to respiratory system in those with competent immune systems.
 - Extrapulmonary dissemination to the meninges can occur in patients with immune compromise or during pregnancy.
 - Patients present with headache, vomiting, and altered level of consciousness.
 - Risk factors for the development of disease include:
 - Travel to or residence in an endemic region
 - Immune deficiency
 - Coccidioidal meningitis is universally fatal if untreated
- Less common fungal causes of meningitis include:
 - *Blastomyces dermatitidis*
 - *Histoplasma capsulatum*
 - *Sporothrix schenckii*
 - Rarely, *Candida* species
 - *B. dermatitidis*, *H. capsulatum*, and *S. schenckii* are all dimorphic fungi with similar presentations to coccidioidal meningitis:
 - Primary infection occurs via inhalation
 - Disseminated infection occurs predominantly in immune compromised populations
 - *B. dermatitidis* and *H. capsulatum* endemic in Mississippi and Ohio River valleys
 - *S. schenckii* reported worldwide, with most cases in the tropical regions of the Americas
 - *Candida* exists only in yeast form:
 - Part of the normal flora of skin and gastrointestinal tract
 - CNS involvement most commonly due to candidemia with subsequent meningeal seeding
 - Predisposing risk factors for candidemia include:
 - Use of broad-spectrum antibiotics
 - Presence of indwelling devices such as vascular or urinary catheters
 - Parenteral nutrition
 - ICU admission
 - Prolonged hospital stay
 - Immune compromise
- Specific risk factors for *Candida* CNS infection include:
 - Ventricular shunts
 - Trauma
 - Neurosurgery
 - Lumbar puncture
 - *C. albicans* the most commonly isolated species
 - Non-*albicans* species becoming more prevalent, particularly in ICU populations
- Meningitis caused by protozoa or helminths is extremely rare.
 - Free-living amoebas *Acanthamoeba*, *Balamuthia*, and *Naegleria fowleri* are associated with fresh water exposure.
 - Usually acquired by individuals diving into contaminated lakes or swimming pools
 - CNS invasion occurs via penetration of nasal mucosa and cribriform plate
 - *N. fowleri* can cause a primary amoebic meningoencephalitis
 - *Acanthamoeba* and *Balamuthia* rarely cause meningitis; they commonly present as encephalitis.
 - *Angiostrongylus cantonensis*, the rat lungworm, is the classic infectious cause of eosinophilic meningitis (>10% eosinophils in the CSF) (Table 73.4).
 - Humans are incidental hosts and develop neurologic symptoms as a result of larval migration through the CNS.
 - Endemic in Southeast Asia and the Pacific Islands
 - Acquired by ingesting raw mollusks such as snails or slugs
 - *Gnathostoma spinigerum*, acquired by ingestion of raw and undercooked fish and poultry, is not primarily neurotropic.
 - May also cause eosinophilic meningitis as a result of migration of larvae up nerve tracts to CNS

TABLE 73.4

CEREBROSPINAL FLUID TESTS IN SUSPECTED CNS INFECTION

Routine tests	Further testing
Cell count and differential	Lactate
	Viral studies:
	Viral culture
	PCR for enteroviruses, HSV, WNV, VZV, influenza
Protein	AFB stain and mycobacterial culture
Glucose (preferably with simultaneous serum glucose)	Cryptococcal antigen test (can send serum as well, sensitivity comparable to CSF)
Gram stain	Fungal culture
Bacterial culture and sensitivity	VDRL, FTA-Abs, <i>T. pallidum</i> PCR ^a
	Cytology
	Cytospin and flow cytometry if available
	Wet mount if PAM suspected
	Lyme-specific Ab and PCR ^a

CNS, central nervous system; PCR, polymerase chain reaction; HSV, herpes simplex virus; WNV, West Nile virus; VZV, varicella-zoster virus; AFB, acid-fast bacillus; CSF, cerebrospinal fluid; VDRL, Venereal Diseases Research Laboratory; FTA-Abs, fluorescent treponemal antibody absorption; PAM, primary amoebic meningoencephalitis.

^aExperimental, available only in research laboratories

- Gnathostomiasis is endemic in Asia, especially Thailand and Japan, and more recently in Mexico.
- *Baylisascaris procyonis*, a roundworm infection of raccoons
 - Rarely causes human eosinophilic meningoencephalitis following accidental ingestion of ova from raccoon feces in contaminated water, soil, or foods

Diagnosis

- LP should be performed emergently in all patients suspected of having bacterial meningitis unless contraindicated.
- Commonly unnecessarily delayed while neuroimaging is performed to exclude mass lesions
- Complications associated with LP uncommon
 - Incidence of life-threatening brain herniation has been reported to range from <1% to 6%
 - Clinical features at baseline associated with abnormal findings on CT scan, and thus, increased risk of brain herniation are:
 - Age ≥ 60 years
 - History of CNS disease such as a mass lesion, stroke, and focal infection
 - Immune compromise such as HIV or immunosuppressive therapy
 - History of seizure ≤ 1 week before presentation
 - Specific abnormal neurologic findings
 - Guidelines for which adult patients should undergo CT prior to LP have been recommended (Table 73.5).
- Nosocomial meningitis rare in nonneurosurgical patients
 - Nevertheless, LP often performed in hospitalized patients with unexplained fever and/or decreased level of consciousness
 - Yield of performing an LP in the nonneurosurgical population is extremely low and of questionable utility
- CSF analysis is extremely important in the diagnosis of meningitis.
 - Basic laboratory analyses, including cell count and differential, protein, glucose, Gram stain, and bacterial cultures, most useful in distinguishing between viral, bacterial, tuberculous, and fungal infection (see Table 73.4)

Bacterial Meningitis

- Usually presents with an elevated systemic WBC count and left shift (immature forms such as bands and myeloids)

TABLE 73.5

INDICATIONS FOR IMAGING PRIOR TO LP IN ADULTS WITH SUSPECTED BACTERIAL MENINGITIS

Immunocompromised state (HIV/AIDS, immunosuppressive therapy)
 History of CNS disease (mass lesion, stroke, or focal infection)
 New-onset seizure (≤ 1 week of presentation)
 Papilledema
 Abnormal level of consciousness
 Focal neurologic deficit (dilated nonreactive pupil, abnormalities of ocular motility, abnormal visual fields, arm or leg drift)

LB, lumbar puncture; HIV, human immunodeficiency virus; AIDS, acquired immunodeficiency syndrome; CNS, central nervous system.

- Leukopenia may occasionally present in severe infection.
- Thrombocytopenia may be a result of sepsis, disseminated intravascular coagulation, or meningococemia alone.
- Renal and hepatic dysfunction may occur as part of multi-organ failure in severe disease.
- Blood cultures are often positive and should always be drawn prior to administration of antimicrobials, particularly if LP cannot be performed immediately.
 - Approximately 66% of patients with bacterial meningitis have positive blood cultures.
- CSF analysis in bacterial meningitis classically shows:
 - Neutrophilic pleocytosis with hundreds to thousands of cells and $>80\%$ neutrophils
 - Low CSF WBC count is usually a marker of poor prognosis in this setting
 - CSF glucose concentration is usually low and should be compared with a simultaneous serum glucose measurement.
 - Abnormal CSF-to-serum glucose ratio (<0.5) common in bacterial meningitis
 - Often much lower than 0.5
 - Acute illness in diabetics may increase serum glucose levels markedly, making the CSF-to-serum glucose ratio inaccurate
 - In postoperative neurosurgical patient, CSF lactate concentrations ≥ 4.0 mmol/L shown to be superior to CSF-to-blood glucose ratios
 - Initiation of empirical antimicrobial therapy in this setting should be considered pending the results of additional studies.
 - CSF protein and opening pressure usually elevated in bacterial meningitis (Table 73.6)
 - Gram staining permits rapid identification of bacterial species
 - Positive in approximately 50% to 60% of patients with bacterial meningitis
 - Presence of bacteria is virtually 100% specific, but sensitivity is variable
 - Gram stain more likely to be positive in patients with high bacterial loads
 - Gram-positive diplococci suggest *S. pneumoniae* infection
 - Gram-negative diplococci suggest *N. meningitidis* infection
 - Gram-positive rods suggest *L. monocytogenes* infection
 - Small pleomorphic coccobacilli suggest *H. influenzae* infection
- CSF bacterial cultures are positive in approximately 70% to 85% of cases
 - Yield decreases significantly in patients treated with antimicrobials prior to CSF collection
 - Antigen assays (latex agglutination tests) have been used in these cases, but due to their low sensitivity are no longer routinely offered by many laboratories
 - Broad-based polymerase chain reaction (PCR) may be useful for excluding the diagnosis of bacterial meningitis but is unavailable in many centers

Viral Meningitis

- In acute viral meningitis, CSF cell count is usually in the low hundreds with lymphocytic predominance.
- Predominance of neutrophils may be seen in the first 24 hours of disease, occasionally confusing the diagnosis.

TABLE 73.6

TYPICAL CSF PARAMETERS IN PATIENTS WITH MENINGITIS

Etiology	WBC count (cells/mm ³)	Predominant cell type	Protein (mg/dL)	Glucose (mg/dL)	Opening pressure (cm H ₂ O)
Normal	0–5	Lymphocyte	15–40	50–75	8–20
Viral	10–500	Lymphocyte ^a	Normal	Normal	9–20
Bacterial	100–5,000	Neutrophil	>100	<40	20–30
Tuberculous	50–300	Lymphocyte	>100	<40	18–30
Cryptococcal	20–500	Lymphocyte	50–200	<40	18–30

CSF, cerebrospinal fluid; WBC, white blood cell.

^aNeutrophils may predominate in the first 24 hours.

- CSF glucose concentration is usually within normal range.
- CSF protein is usually mildly elevated.
- Opening pressure is usually normal.
- Viral cultures and nucleic acid amplification tests are most commonly used in the diagnosis of viral meningitis.
 - Enteroviruses may be cultured from CSF, throat, or rectal swabs.
 - Sensitivity of 65% to 70%
- Or identified by nucleic acid amplification testing
 - PCR is both sensitive and specific
- PCR for HSV is also widely available
 - In studies of HSV-1 encephalitis, HSV PCR demonstrated a specificity of approximately 100% and sensitivity of 75% to 98%
 - False negatives occur mostly within the first 72 hours of infection.
- Diagnosis of WNV can be made by detection of serum immunoglobulin-M (IgM) or a fourfold rise in IgG between acute and convalescent titers
- WNV PCR of serum and CSF are also available
 - Sensitivity higher in CSF specimens due to short-lived viremia in humans

Other Less Common Causes

- CSF analysis in syphilitic meningitis characterized by:
 - Mild lymphocytic pleocytosis
 - Decreased glucose
 - Elevated protein
- *T. pallidum* cannot be cultured.
 - Diagnosis made using alternate methods, predominantly serology.
 - Direct visualization by darkfield microscopy or direct fluorescent antibody testing possible if primary chancre or skin lesion of secondary syphilis—condyloma latum or mucous patch—is present.
 - Serologic testing should include:
 - Nontreponemal (RPR, rapid plasma reagin; VDRL, Venereal Diseases Research Laboratory)
 - And treponemal (TPPA, *Treponema pallidum* particle agglutination; FTA-Abs, fluorescent treponemal antibody absorption) tests for the diagnosis of active syphilis infection
 - *Treponema*-specific enzyme immunoassays (EIA) for IgM and IgG, replacing above traditional serologic tests as initial laboratory diagnostic test
 - CSF VDRL used in diagnosis of syphilitic meningitis
 - Specificity is high, but false positives occur in bloody specimens
 - Major limitation of CSF VDRL is low sensitivity (30% to 70%), so a negative result should not be used to rule out infection in setting of high clinical suspicion
- CSF FTA-Abs more sensitive
 - False positives common due to serum antibody leak into the CSF
- PCR recently used to detect *T. pallidum* DNA in CSF
- Lyme meningitis is characterized by:
 - Mild lymphocytic pleocytosis
 - Low glucose
 - Elevated protein
 - CSF concentration of *B. burgdorferi* antibody
 - Compared to serum levels, is a sensitive and specific diagnostic method
 - PCR is currently available only in research laboratories
 - CSF oligoclonal bands and *B. burgdorferi* culture also available
 - But neither is sensitive or specific
- CSF analysis in tuberculosis meningitis demonstrates:
 - Lymphocytic pleocytosis
 - Low glucose
 - Markedly elevated protein
 - Markedly elevated opening pressure
 - Elevation in protein particularly marked in setting of CSF block
 - Acid-fast bacillus (AFB) smears are very low yield
 - Only 10% to 22% of cases positive
 - Mycobacterial cultures, although slow growing—taking several weeks—become positive in up to 88% of cases
 - DNA probes and nucleic acid amplification techniques (mainly PCR) recently available with great improvements in sensitivity and specificity
 - Meningeal biopsy is rarely performed but may show caseating granulomata
 - Skin testing and QuantiFERON-TB Gold testing have been discussed in the previous section
 - Sputum and urine AFB and mycobacterial blood cultures are part of the TB workup in these patients.
- Cryptococcal meningitis characterized by:
 - Lymphocytic pleocytosis
 - Decreased glucose
 - Elevated protein
 - Opening pressures may be markedly elevated
 - Culture of *C. neoformans* or *C. gattii* from the CSF diagnostic
 - Detection of serum or CSF cryptococcal antigen (CrAg) >90% sensitive
 - India ink previously regarded as standard diagnostic test

- Due to low sensitivity (50%) largely replaced by antigen testing
- Fungal blood cultures may also be useful, as cryptococcal meningitis occasionally occurs in the setting of disseminated cryptococcal infection with cryptococemia, especially in HIV-infected patients
- Other fungal meningitides similarly characterized by:
 - Lymphocytic pleocytosis
 - Low to normal glucose
 - Elevated protein
 - Coccidioidal meningitis may present with eosinophilic pleocytosis and peripheral eosinophilia
 - Fungal cultures diagnostic and most useful in *Candida* or *Aspergillus* infection
 - Dimorphic fungal infection diagnosed serologically, as isolating these organisms from the CSF is challenging and of low yield
 - Detection of complement-fixing (CF) IgG antibodies or immunodiffusion tests for IgM and IgG in CSF currently standard diagnostic tests
 - Low-titer false positives may occur in setting of parameningeal foci
 - False negatives may occur in early disease
- Primary amoebic meningoencephalitis due to *N. fowleri* results in:
 - Neutrophilic pleocytosis
 - Increased red blood cells
 - Low glucose
 - Elevated protein
 - Demonstration of motile trophozoites on wet mount of CSF or biopsy specimens diagnostic
- Diagnosis of *A. cantonensis*, *G. spinigerum*, or *B. procyonis* requires:

- Appropriate epidemiologic exposure
- Peripheral blood eosinophilia
- Characteristic eosinophilic pleocytosis
- Serologic tests helpful but performed only in reference laboratories

Treatment

- Initial management of patient with suspected meningitis primarily guided by epidemiologic risk factors and lumbar puncture results.
- CSF cell count, glucose, and Gram stain crucial in guiding empiric therapy
- If LP delayed for any reason, empiric antimicrobial therapy should not be withheld (Table 73.7)
 - Delays in therapy associated with adverse clinical outcomes and increased mortality
 - Administration of antimicrobials should immediately follow blood culture collection and should not be delayed by neuroimaging or other tests performed prior to LP.

Bacterial Meningitis

- LP should be performed urgently in those with suspected meningitis.
- Imaging should be performed prior to LP in specific populations (see Table 73.5)
 - Should not result in a delay in initiation of antimicrobial therapy
 - Empiric therapy based on age, underlying host factors, and initial CSF Gram stain results (see Table 73.7)
- Choice of antimicrobial therapy in bacterial meningitis influenced by:

TABLE 73.7

EMPIRIC THERAPY OF BACTERIAL MENINGITIS BASED ON AGE AND HOST FACTORS

	Most common causes	Recommended therapy
Age: Preterm to <1 month	<i>Streptococcus agalactiae</i> <i>Escherichia coli</i> <i>Listeria monocytogenes</i>	Ampicillin + cefotaxime or ceftriaxone
Age: 1 month to 50 years	<i>Streptococcus pneumoniae</i> <i>Neisseria meningitidis</i> <i>Haemophilus influenzae</i>	Cefotaxime or ceftriaxone + vancomycin ^a + dexamethasone ^b
Age: >50 years or alcoholism or other debilitating diseases or impaired cellular immunity	<i>Streptococcus pneumoniae</i> <i>Listeria monocytogenes</i> Coliform Gram-negative bacilli	Ampicillin + cefotaxime or ceftriaxone + vancomycin ^a + dexamethasone ^b
Postneurosurgery, neurotrauma, or cochlear implant	<i>Streptococcus pneumoniae</i> <i>Staphylococcus aureus</i> Coliform Gram-negative bacilli <i>Pseudomonas aeruginosa</i>	Vancomycin + ceftazidime or meropenem
Ventriculitis/meningitis due to infected shunt	<i>Staphylococcus epidermidis</i> <i>Staphylococcus aureus</i> Coliform Gram-negative bacilli Diphtheroids <i>Propionibacterium acnes</i>	Vancomycin + ceftazidime or meropenem

^aVancomycin should be added in centers where *S. pneumoniae* may be resistant to third-generation cephalosporins.

^bDexamethasone is efficacious in children with *H. influenzae* and in adults with *S. pneumoniae*. The first dose is to be given 15 to 20 minutes prior to or concomitant with first dose of antibiotic. Dose, 0.15 mg/kg IV every 6 hours for 2 to 4 days; discontinue if micro-organism isolated other than listed above.

- Blood–CSF barrier penetration
- Effect of meningeal inflammation on penetration
- Bactericidal efficacy
- CSF penetration is enhanced in meningeal inflammation due to increased permeability
- High lipid solubility, low molecular weight, and low protein binding increase CSF drug levels
- Bactericidal efficacy may be decreased in purulent CSF, particularly with aminoglycosides, due to low pH
- Penicillins, third-generation cephalosporins, carbapenems, fluoroquinolones, and rifampin achieve high CSF levels and are all bactericidal
- Should be adjusted based on renal and hepatic function
- Therapeutic drug monitoring may be required to ensure adequate levels and prevent toxicity (e.g., vancomycin, aminoglycosides).
- Should be adjusted based on culture and susceptibility results as soon as possible (Table 73.8)
- In suspected meningococcal or *H. influenzae* meningitis, droplet isolation strictly enforced until 24 hours of effective antimicrobial therapy completed or alternate diagnosis reached
 - Single room
 - Gowns
 - Gloves
 - Surgical masks
 - Dedicated patient care equipment

TABLE 73.9**MORTALITY RATES IN BACTERIAL MENINGITIS BY PATHOGEN**

Cause	Mortality
<i>Neisseria meningitidis</i>	3%–13%
<i>Streptococcus pneumoniae</i>	19%–30%
<i>Haemophilus influenzae</i>	3%–6%
<i>Listeria monocytogenes</i>	15%–29%
<i>Streptococcus agalactiae</i>	7%–27%
<i>Staphylococcus aureus</i>	14%–77%

- Isolation in other cases of meningitis, including pneumococcal meningitis, not required (Table 73.9)
- *Streptococcus pneumoniae*. Empiric therapy guidelines for pneumococcal meningitis recently modified due to increasing incidence of penicillin resistance
- Once uniformly susceptible to penicillin, mutations in penicillin-binding proteins have resulted in varying levels of resistance
- Empiric therapy consists of:
 - Third-generation cephalosporin until susceptibility available
 - Once minimum inhibitory concentration (MIC) available, adjust therapy accordingly

TABLE 73.8**SPECIFIC THERAPY OF BACTERIAL MENINGITIS**

Bacterium	Recommended therapy
<i>Haemophilus influenzae</i>	
Ampicillin susceptible	Ampicillin
Ampicillin resistant	Cefotaxime or ceftriaxone
<i>Neisseria meningitidis</i>	
Penicillin MIC <0.1 µg/mL	Penicillin G or ampicillin
Penicillin MIC 0.1–1.0 µg/mL	Cefotaxime or ceftriaxone
<i>Streptococcus pneumoniae</i>	
Penicillin MIC <0.1 µg/mL	Penicillin G or ampicillin
Penicillin MIC ≥0.1 µg/mL	Cefotaxime or ceftriaxone
Ceftriaxone MIC ≥1.0 µg/mL	Vancomycin plus cefotaxime or ceftriaxone
Enterobacteriaceae	Cefotaxime or ceftriaxone unless member of SPICEM group ^a
<i>Pseudomonas aeruginosa</i>	Meropenem or ceftazidime or cefepime or aztreonam or ciprofloxacin PLUS tobramycin
<i>Listeria monocytogenes</i>	Ampicillin or penicillin G
<i>Staphylococcus aureus</i>	
Methicillin susceptible	Nafcillin or oxacillin
Methicillin resistant	Vancomycin
Prosthesis associated	Consider adding rifampin to above choices
<i>Staphylococcus epidermidis</i>	Vancomycin
Prosthesis associated	Consider adding rifampin
<i>Streptococcus agalactiae</i>	Ampicillin or penicillin G

MIC, minimum inhibitory concentration.

^aSPICEM group includes *Serratia marcescens*, *Providencia*, indole-positive *Proteus* (*P. vulgaris*), *Citrobacter freundii* group, *Enterobacter* spp., and *Morganella morganii*). These micro-organisms carry chromosomal, inducible β-lactamases (ampC), which are capable of inactivating third-generation cephalosporin even if reported to be susceptible. Carbapenems (meropenem has greatest cerebrospinal fluid penetration), fluoroquinolones, or trimethoprim/sulfamethoxazole may be used to treat these micro-organisms, if susceptible.

- Isolates with penicillin MIC <0.1 $\mu\text{g/mL}$, penicillin G (4 million units intravenous [IV] every 4 hours) or ampicillin (2 g IV every 4 hours) should be used
- Isolates with a MIC ≥ 0.1 $\mu\text{g/mL}$, treatment with a third-generation cephalosporin should be continued
 - Either cefotaxime (2 g IV every 6 hours) or ceftriaxone (2 g IV every 12 hours)
 - Isolates with ceftriaxone MIC ≥ 1 $\mu\text{g/mL}$, vancomycin and a third-generation cephalosporin are recommended therapy
 - Vancomycin dosed 1 g IV every 12 hours, or 500 to 750 mg IV every 6 hours, to maximum of 2 to 3 g per day
 - Adjusted based on therapeutic drug monitoring to maintain a trough serum concentration of between 15 and 20 $\mu\text{g/mL}$
 - Meropenem a reasonable alternative
 - Does not carry the theoretical risk of decreasing seizure threshold seen with imipenem
 - Efficacy of newer antimicrobials, such as linezolid and daptomycin, not established
 - Dexamethasone **should be administered** prior to or with the first dose of antimicrobial
 - Treatment duration is 10 to 14 days
- ***Neisseria meningitidis***. Initial treatment of meningococcal meningitis is with a third-generation cephalosporin
 - Cefotaxime (2 g IV every 6 hours) or ceftriaxone (2 g IV every 12 hours)
 - Should be stepped down to penicillin if susceptibility confirmed
 - Duration of treatment is 7 days
 - Chloramphenicol (25 mg/kg, to a maximum of 1 g IV every 6 hours) a reasonable alternative in the beta-lactam-allergic patient
 - Meropenem (2 g IV every 8 hours) is another alternative
 - A high degree of cross-reaction in penicillin-allergic patients
 - Dexamethasone **not indicated** in confirmed meningococcal meningitis
- ***Haemophilus influenzae***. Therapy for *H. influenzae* meningitis initially a third-generation cephalosporin
 - Can be changed to ampicillin, 2 g IV every 4 hours if susceptibility confirmed
 - Total of 7 days of therapy recommended
 - Dexamethasone **should be administered** as adjunctive therapy in children
- ***Listeria monocytogenes***. *L. monocytogenes* meningitis should be treated with ampicillin, 2 g IV every 4 hours
 - Gentamicin may be added for antimicrobial synergy, but aminoglycosides have poor penetration into CSF.
 - Gentamicin administered as a 2 mg/kg loading dose, followed by 1.7 mg/kg every 8 hours
 - Trimethoprim/sulfamethoxazole (TMP/SMX), 20 mg/kg per day of the trimethoprim component, divided into 6 to 12 hourly doses, can be used in penicillin-allergic patients
 - Alternate therapies include meropenem and, potentially, linezolid and rifampin
 - Third-generation cephalosporins have no activity against *L. monocytogenes*
 - Treatment duration is 14 to 21 days
- **Aerobic Gram-negative bacilli**: Aerobic Gram-negative bacilli treated empirically with a third-generation cephalosporin or meropenem
 - Susceptibility results should be obtained to guide therapy in consultation with an infectious diseases specialist
 - For *Pseudomonas aeruginosa* infections, ceftazidime or cefepime, 2 g IV every 8 hours, or meropenem, 2 g IV every 8 hours, with tobramycin 2 mg/kg IV every 8 hours, should be used
 - Cefotaxime and ceftriaxone not used; no antipseudomonal activity
 - Ciprofloxacin or aztreonam is acceptable alternative if the isolate is susceptible
 - Duration of therapy is prolonged, generally 21 days
- **Staphylococcus**: Staphylococcal meningitis therapy depends on methicillin susceptibility
 - Methicillin-susceptible strains should be treated with nafcillin or oxacillin, 2 g IV every 4 hours
 - Methicillin-resistant strains should be treated with vancomycin, 1 g IV every 12 hours or 500 to 750 mg IV every 6 hours, to a maximum of 2 to 3 g per day
 - Ensure adequate serum levels of 15 to 20 $\mu\text{g/mL}$
 - Vancomycin is recommended in patients with penicillin allergy
 - Infected prosthetic material should be removed if possible
 - Antimicrobial therapy continued for 10 to 14 days after removal
 - If removal not possible, rifampin may be added
 - Cure rates are poor with hardware retention
 - Linezolid and daptomycin may become alternate therapies, but data are lacking
- Adjunctive therapies in bacterial meningitis include:
 - Corticosteroids
 - Procedures to reduce intracranial pressure
 - Surgery
 - Corticosteroid therapy decreases inflammatory response while allowing antimicrobial therapy to eradicate infection
 - Administration may decrease CSF penetration and bactericidal activity of antimicrobials but randomized controlled trials suggest benefit
 - In children, administration of dexamethasone has demonstrated reduction in incidence of hearing impairment and severe neurologic complications in *H. influenzae* meningitis
 - Adjunctive corticosteroid therapy has also been evaluated in adults, showing a mortality benefit in patients with pneumococcal meningitis
 - Treatment recommendations suggest dexamethasone, 0.15 mg/kg 10 to 20 minutes before, or at least concomitant with, the first dose of antimicrobial therapy and continued every 6 hours
 - Should be continued for 2 to 4 days only if the Gram stain or cultures demonstrate *H. influenzae* in children or *S. pneumoniae* in adults
 - Intracranial pressure monitoring may be beneficial for patients with bacterial meningitis and elevated intracranial pressure (ICP)
 - Complications of bacterial meningitis divided into neurologic and nonneurologic
 - Neurologic complications include seizures, cerebral edema, cerebral infarction, cranial nerve palsies, venous

sinus thrombosis, brain abscess, subdural empyema, and coma.

- Late complications include hearing impairment, obstructive hydrocephalus, learning disabilities, sensory and motor deficits, mental retardation, cortical blindness, and seizures.
- Nonneurologic complications include septic shock, coagulopathy, and the syndrome of inappropriate antidiuretic hormone secretion (SIADH).

Viral Meningitis

- Treatment for viral meningitis is supportive, given its benign and self-limited course.
- IV immunoglobulin[MB2] has been used in agammaglobulinemic patients with chronic enteroviral meningitis.
- No specific therapy exists for arboviruses, mumps, or LCM.
- HIV-associated meningitis should be treated with combination antiretroviral therapy.
- Not clear whether antiviral treatment alters course of HSV meningitis
 - Nevertheless, primary episodes of genital herpes treated as per guidelines
 - Some extend therapy to 14 days with concomitant meningitis
 - Intravenous acyclovir, 5 mg/kg every 8 hours, used in severe disease
- Ganciclovir the treatment of choice for CMV meningitis in immunocompromised hosts

Other Less Common Causes

- Syphilitic meningitis does not respond to benzathine penicillin.
 - Used to treat most forms of syphilis
 - Requires a 2-week course of high-dose IV penicillin G (4 million units every 4 hours)
 - RPR titers should be monitored after therapy.
 - Repeat CSF examination should be performed if titers do not decline fourfold at 6 months after therapy.
 - All HIV patients with syphilitic meningitis should have a LP repeated 6 months following therapy.
 - Patients with penicillin allergy should undergo desensitization, as there are no proven effective alternative therapies for syphilitic meningitis.
- Treatment of Lyme meningitis achieved with ceftriaxone, 2 g daily, or cefotaxime, 2 g IV every 8 hours for 14 to 28 days
 - Alternate therapy is penicillin (4 million units every 4 hours) for 14 to 28 days
- Treatment of tuberculous meningitis depends on resistance pattern in community and results of susceptibility testing
 - Consultation with an ID[MB3] specialist recommended
 - In general, standard combination therapy includes isoniazid (INH), rifampin (RIF), ethambutol (ETB), and pyrazinamide (PZA)
 - ETB may be discontinued once INH and RIF susceptibilities confirmed
 - Treatment continued for minimum of 12 to 24 months
 - Adjunctive therapy with dexamethasone for the first month has been shown to decrease complications and is recommended
 - Pyridoxine, 25 to 50 mg daily, administered to prevent INH-related neuropathy
- Therapy for fungal meningitis is complicated by the lack of standardized susceptibility testing and interpretation for many fungi.
- Area of antifungal therapy is an evolving area with an increasing number of antifungal agents from which to choose.
- Cryptococcal meningitis treated with:
 - 14-day induction phase of amphotericin B, 0.7 to 1 mg/kg per day IV, with or without flucytosine, 100 mg/kg per day orally dosed every 6 hours
 - Consolidation therapy with fluconazole, 400 mg daily, should be continued for 8 weeks following induction
 - Maintenance (or suppressive) therapy with fluconazole, 200 mg per day, continued in patients with HIV/AIDS until immune reconstitution achieved
 - May require:
 - Daily therapeutic lumbar punctures
 - An external ventricular drain
 - Ventriculoperitoneal shunt to relieve increased intracranial pressure
 - Therapy is identical in non-HIV/AIDS patients, with the exception that consolidation therapy is continued for 10 weeks
 - Further prolongation may be required in transplant patients
 - Echinocandins, such as caspofungin and micafungin, are not active in cryptococcosis
- Treatment for coccidioidal meningitis is oral fluconazole, 400 mg daily
 - Some initiate therapy with dose of 800 mg per day or may add intrathecal amphotericin B
 - Treatment must be continued lifelong, as relapses are frequently lethal
- Therapy for *H. capsulatum* meningitis consists of amphotericin B, 0.7 to 1 mg/kg per day to complete a total dose of 35 mg/kg
 - Fluconazole, 800 mg per day, for an additional 9 to 12 months, may be used to prevent relapse
 - If relapse occurs, long-term therapy with fluconazole or intraventricular amphotericin B recommended
 - Itraconazole avoided due to poor CSF penetration
- Although very rare, *S. schenckii* meningitis treated with amphotericin B
 - Itraconazole, despite its poor CSF penetration, may be tried after initial therapy for lifelong suppression.
- For candidal meningitis preferred initial therapy is amphotericin B, 0.7 mg/kg per day
 - With flucytosine, 25 mg/kg dosed every 6 hours and adjusted to maintain serum levels of 40 to 60 μ g/mL
 - Fluconazole therapy, in susceptible species, may be used for follow-up or suppressive therapy.
 - Therapy should continue for at least 4 weeks after resolution of symptoms.
 - All prosthetic material must be removed to achieve cure.
- Primary amoebic meningoencephalitis caused by *N. fowleri* usually fatal
 - A few cases successfully treated with early diagnosis and treatment with high-dose intravenous and intrathecal amphotericin B or miconazole and rifampin
- Eosinophilic meningitis caused by *A. cantonensis* and *G. spinigerum* treated supportively

- Corticosteroids recommended to decrease inflammatory response to intracranial larvae
 - Antihelminthic therapy relatively contraindicated
 - Clinical deterioration and death may occur following severe inflammatory reactions to dying larvae

Prevention

- Chemoprophylaxis (medications) and immunoprophylaxis (vaccines) available to prevent infection in contacts of cases or in times of epidemic spread
- Prophylaxis indicated for cases of *H. influenzae* type b in household contacts
 - Those residing with index case or with more than 4 hours of close contact
- And day care contacts
 - Same day care as index case for 5 to 7 days before onset of disease
- If there is unvaccinated contact at 4 years of age or younger in the household, chemoprophylaxis recommended for all household contacts except pregnant women
 - Rifampin, 20 mg/kg, with a usual adult dose of 600 mg daily, for four doses, recommended therapy
- Prophylaxis for *N. meningitidis* is recommended for close contacts of cases
 - Includes intimate contacts (e.g., kissing)
 - Close contacts with ≥ 4 hours contact 1 week prior to the onset of illness
 - Close contacts include roommates, day care center contacts, cellmates, and/or military recruits
 - Medical personnel exposed to oropharyngeal secretions during intubation, nasotracheal suctioning, or mouth-to-mouth resuscitation should also receive chemoprophylaxis.
 - Rifampin, 600 mg orally every 12 hours for a total of four doses, or single doses of ciprofloxacin (500 mg orally) or ceftriaxone (250 mg intramuscularly) all efficacious
 - Avoid ciprofloxacin in children younger than 16 years and pregnant women, based on joint cartilage injury demonstrated in animal studies
- Vaccination available for prevention of *H. influenzae*, *N. meningitidis*, and *S. pneumoniae*
 - *H. influenzae* type b vaccination is part of routine childhood immunization
 - Unvaccinated children 2 years or younger exposed to index case should receive chemoprophylaxis and vaccination.
 - *S. pneumoniae* vaccination available in two preparations:
 - Not indicated as postexposure prophylaxis
 - 23-valent polysaccharide vaccine
 - Recommended for all individuals >65 years and those >5 years old with high-risk conditions (see below)
 - Of limited immunogenicity and efficacy
 - 7-valent conjugate vaccine
 - Recommended routinely in all children 23 months and younger and in those at high risk of invasive disease older than 23 months
 - Sickle cell disease and other hemoglobinopathies
 - Functional or anatomic asplenia
 - HIV infection
 - Immunocompromising conditions
 - Chronic medical conditions

- *N. meningitidis* vaccine available in two forms:
 - Conjugate and polysaccharide
 - Available conjugate vaccines include a quadrivalent (MCV4) vaccine, as well as the monovalent serogroup C (Men-C) vaccine
 - Available polysaccharide vaccines include a quadrivalent vaccine containing A, C, Y, and W-135 and a bivalent vaccine with serogroups A and C.
 - Vaccination indicated in:
 - High-risk populations, including those with specific immune deficiencies (see Table 73.2)
 - Those traveling to endemic and epidemic regions
 - Laboratory workers routinely exposed to *N. meningitidis*
 - First-year college students living in dormitories
 - Military recruits

ENCEPHALITIS

Key Points

- Distinguishing encephalitis from meningitis, most useful finding is altered mental status
- Encephalitis most commonly viral or postinfectious in etiology
- Herpes simplex encephalitis the most common cause of sporadic encephalitis in Western countries
 - Accounts for 10% to 20% of cases
 - Temporal lobe involvement on MRI and electroencephalographic (EEG) characteristic
 - PCR 75% to 98% sensitive
 - False negatives occur predominantly during first 72 hours of illness
 - Mortality approaches 70% without therapy
 - Significantly reduced with early antiviral therapy
- Defined as inflammation of brain parenchyma
 - Encephalitis and meningitis may present with similar clinical findings
 - Two syndromes are pathophysiologically distinct
 - Major distinguishing feature is presence or absence of normal brain function
 - Patients with meningitis may be drowsy or lethargic but should have normal cerebral function
 - Those with encephalitis generally have altered mental status
 - Occasionally patients may present with combination of findings in overlap syndrome of meningoencephalitis
 - Important to distinguish between syndromes, as etiologic agents and treatments may differ
- Encephalitis most commonly viral or postinfectious (Table 73.10)
 - Viral encephalitis caused by direct viral invasion of the CNS
 - Postinfectious encephalitis an immune-mediated process
 - May be difficult to differentiate the two
 - Encephalitis with resolving infectious symptoms suggests a postviral cause
 - Most common viruses causing postinfectious encephalitis include mumps, measles, varicella-zoster virus, rubella, and influenza
 - Access to the CNS highly virus specific

TABLE 73.10

MOST COMMON VIRAL CAUSES OF ENCEPHALITIS, THEIR VECTORS OR ANIMAL HOSTS, AND GEOGRAPHIC DISTRIBUTIONS

Viral cause	Vector or animal host	Geographic distribution
Alpha viruses	Mosquitoes	
Eastern equine (EEE)	<i>Culiseta melanura</i>	New England
Western equine (WEE)	<i>Culex tarsalis</i>	West of Mississippi River
Venezuelan equine (VEE)	<i>Culex</i> spp.	South and Central America
Flaviviruses	Mosquitoes or ticks	
St. Louis	<i>Culex</i> spp.	Throughout the United States
West Nile (WNV)	<i>Culex pipiens</i> and <i>tarsalis</i>	Americas, Africa, Asia, Middle East, Europe
Japanese	<i>Culex tritaeniorhynchus</i>	Asia and SE Asia
Murray Valley	<i>Culex</i> and <i>Aedes</i> spp.	Western Australia
Tick-borne	<i>Ixodes ricinus</i> and <i>persulcatus</i> ticks	Russia, Central Europe, China, North America, British Isles
Powassan virus		
Louping ill virus		
Herpes viruses	N/A	Worldwide
Herpes simplex virus (HSV-1)		
Varicella-zoster virus (VZV)		
Cytomegalovirus (CMV)		
Epstein-Barr virus (EBV)		
Human herpesviruses 6, 7		
Enteroviruses	N/A	Worldwide
Polioviruses		
Coxsackieviruses		
Echoviruses		
Adenoviruses	N/A	Worldwide
Human immunodeficiency virus (HIV)	N/A	Worldwide; particularly high prevalence in sub-Saharan Africa, Central and Southeast Asia, Eastern Europe
Rabies	Dogs, cats, raccoons, wolves, foxes, bats	Worldwide
Colorado tick fever	<i>Dermacentor andersoni</i> tick	Western United States and Canada
Mumps	N/A	Unvaccinated populations worldwide
Measles	N/A	Unvaccinated populations worldwide

N/A, not applicable.

- Occurs via hematogenous or neuronal routes
- After CNS entry, viruses enter neural cells, causing inflammation and cell dysfunction
- Clinical manifestations the result of specific cell-type invasion
 - Oligodendroglial cell invasion causes demyelination
 - Cortical invasion results in altered mental status
 - Neuronal invasion may result in focal or generalized seizures
- Focal pathology is the result of specific neural tropism
- Muscle weakness and flaccid paralysis may present concurrently in patients with encephalitis
- Arboviruses are acquired via vector exposure, mainly mosquitoes and ticks, and are most prevalent during summer and early fall months when vectors most active
 - Eastern equine encephalitis (EEE)
 - Western equine encephalitis (WEE)
 - St. Louis encephalitis
 - Venezuelan equine encephalitis (VEE)
 - California encephalitis (caused by La Crosse virus)
 - Japanese encephalitis
 - Yellow fever
 - WNV
- EEE has a high mortality rate, whereas WEE is a much milder illness
- WNV, identified in North America in 1999, causes WNNS in <1% of exposed individuals
 - WNNS most commonly manifests as encephalitis and occurs in those with diabetes mellitus, alcoholism, and of older age
- Japanese virus encephalitis, occurring principally in Southeast Asia, China, India, and Japan, the most common viral encephalitis outside the United States
- Colorado tick fever prevalent in western United States
 - Most affected individuals have history of camping and hiking in wooded endemic areas
- Malaria, in those with an appropriate travel history, should also be considered in the differential diagnosis of encephalitis
- Rabies, a zoonotic disease that requires contact with infected animals, should be considered in all cases of encephalitis.
 - Once CNS infection is established, the mortality is essentially 100%.
 - Can be acquired from many sources including dogs, cats, raccoons, bats, and foxes

- History of animal bite, useful if present, is absent in most cases of rabies
- Herpes viruses cause disease by primary infection or reactivation
 - Herpes simplex encephalitis (HSE), the most common cause of sporadic encephalitis in Western countries, accounting for 10% to 20% of cases
 - Caused by type 1 virus in >90% of cases, occurs year-round, and affects all age groups
 - Two-thirds of cases due to reactivation of virus in trigeminal ganglion, with retrograde transport along the olfactory tract to the orbitofrontal and mediotemporal lobes
 - Untreated HSE has mortality rate of 50% to 75%
 - All survivors suffer neurologic sequelae
 - Outcomes correlate strongly with severity of disease at presentation, as well as time to initiation of antiviral therapy
 - Varicella-zoster encephalitis generally affects immunocompromised patients and may occur with or without concomitant cutaneous lesions.
- Nonviral causes of encephalitis include bacterial, rickettsial, fungal, and parasitic infections.
 - Bacterial causes include *Mycoplasma*, *Listeria monocytogenes*, *Borrelia burgdorferi* (Lyme disease), *Leptospira* spp., *Brucella*, *Legionella*, *Nocardia*, *Treponema pallidum* (syphilis), *Salmonella typhi*, and mycobacterial species, *Coxiella burnetii* (Q-fever), and Ehrlichia.
 - Most common rickettsial species include *R. rickettsii* (Rocky Mountain spotted fever) and *R. typhi* (endemic typhus)
 - Fungal causes include *Cryptococcus* spp., *Aspergillus* spp., *Candida*, *Coccidioides immitis*, *Histoplasma capsulatum*, and *Blastomyces dermatitidis*
 - *Trypanosoma brucei* complex (African sleeping sickness), malaria, *Toxoplasma gondii*, *Echinococcus granulosus*, and *Schistosoma* spp. can cause encephalitis but require epidemiologic exposures or specific risk factors
 - For example, toxoplasma encephalitis most common in advanced HIV
- Clinical findings of encephalitis include:
 - Classic triad of fever, headache, and altered mental status
 - Onset of symptoms may be acute, subacute, or chronic
 - Acuity and severity of symptoms at presentation correlate with prognosis
 - Symptoms may be preceded by a viral prodrome consisting of fever, headache, nausea, vomiting, lethargy, and myalgias.
 - Disorientation, amnesia, behavioral and speech changes, movement disorders, and focal or diffuse neurologic abnormalities such as hemiparesis, cranial nerve palsies, or seizures are common presenting.
 - Neck stiffness and photophobia may also be noted.
 - Varicella-zoster virus (VZV), EBV, CMV, measles, and mumps may present with rash, lymphadenopathy, and hepatosplenomegaly.
 - HSE incidence is unrelated to a history of oral or genital lesions.
- Laboratory findings may include:
 - Peripheral leukocytosis or leucopenia
 - CSF examination usually reveals a pleocytosis with lymphocytic predominance
 - Neutrophilic predominance may be present early in infection.
 - Red blood cells, in the absence of a traumatic tap, are suggestive of HSV but may be seen in other necrotizing viral encephalitis.
 - Protein levels usually elevated, and glucose may be normal or slightly decreased
 - Viral cultures are rarely positive, molecular methods have become the diagnostic tests of choice
 - Demonstration of HSV DNA in the CSF by PCR is both sensitive and specific (75%–98% and 100%, respectively)
 - May miss cases in first 72 hours of illness
 - PCR testing available for WNV, VZV, enteroviruses, adenoviruses, rabies, CMV, EBV, HHV-6, and HHV-7 in most reference laboratories
 - Serology may be diagnostic if IgM is detected or a fourfold rise in acute and convalescent IgG titers is demonstrated
 - Corneal or neck (posterior, at the hairline) biopsies and saliva PCR can be diagnostic for rabies
 - Brain biopsy may be considered if all other tests are non-diagnostic
 - Other investigations that may aid in diagnosis include EEG, CT, or MRI
 - EEG particularly helpful in HSE, showing characteristic focal changes (spiked and slow wave patterns) from temporal regions in 80% of patients
 - MRI the most sensitive imaging modality at detecting early viral encephalitis and may show virus-specific changes
 - CT scans are more available on an urgent basis and are useful in ruling out space-occupying lesions.
 - Rarely able to visualize encephalitic changes
 - There are few specific therapies for viral encephalitis
 - Treatment of HSE with acyclovir, 10 mg/kg IV every 8 hours the main exception
 - Treatment should be initiated as soon as possible, delays correlate with mortality
 - Therapy should be started empirically in all patients with encephalitis until confirmatory testing is available, given the dramatic effect on outcome
 - Acyclovir should also be considered in VZV encephalitis even though data regarding efficacy in this form of VZV disease are only anecdotal.
 - Supportive therapy, including ICU admission with intubation and mechanical ventilation, may be required.
 - Ganciclovir or foscarnet for ganciclovir-resistant strains used to treat CMV encephalitis
 - Role of antivirals for EBV and HHV-6 encephalitis unproven
 - International Herpes Management Forum recommends use of ganciclovir or foscarnet for HHV-6 encephalitis*
 - Outcomes related to multiple factors include:
 - Host age and immune response
 - Organism virulence
 - Time to effective therapy
 - Poor outcomes more common in younger (<1 year) and older (>55 years) populations
 - HSE, Japanese encephalitis, and EEE have highest mortality rates

*Data on CMV encephalitis come from several papers related to HIV patients, including International Herpes Management Forum (IHMF) recommendations (*Herpes*. 2004;11(Suppl 2):95A–104A). Data on HHV-6 are more limited, but antivirals are still suggested by the IHMF (*Herpes*. 2004;11(Suppl 2):105A–111A).

- HSE mortality approaches 70% without therapy but can be reduced to 28% with early antiviral treatment.
- 62% of HSE patients recover with significant neurologic deficits
 - Paresis, seizures, cognitive and memory deficits

BRAIN ABSCESS

Key Points

- Brain abscess results from focal infection, trauma, or surgery.
- Solitary abscess usually result of contiguous infection from otitis, mastoiditis, sinusitis, or dental infection
- Multiple abscesses commonly result from hematogenous spread from chronic pulmonary, endocardial, skin, intra-abdominal, or pelvic infections
- Microbiology of brain abscess depends on primary site of infection, patient age, and underlying host factors. Infections commonly polymicrobial, and empiric therapy should include targeted anaerobic activity.
- Clinical manifestations nonspecific and depend on size and location of abscess. Headache is the most common presenting feature.
- MRI more sensitive than CT scanning and is neuroimaging test of choice
- Blood and abscess culture results should be used to tailor antimicrobial therapy, which is generally prolonged (6 to 8 weeks) and guided by serial imaging
- Surgical excision may be indicated in patients with traumatic brain abscesses, fungal abscesses, and multiloculated or large (>2.5 cm) abscesses.
- Brain abscess uncommon but potentially life-threatening infection
 - Characterized by localized intracranial suppurative collections
 - Usually the result of:
 - Extension of focal infection (45%)
 - Trauma (10%)
 - Surgery
 - Bacteria may gain entry to CNS by hematogenous seeding in 25% of cases
 - Mortality rates with treatment range from 4.5% to 13%
 - Even with new imaging techniques, antimicrobials, and surgical therapies
 - Infection begins as a localized area of cerebritis, with subsequent central necrosis, suppuration, and fibrous capsule formation (Table 73.11)
 - Solitary abscesses
 - Usually result of contiguous infection including otitis, mastoiditis, frontal or ethmoid sinusitis, or dental infection
 - Bullet fragments or other foreign bodies may serve as nidus of infection and develop into abscesses even years after initial injury.
 - Postneurosurgical brain abscesses may also present in a delayed fashion.
 - Multiple abscesses
 - More commonly result of hematogenous seeding from chronic pulmonary, endocardial, skin, intra-abdominal, or pelvic infections

TABLE 73.11

RISK FACTORS FOR BRAIN ABSCESS

Otic infection (otitis media, mastoiditis)
 Sinusitis (frontal, ethmoid, sphenoid)
 Dental infection
 Neurosurgical intervention or neurotrauma
 Bacterial endocarditis
 Neutropenia
 Immune compromise (HIV infection, immunosuppressive therapy)
 Chronic lung infection (abscess, bronchiectasis, empyema)
 Congenital heart disease

HIV, human immunodeficiency virus.

- Patients with hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome) and children with coronary heart disease predisposed to brain abscesses
- Primary site or underlying condition cannot be identified in 20% to 40% of patients with brain abscess.
- Location of brain abscess may be suggestive of source
 - Temporal lobe or cerebellar abscesses commonly result from otic infections
 - Frontal lobe abscesses from sinusitis or dental infection
 - Abscesses in the distribution of the middle cerebral artery from hematogenous seeding
- Microbiology of brain abscesses diverse and depends on primary site of infection, age of patient, underlying host factors:
 - Common aerobic species include:
 - Streptococci (viridans, anginosus group, and microaerophilic species) isolated in up to 70% of cases
 - Aerobic Gram-negative bacilli—*Klebsiella pneumoniae*, *Pseudomonas* spp., *Escherichia coli*, and *Proteus* spp.—and *S. aureus* are common pathogens with contiguous infection
 - Less common pathogens, *Rhodococcus*, *Listeria*, *Nocardia*, mycobacteria, and fungi—*Candida*, *Cryptococcus*, *Aspergillus*, agents of zygomycosis, *Pseudoallescheria boydii*, and the dimorphic fungi such as *Histoplasma*, *Coccidioides*, and *Blastomyces*—cause disease in immunocompromised hosts.
 - Postsurgical or posttraumatic abscesses usually due to *S. aureus* and aerobic Gram-negative bacilli
 - Advanced HIV-infected patients commonly present with *Toxoplasma gondii* infection
 - Anaerobes present in 40% to 100% of brain abscesses
 - Although anaerobic cultures not routinely performed in all laboratories and may be falsely negative
 - May originate from the oropharynx with contiguous head and neck infections, or from the abdomen or pelvis when infection is due to hematogenous seeding
 - Commonly isolated anaerobes include *Peptococcus*, *Peptostreptococcus*, *Bacteroides* spp., *Prevotella* spp., *Propionibacterium*, *Fusobacterium*, *Eubacterium*, *Veillonella*, and *Actinomyces*.
 - Helminths occasionally cause localized brain infection in immigrant populations.
 - Neurocysticercosis, intracranial infection with the larval cyst of *T. solium* or pork tapeworm, most common and results from the ingestion of *T. solium* ova

TABLE 73.12

COMMON PRESENTING FEATURES IN BRAIN ABSCESS

Headache
Mental status changes
Fever
Focal neurologic deficits
Neck stiffness
Papilledema, nausea, or vomiting with increased intracranial pressure
Seizures

- *Entamoeba histolytica*, *Schistosoma japonicum* and *mekongi* species, *Paragonimus*, and *Toxocara* also described as causes of brain abscess
- Clinical manifestations of brain abscess are relatively nonspecific, resulting in delays in presentation and diagnosis (Table 73.12)
- Onset may be acute or chronic
 - Most of presenting features related to size and location of abscess
 - Systemic toxicity uncommon
 - Headache is most common presenting symptom, usually localized to side of abscess
 - Sudden worsening of headache may be due to rupture of abscess into ventricular space
 - Fever present in only half of patients and not a reliable sign
 - Seizure a common presenting feature
 - Focal neurologic findings relatively uncommon
 - Neck stiffness occurs in 15% of patients most commonly seen with occipital abscesses
 - Altered mental status and vomiting are late signs, indicating the development of elevated intracranial pressure.
- Specific presenting features correlate with abscess location
 - Frontal lobe abscesses often present with changes in personality or mental status, hemiparesis, motor speech difficulties, and seizures.
 - Temporal lobe abscesses may cause visual field defects or dysphasia if located in the dominant hemisphere.
 - Cerebellar abscesses may present with ataxia, nystagmus, and dysmetria.
 - Brainstem abscesses usually extend longitudinally, with minimal compressive effect, and therefore present with few classic features.
 - Papilledema occurs late with increased intracranial pressure.
- Imaging of the brain parenchyma diagnostic test of choice
 - LP contraindicated in patients with focal findings or papilledema
 - Should be avoided in patients with suspected brain abscess
 - CT scanning or MRI should be performed, with choice of test depending on stability of the patient and availability of imaging technique
 - Contrast CT scanning not as sensitive as MRI but more easily obtained urgently
 - MRI with gadolinium enhancement more sensitive than CT in detecting early cerebritis
 - Can more accurately estimate extent of central necrosis, ring enhancement, and cerebral edema
- MRI also better able to visualize the brainstem, cerebellum, and spinal cord and can detect lesions 1.5 cm or smaller, which the CT scan may miss
- Blood cultures should be drawn in all patients with suspected or confirmed brain abscess
- Abscess specimens obtained by stereotactic CT-guided aspiration or surgery to confirm diagnosis and guide antimicrobial therapy
- Bacterial, mycobacterial, and fungal cultures should be requested
 - Serology may be helpful for specific causes, such as *Toxoplasma gondii* and neurocysticercosis
 - In toxoplasma brain abscesses, IgG should be positive, as most infections are reactivation, not primary infection
 - Positive IgG antibody, however, does not prove *T. gondii* is the cause of a brain abscess
 - Brain biopsy may establish diagnosis but not routinely recommended
- Empiric therapy without aspiration for microbiologic samples not generally advised except in specific situations where a high likelihood of specific pathogen
 - If clinical and radiologic responses not evident within 7 and 14 days, respectively, microbiologic specimen should be obtained
- Therapy for brain abscess requires combination medical and surgical therapy for cure
- Antimicrobial therapy alone rarely effective
- Empiric therapy should be initiated after imaging confirms the presence of an intraparenchymal lesion, pending aspiration for definitive diagnosis
- Therapy directed by most likely source and respective pathogens
- Presumed otic, mastoid, sinus, or dental sources, or temporal or cerebellar abscesses
 - Third-generation cephalosporin (cefotaxime, 2 g IV every 4 hours, or ceftriaxone, 2 g IV every 12 hours) and metronidazole (15 mg/kg IV load, followed by 7.5 mg/kg IV every 8 hours)
- Suspected hematogenous spread
 - Antimicrobial with activity against *S. aureus* should be used
 - Nafcillin or oxacillin, 2 g IV every 4 hours appropriate in settings with low prevalence of methicillin resistance
 - Vancomycin, 15 mg/kg IV every 12 hours—adjusted for renal function and monitored with therapeutic drug levels—used where methicillin resistance common or in penicillin-allergic patients
 - Vancomycin penetrates CNS poorly
 - Need a trough level of 15 to 20 µg/mL
 - Metronidazole and/or a third-generation cephalosporin may be added, depending on the clinical setting
- For postneurosurgical or posttrauma patients with brain abscess:
 - Nafcillin, oxacillin, or vancomycin plus meropenem, a third-generation cephalosporin, preferably one with antipseudomonal activity such as ceftazidime, should be used
- Therapy adjusted once pathogen identification and susceptibility results are available and continued intravenously for 6 to 8 weeks
 - Guided by clinical response and serial imaging
 - Oral antimicrobial therapy for 2 to 6 months often administered

- Efficacy of this approach has not been established
- Therapy continued until complete resolution of symptoms and CT/MRI findings
- Antifungal therapy guided by fungal cultures and used in combination with surgical therapy
 - Candidal brain abscesses treated with amphotericin B and flucytosine
 - Efficacy of fluconazole not sufficiently evaluated to recommend use
 - Aspergillus brain abscesses historically treated with amphotericin B
 - Voriconazole has become treatment of choice
 - Combination antifungal therapy with voriconazole, plus either an echinocandin or an amphotericin B formulation, increasingly used
 - Cerebral zygomycosis almost invariably fatal, although amphotericin B the treatment of choice
 - Posaconazole may be alternative for zygomycoses
 - Voriconazole inactive in these cases
 - *P. boydii* demonstrates *in vitro* resistance to amphotericin B
 - Voriconazole recommended as antifungal of choice in these cases
- Neurosurgical consultation should be sought at time of diagnosis
 - Aspiration through burr hole or complete excision following craniotomy both appropriate treatment options
 - Therapeutic aspiration may be performed with CT/MRI guidance
 - Surgical excision indicated with traumatic brain abscesses, fungal abscesses, and large (>2.5 cm) or multiloculated abscesses
 - If no clinical improvement within 1 week of initiation of treatment and aspiration, mental status declines, or intracranial pressure or abscess size increases despite therapy:
 - Surgical excision also indicated
 - Antibiotic therapy may be shortened to 2 to 4 weeks following surgical excision
 - Dexamethasone should be initiated with significant edema and mass effect
 - Prophylactic antiseizure medications frequently administered
 - Poor prognostic factors in brain abscess include:
 - Rapid progression
 - Mental status or neurologic impairment on presentation
 - Rupture into a ventricle
 - Neurologic sequelae, usually seizures, occur in 30% to 60% of patients

CRANIAL SUBDURAL EMPYEMA (CSE)

Key Points

- CSE and brain abscess share epidemiologic risk factors and microbiology
- Presenting symptoms include:
 - High fever
 - Unilateral headache
 - Recent history of contiguous otic, mastoid, sinus, or meningeal infection
- MRI is the diagnostic test of choice
- Therapy should include prolonged antimicrobials and surgical drainage for cure
- CSE is an intracranial collection of pus in subdural space
 - Potentially life-threatening condition
 - Accounts for 15% to 20% of all intracranial infections
 - Universally fatal prior to antimicrobial therapy
 - Mortality with combined medical and surgical therapy now approximates 12%
 - Usually complete recovery in survivors
 - Spread of infection to subdural space occurs via emissary veins or by direct extension of cranial osteomyelitis with accompanying epidural abscess
 - Subdural space lacks septations, infection spreads rapidly and progressively
 - Most CSEs involve frontal lobe
 - But area of involvement generally related to contiguous infection
 - Cerebral edema and hydrocephalus may develop when blood or cerebrospinal flow is disrupted by increased ICP
 - Cerebral infarction may also result from septic venous thrombosis
 - Common predisposing infections include:
 - Otic and sinus infections in up to 50% to 80% of cases
 - With chronic otitis media, the middle ear and mastoids are commonly predisposing sites of infection
 - Traumatic brain injury with skull fracture
 - Neurosurgical procedures
 - Infection of a preexisting hematoma
 - Chronic pulmonary infection
 - Preceding meningitis
 - CSE invariably polymicrobial, including:
 - Streptococci, staphylococci, aerobic Gram-negative bacilli, and anaerobes
 - *S. aureus*, Enterobacteriaceae, and *Pseudomonas* more common following neurosurgical procedures or neuro-trauma
- Clinical presentation of CSE rapidly progressive; early diagnosis and treatment crucial
- Presenting symptoms generally include:
 - High fever and unilateral headache
 - History of sinusitis, otitis media, mastoiditis, meningitis, cranial surgery or trauma, sinus surgery, or pulmonary infection within 2 weeks common
 - Altered mental status present in approximately 50% of patients on admission
 - Initially characterized by confusion and drowsiness
 - Progresses to coma in most untreated cases
 - Focal neurologic signs most commonly include:
 - Hemiparesis or hemiplegia
 - Seizures develop in up to 50% of patients
 - Cranial nerve palsies
 - Homonymous hemianopsia
 - Dysarthria or dysphasia
 - Ataxia
 - Fixed, dilated pupil portends imminent cerebral herniation
 - Requires emergent surgical intervention
- Diagnosis of CSE requires high index of suspicion
 - Should be considered in patients presenting with meningeal signs and focal neurologic deficits, with or without systemic toxicity

- LP contraindicated because of risk of cerebral herniation with increased ICP
- Diagnostic imaging tests of choice are contrast CT or MRI
 - Demonstrate typical crescentic collection running parallel to cranial vault
 - Midline shift implies significant mass effect
 - Gadolinium-enhanced MRI the most sensitive, visualizing subdural empyemas too small to be detected by CT
 - MRI can also detect falcine, basal, and posterior fossa empyemas and differentiate between subdural empyemas and cystic hygromas or chronic hematomas, which CT is unable to do
 - Imaging of sinuses, middle ear, and/or mastoids performed in appropriate clinical settings to identify potential sources
- Treatment of CSE requires emergent combined medical and surgical therapy
 - Surgical drainage mandatory, as antimicrobials alone cannot effectively cure
 - Cultures required to guide antimicrobial therapy
 - Antiepileptic treatment and/or prophylaxis may be warranted
 - Standard therapy for increased ICP should be instituted
 - Empiric antimicrobial therapy initiated as soon as aspiration of empyema performed or immediately on admission in unstable patients
 - Guided by most likely source of primary infection
 - Recommended therapy includes:
 - Third-generation cephalosporin (cefotaxime, 2 g IV every 4 hours, or ceftriaxone, 2 g IV every 12 hours)
 - Or meropenem, 2 g IV every 8 hours with metronidazole (15 mg/kg IV load, followed by 7.5 mg/kg IV every 12 hours)
 - If *S. aureus* is suspected, nafcillin or oxacillin (2 g IV every 4 hours) should be used
 - Vancomycin, 1 g IV every 12 hours or 500 to 750 mg IV every 6 hours, to maximum of 2 to 3 g per day used in patients with penicillin allergy or in regions with high prevalence of methicillin resistance
 - Want serum trough level of 15 to 20 µg/mL
 - If *Pseudomonas aeruginosa* infection is suspected, ceftazidime, cefepime, or meropenem should be used in place of other third-generation cephalosporins.
 - IV antimicrobials administered for 3 to 6 weeks
 - Depends on clinical response and serial imaging
 - Therapy for 6 to 8 weeks warranted if contiguous osteomyelitis or mastoiditis is present
 - Surgical therapy of CSE includes:
 - Burr hole drainage or craniotomy
 - Debridement of necrotic bone and surgical correction of sinus and otic infections important adjuvant surgical therapies

EPIDURAL ABSCESS (EA)

Key Points

- An EA a localized collection of pus between the dura and overlying skull (cranial epidural abscess) or vertebral column (spinal epidural abscess)
- Severe symptoms may result due to compression of brain or spinal cord
- Prompt diagnosis and treatment are crucial
- Cranial EA commonly accompanied by CSE
 - Emissary veins may translocate infection across cranial dura
 - Microbiology identical to CSE (see previous section)
- Spinal EA nine times more common than cranial EA
 - Epidural space a potential space extending from foramen magnum down length of spinal canal
 - Space is larger in lumbar area and predominantly posterior
 - Most spinal EAs occur in this area
 - Spinal EA most commonly originate when intervertebral disk (diskitis) or vertebral body (osteomyelitis) become infected via hematogenous seeding
 - As abscess extends may track longitudinally in epidural space, causing damage via direct compression of spinal cord or local vascular damage (thrombosis, thrombophlebitis, vasculitis)
 - Most spinal EAs extend approximately three to five vertebral spaces
 - But can extend entire length of spinal canal
 - Risk factors for development of spinal EA includes:
 - Injection drug use
 - Diabetes mellitus
 - Bacteremia
 - Infective endocarditis
 - Chronic indwelling venous catheterization
 - Epidural catheterization
 - Decubitus ulcers
 - Chronic skin conditions
 - Paraspinal abscess
 - Back surgery
 - Lumbar puncture
 - CT-guided needle biopsies
 - Blunt or penetrating spinal trauma
 - Secondary hematogenous spread occurs in 25% to 50% of cases
 - *S. aureus* is most common pathogen isolated from spinal EAs
 - Accounts for approximately 65% of cases
 - Other implicated micro-organisms include:
 - Streptococci
 - Aerobic Gram-negative bacilli, particularly *Escherichia coli* and *Pseudomonas aeruginosa*
 - Coagulase-negative staphylococci, usually with previous spinal instrumentation
 - Anaerobes
 - Less common pathogens include *Actinomyces*, *Nocardia*, and fungi, predominantly *Candida*
 - Infections polymicrobial in 5% to 10% of cases
 - *M. tuberculosis* makes up approximately 25% of spinal EA and should be suspected in patients with previous history of tuberculosis, residence in a TB-endemic region, or other TB risk factors
- Clinical manifestations in patients with cranial EA usually insidious
 - Headache the most common presenting feature
 - Once infection spreads to involve meninges, subdural space, and brain parenchyma, focal neurologic signs and symptoms may develop
 - If abscess is located near the petrous bone, osteomyelitis of the petrous ridge may result in Gradenigo syndrome—cranial nerve V and VI palsies with unilateral pain or otalgia

- Spinal EA presents classically with:
 - Fever
 - Back pain
 - Usually first symptom
 - Neurologic deficits
 - All three symptoms present in only 13%
 - Paresthesias, motor weakness, and sensory changes occurring in affected nerve roots
 - Bladder and bowel dysfunction, as well as paralysis late signs; should prompt urgent surgical consultation
- Diagnosis of EA begins with identification of risk factors and clinical suspicion
- Routine blood work may demonstrate peripheral leukocytosis or elevated erythrocyte sedimentation rate or C-reactive protein
- MRI with gadolinium enhancement imaging modality of choice for both cranial and spinal EAs
 - CT scanning cannot visualize spinal cord adequately and less sensitive at identifying contiguous diskitis or osteomyelitis
- Blood cultures should be collected in all patients
 - Positive in 62% of patients
 - LP relatively contraindicated in setting of EA
 - CSF analysis routinely Gram stain negative
 - Cultures positive in 19% of cases
 - Highest-yield (90%) culture comes from abscess itself
 - Ultrasound- or CT-guided drainage should be performed as soon as possible
 - Bacterial, mycobacterial, and fungal cultures should be requested
 - Additional studies to diagnose active tuberculosis should be performed in patients with suspected spinal TB
 - Sputum AFB smears and cultures
 - Urine AFB culture
 - Tuberculin skin testing or QuantiFERON-TB Gold testing
- Management of EA requires combination of medical and surgical therapy
 - Empiric antimicrobial therapy for cranial EA should include third-generation cephalosporin or meropenem plus metronidazole
 - Nafcillin, oxacillin, or vancomycin may be added if *S. aureus* is strongly suspected
 - Surgical drainage is crucial for cure
 - Management of spinal EA similarly requires empiric antimicrobial therapy and surgical decompression, drainage, and debridement
 - Because of predominance of *S. aureus* infection, empiric therapy fairly targeted
 - Vancomycin if methicillin-resistant *S. aureus* likely or if patient is penicillin allergic
 - Nafcillin or oxacillin if local prevalence of methicillin resistance low
 - Surgical intervention within first 24 hours of presentation results in improved outcomes.
 - Medical therapy alone may be successful when blood or abscess aspirate cultures are available to guide therapy and there are no neurologic deficits on presentation.
 - Serial imaging required in these cases to confirm improvement in abscess size

- Surgery pursued if neurologic deterioration occurs at any time or if resolution of abscess not evident with medical therapy alone
- Therapy with antimicrobials is prolonged:
 - Usually 4 to 8 weeks
 - Guided by serial imaging to ensure complete resolution of the abscess
 - Repeat imaging occurs at approximately 4-week intervals or at any time if neurologic deterioration occurs
 - Prognosis is fair but 37% of patients experience residual neurologic deficits.
 - Degree of residual deficit affected by duration of neurologic deficit prior to surgery and diagnostic delays of >24 hours

SUPPURATIVE INTRACRANIAL THROMBOPHLEBITIS (SIT)

Key Points

- SIT is septic venous thrombosis of the cortical veins
- Occurs as complication of infections in:
 - Sinus
 - Middle ear
 - Mastoid
 - Oropharynx
 - Face
- Bacterial meningitis, EA, or subdural abscess may also result in SIT
- Absence of valves in the cerebral veins and venous sinuses aids spread of infection from proximal sites
- Location of intracranial infection depends on original source of infection
 - Bacterial meningitis, infection spread via drainage of meningeal veins into superior sagittal sinus
 - Superior sagittal sinus may also be involved following facial, scalp, subdural, and epidural space infections
 - Otitis media and mastoiditis are usual causes of lateral sinus and petrosal sinus thromboses
 - Paranasal sinus, facial, or oropharyngeal infections may result in cavernous sinus thrombosis
- Risk factors for cerebral venous stasis include:
 - Hypercoagulable states—specifically antiphospholipid antibody syndrome
 - Volume depletion
 - Polycythemia
 - Pregnancy or use of oral contraceptives
 - Malignancy
 - Sickle cell disease
 - Traumatic brain injury
- Bacterial pathogens involved in SIT depend on originating source of infection:
 - *S. aureus* commonly involved following facial infection
 - Otherwise, sinusitis and otitis media pathogens cause most infections; these include:
 - Staphylococci
 - Streptococci
 - Aerobic Gram-negative bacilli
 - Anaerobes such as *Fusobacterium* and *Bacteroides*
 - *Aspergillus* and agents of zygomycosis rarely cause SIT

- Most often seen in patients with diabetes mellitus or immune deficiencies
- Clinical manifestations of SIT depend on anatomic site(s) involved
 - Septic thrombosis of the superior sagittal sinus presents with:
 - Fever, headache, confusion, nausea, vomiting, and seizures
 - Mental status depression and progression to coma may occur rapidly
 - Upper motor neuron lower extremity weakness or hemiparesis may be present
 - When a complication of bacterial meningitis, nuchal rigidity may be present
 - Compressive cranial nerve palsies may result from increased pressure in cavernous sinus.
 - Cranial nerves III, IV, V-1, V-2, and VI, and the internal carotid artery travel through cavernous sinus
 - Classic symptoms of septic cavernous sinus thrombosis include:
 - Fever, headache, diplopia, and retro-orbital pain
 - Depending on specific nerves involved, ptosis, proptosis, chemosis, hyperesthesia, and decreased corneal reflexes may be present
 - Venous engorgement of retinal veins and papilledema are common
 - Septic transverse sinus thrombosis presents with:
 - Headache and otitis
 - SIT may also be a complication of Gradenigo syndrome, with spread of infection around the carotid sheath and surrounding venous plexus.
 - Patients with sigmoid sinus and internal jugular vein thrombosis may present with neck pain.
- Diagnosis of SIT made by MRI, demonstrating absence of flow within affected veins and venous sinuses
- MR venography or angiography used to confirm diagnosis, and sinus imaging should be concomitantly performed
- Compared to CT scanning, MRI offers additional benefits of detecting cerebritis, intracranial abscess, cerebral infarction, hemorrhage, or edema
- Despite lower sensitivity, CT scanning is commonly performed before MRI, as it is more easily obtained on an urgent basis.
- Treatment of suppurative intracranial thrombophlebitis includes:
 - Antimicrobials
 - Surgical therapy
 - Anticoagulation
 - Choice of antimicrobial therapy depends on:
 - Risk factors
 - Most probable source of infection
 - Culture results, if available
 - In antecedent sinusitis, empiric therapy with cefotaxime or ceftriaxone, and metronidazole reasonable
 - In cavernous sinus thrombosis, an agent active against *S. aureus* should be included
 - Antimicrobial therapy continued for 6 weeks or until radiographic resolution of thrombosis
 - If antimicrobial therapy is ineffective:
 - Surgical therapy may be required for drainage of infected sinuses, ligation of internal jugular vein, or for source control (e.g., oropharyngeal or dental infections)
 - Anticoagulation with heparin is beneficial in cavernous sinus thrombosis, particularly if used early, and should be strongly considered.
 - Small intracerebral hemorrhage not an absolute contraindication to heparin therapy
 - Efficacy of thrombolysis in SIT not adequately evaluated

CHAPTER 74 ■ INFECTIONS OF THE HEAD AND NECK

OTOLOGIC INFECTIONS

Otitis Externa (OE)

- Acute OE (AOE) is diffuse inflammation of the external ear canal and may also involve the pinna or tympanic membrane.
- Also known as “swimmer’s ear” or “tropical ear” due to a higher prevalence with prolonged water exposure during swimming or living in warm and humid climates
- Annual incidence of AOE is about 1:100 to 1:250 within general population
- Risk factors for AOE are:
 - Prolonged exposure to water from swimming
 - Dermatologic conditions such as seborrhea, psoriasis, eczema
 - Trauma from ear cleaning and foreign objects
 - Use of assistive devices such as earplugs or hearing aids
 - Anatomic abnormalities such as exostoses and narrow ear canals
 - Immunocompromising systemic conditions such as diabetes or human immunodeficiency virus (HIV)
 - Concomitant ear diseases such as cholesteatoma, suppurative otitis media
 - History of cancer radiotherapy
- Symptoms and signs of ear canal inflammation usually rapid onset
 - Some presenting symptoms may be:
 - Otalgia
 - Itching
 - Aural fullness
 - Decreased hearing
 - Pain with chewing
 - AOE has disproportionately severe pain and significant tenderness when pushed on the tragus or with manipulation of pinna
 - Otoscopic examination usually reveals ear canal cellulitis and edema
 - Depending on severity of ear canal swelling, tympanic membrane may or may not be visualized
 - Ear canal often filled with purulent discharge and debris
 - Regional lymphadenopathy may be present on examination
- Most cases of AOE are bacterial
 - *Pseudomonas aeruginosa* and *Staphylococcus* species the most common pathogens
 - Fungal involvement uncommon in primary AOE
 - More often seen in chronic otitis externa or as secondary overgrowth following treatment of bacterial infection
- Initial treatment of AOE involves:
 - Removal of debris from external ear canal

- Pain control
- Use of topical medications
 - If marked edema of ear canal prevents proper penetration of medicated drops into canal, placement of cotton wick directly into ear canal for several days facilitates delivery of medication
- Acidification of ear canal
- Control of predisposing factors
- Recommended topical preparations consist of antibiotics and steroid combinations
 - Quinolone antibiotic preparations may have broader microbial coverage and a low risk of contact dermatitis
 - Neomycin-containing topical preparations have potential for neomycin to cause contact sensitivity and lead to worsening of symptoms
 - Also have low risk of causing permanent sensorineural hearing loss
 - Use with caution in patients with perforated tympanic membranes
 - Acetic acid, boric acid, aluminum acetate, and silver nitrate also effective
 - In immunocompromised patients or if AOE spread beyond ear canal, consider using systemic antibiotics
 - Choice based on antipseudomonal and antistaphylococcal properties

Chronic Otitis Externa (COE)

- Persistent inflammatory disorder of ear canal
 - Usually caused by repeated mechanical debridement or water exposure
 - Other potential causes are allergic, contact dermatitis, or dermatologic disorders
 - Chronic inflammation may lead to development of granulation
- Treatment involves debridement, avoidance of ear canal manipulation, elimination of the offending agent, and topical corticosteroids
- Regular flushing of canal with mild acidic solution, acetic acid or vinegar and distilled water, can help to eradicate infection and keep canal free of debris

Otomycosis

- A fungal infection of external ear canal
 - Constitutes roughly 10% of all cases of otitis externa
 - More common in geographic locations with a warm and humid climate, in patients following long-term topical

antibiotic therapy, and in patients with diabetes, HIV, or other immunocompromising condition

- Canal will often have cellulitis and edema on otoscopic examination
- Canal debris may have cheeselike or grayish appearance with visualized fungal hyphae
- *Aspergillus* species and *Candida* species most common pathogens
- Treatment consists of debridement, acidification, and drying of the ear canal
 - For candidal infections, topical antifungal therapy may also be effective

Necrotizing/Malignant Otitis Externa (MOE)

- MOE is an aggressive infection that begins as otitis externa but spreads through surrounding tissues toward the skull base.
- Seen predominantly in the elderly, diabetic, or immunocompromised patient
- *Pseudomonas aeruginosa* the most common causative pathogen
 - Staphylococcal species also known to cause infection
 - Fungal causes less common, *Aspergillus* species the predominating pathogen
- Initially presents with AOE symptoms and signs
 - Subsequently progresses to temporal bone osteomyelitis and affects adjacent cranial nerves (VII–XII), blood vessels, and soft tissue
 - If not treated aggressively can expand intracranially
 - On otoscopic examination, granulation tissue classically seen at bony-cartilaginous junction
 - Raised erythrocyte sedimentation rate (ESR) and abnormal computed tomography (CT) or magnetic resonance imaging (MRI) helps with confirmation
 - Other imaging techniques that assist in diagnosis include:
 - Gallium scan
 - Indium-labeled leukocyte scan
 - Technetium bone scan
 - Single photon emission tomographs
- Treatment is with systemic antibiotics that cover pseudomonas and staphylococcal infection, including methicillin-resistant *Staphylococcus aureus*

Furunculosis (Ear Canal Abscess)

- A localized infection of ear canal usually caused by infected hair follicle
 - May present with otalgia, otorrhea, and localized tenderness
 - Tender, often fluctuant nodule within lateral ear canal identified on examination
 - Most common pathogen is *S. aureus*
- Treatment includes application of heat, incision and drainage of the infected area, and systemic antibiotic treatment with staphylococcal coverage

Acute Otitis Media (AOM)

- AOM an inflammation of middle ear generally characterized by rapid onset of otalgia, aural fullness, and occasionally fever
 - In pediatrics common signs are irritability, sleeplessness, and pulling at affected ear
 - On pneumatic otoscopy, the tympanic membrane (TM) has red, opaque, and bulging appearance with decreased mobility due to accumulation of purulent fluid in middle ear space
 - Erythema of TM may be noted
 - If TM is ruptured patients will present with otorrhea
- Predominant pathogens in AOM are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*
- Observation for 24 to 48 hours in case of nonsevere illness in otherwise healthy individual >6 months old an initial option
 - If symptoms persist, antimicrobial therapy initiated
 - Amoxicillin recommended for initial treatment of AOM, dose of 80 to 90 mg/kg per day
 - In penicillin allergy, azithromycin, clarithromycin, erythromycin-sulfisoxazole, or trimethoprim-sulfamethoxazole used
 - With increased incidence of β -lactamase-producing organisms
 - Bacterial coverage expanded if no improvement within 48 to 72 hours
 - Rarely if pain or fever is excessive, immediate tympanocentesis or myringotomy required
- Otitis media with effusion is a presence of fluid in middle ear without signs or symptoms of acute ear infection and should be distinguished from AOM.
- Otitis media with effusion occurs as a result of eustachian tube dysfunction or middle ear inflammation following acute infection.
 - Most common in pediatric population between ages of 6 months and 4 years
 - On pneumatic otoscopy, TM usually retracted, has decreased mobility, and air-fluid level or bubbles often visualized
 - Patients often report a decrease in hearing
- Often self-limited and likely to resolve spontaneously within 3 months
- If persistent, hearing testing is recommended, particularly in children with language delay, learning problems, or suspicion of significant hearing loss
- With persistent middle ear effusion leading to hearing loss or structural damage, myringotomy with tympanostomy tube insertion should be considered
- Decongestants not shown effective in treatment of middle ear effusion
- In adult presenting with unilateral middle ear effusion, examination of nasopharynx performed to rule out possibility of nasopharyngeal mass causing obstruction of eustachian tube.

Chronic Otitis Media (COM)

- COM diagnosed when infection persists more than 1 to 3 months
 - May present as:

- Chronic suppurative otitis media (CSOM) characterized by persistent bacterial infection and drainage from ear
- Chronic otitis media with effusion (COME) resulting from unresolving inflammation of middle ear and persistent middle ear secretions with intact TM
- COM may be associated with cholesteatoma
- Keratin cyst forming from accumulation of squamous debris in middle ear with potential for growth and erosion of surrounding structures
- CSOM will present with hearing loss, painless purulent otorrhea, and chronic TM perforation
 - Evaluation includes visual examination, bacterial culture, and radiographic imaging
 - Gram-negative and anaerobic organisms usually seen on cultures
 - *Pseudomonas aeruginosa* predominant organism
 - Temporal bone CT scan allows evaluation of extent of disease and reveals potential complications
 - Medical treatment of CSOM is topical debridement, topical and systemic antibiotics
 - Topical drops consist of antibiotic and steroid combinations
 - Ciprofloxacin recommended for systemic use
 - Cannot be given to children younger than 17 years old
 - Surgical treatment used for eradication of infection and middle ear reconstruction
- COME characterized by persistent hearing loss and middle ear space filled with thick mucus
 - Chronic inflammation of middle ear begins with obstruction of eustachian tube
 - Resulting negative pressure in middle ear leads to transudate
 - Secondary to chronic inflammation, middle ear lining becomes hyperplastic and produces further mucus
 - On examination TM intact and has thickened, opaque appearance
 - Pneumatic otoscopy shows TM not moving
 - With progression TM retracts and drapes over ossicles
 - Nasal obstruction and sinus disease may contribute to eustachian tube insufficiency and lead to middle ear fluid accumulation
 - Treatment of COME consists of fluid drainage, which is accomplished by myringotomy with ventilation tube insertion
 - Treating sinus disease and relieving nasal obstruction may improve eustachian tube function
- Untreated acute or chronic OM may lead to complications (Table 74.1).

Labyrinthitis

- Inflammation or infection of vestibular apparatus
- Patients present with vertigo, nausea, vomiting, and malaise
- Cause most often viral or traumatic but can be bacterial
 - Bacterial labyrinthitis often arises as spread of infection from meningitis or OM
 - Can be serous or suppurative
- Viral infections such as mumps, measles, Lassa fever, varicella-zoster, and herpes simplex associated with labyrinthitis

TABLE 74.1

COMPLICATIONS OF OTITIS MEDIA

Intratemporal

Tympanic membrane perforation
Mastoiditis
Petrositis
Facial nerve paralysis
Labyrinthitis
Ossicular discontinuity

Intracranial

Meningitis
Extradural abscess
Subdural empyema
Encephalitis
Brain abscess
Sigmoid sinus thrombosis
Hydrocephalus

- Labyrinthitis may or may not be associated with a sensorineural hearing loss, which can be temporary or permanent depending on cause, patient's age, and severity of loss

Bell's Palsy

- Defined as acute unilateral peripheral facial nerve weakness
 - Diagnosis made when other causes of facial nerve paralysis such as systemic diseases, infection, trauma, central nervous system disorders, and neoplasm ruled out
 - Usually present with abrupt onset of unilateral facial weakness
 - Other symptoms may include numbness or pain around ear, decreased taste, and increased sensitivity to sounds
 - Herpes simplex virus thought to be etiologic factor for disease
 - Most commonly occurs in individuals between 10 to 40 years of age
 - Pregnant women and diabetics at higher risk
 - Usually spontaneously improves within 6 months
 - Residual facial nerve weakness persists in about 15%
 - Treatment consists of early administration of high-dose prednisone and acyclovir
 - Artificial tears and protecting the eyes during sleep prevent corneal abrasion and eye infection
 - Treatment should be initiated within 72 hours of onset of symptoms

Ramsay Hunt Syndrome

- Caused by reactivation of varicella-zoster virus (VZV) in geniculate ganglion
- Associated with eruption of auricular or oropharyngeal vesicular rash, facial paralysis, and otalgia
 - Tinnitus, hearing loss, nausea, vomiting, vertigo, and nystagmus can accompany
- Patients with Ramsay Hunt syndrome present more severe symptoms and have a worse prognosis for recovery of facial nerve function relative to patients with Bell's palsy.

- Timing between onset of facial paralysis and vesicular eruption may vary.
- Some patients present with facial paralysis, have a rise in VZV antibody, but never develop cutaneous manifestations.
 - Termed *Ramsay Hunt sine herpete* and often labeled as Bell's palsy
- Initiation of early treatment with prednisone and acyclovir is currently recommended.

Chondritis/Perichondritis

- Chondritis/perichondritis of the ear is an infection of auricular cartilage/perichondrium
 - Often caused by penetrating injury to ear, particularly piercing of pinna
 - Blunt trauma with auricular hematoma can lead to infection
 - Cartilage involvement can also be seen in spreading otitis externa
 - Due to its relative avascularity, cartilage is more susceptible to infection
 - Infections are more often reported during warm weather, after exposure to water in pools, lakes, or hot tubs
- Patients present with a very tender, erythematous, and indurated auricle
 - Generally doughy on palpation and rarely fluctuant
 - *Pseudomonas aeruginosa* the most likely cause of the infection
- Treatment consists of removing foreign body and drainage of abscess or hematoma
 - Treat aggressively with antibiotics providing coverage for *Pseudomonas*
 - Cartilage necrosis or subperichondrial fibrosis, leading to auricular deformity, may be seen following infectious process.
- Recurrent auricular chondritis raises suspicion for diagnosis of relapsing polychondritis.

NASAL INFECTIONS

Septal Abscess

- Rare and is defined as collection of pus between cartilaginous (bony) nasal septum and overlying mucoperichondrium or mucoperiosteum
 - Leading cause is trauma that leads to septal hematoma
 - Also shown in association with influenza, sinusitis, nasal furuncle, and dental infection
 - Immunocompromised patients at higher risk of dangerous complications
- Patients complain of nasal congestion, nasal pain, fever, and headache
 - On examination there is evidence of anterior intranasal mass
 - The septum will appear swollen and fluctuant
- Most common causative organisms are *S. aureus* and group A β -hemolytic streptococcus
 - *Staphylococcus epidermidis*, *S. pneumoniae*, *H. influenzae*, and anaerobes possible pathogens
- Treatment involves antibiotics and surgical drainage
 - Ischemic necrosis of septal cartilage may lead to saddle nose deformity or septal perforation

- Complications may involve intracranial infections such as meningitis, brain abscess, and subarachnoid empyema.

Rhinoscleroma

- A chronic infectious granulomatous disease originates in nose but can involve any part of respiratory tract
 - More common in the Middle East, parts of Latin America, and Eastern Europe
 - Often diagnosed in young adults
- Three clinical stages are recognized:
 - The catarrhal-atrophic stage: mucosal congestion and suppurative discharge
 - The granulomatous stage: presents with epistaxis and nasal deformity and is associated with granulomatous nodules and infiltration
 - The sclerotic stage: fibrosis and stenosis develop
- Typically patients present with crusting and nodular thickening of the nasal mucosa
 - Biopsy and culture of diseased area provides diagnosis
 - Presence of *Klebsiella rhinoscleromatis* diagnostic
 - Diagnosis is usually made in the proliferation stage
 - Biopsy shows an abundance of Mikulicz cells
 - Surgical debridement, prolonged antibiotic therapy effective against disease
 - Streptomycin, tetracycline, rifampin, second- or third-generation cephalosporins, and fluoroquinolones effective
 - Treatment requires months to years, and relapses are common.
 - Patients require long-term follow-up with repeat cultures and biopsies.

Rhinosinusitis

Acute Bacterial Rhinosinusitis

- Most often develops following a viral upper respiratory infection
 - Presenting diagnostic symptoms include purulent nasal discharge; nasal congestion; maxillary, tooth, or facial pain; and worsening of symptoms following initial improvement
 - Other symptoms include general malaise and a more generalized headache, fever unusual
 - Predisposing physiologic factors include obstruction of sinus ostia, reduction in number or function of sinus cilia, and a change in the quality of secretions
- Most common pathogens are *S. pneumoniae*, *H. influenzae*, *Moraxella catarrhalis*, and *S. aureus*
 - In immunocompromised, cystic fibrosis, and sinusitis of nosocomial origin (on mechanical ventilation, with nasal tubing) patients, *P. aeruginosa* and other aerobic Gram-negative rods common causative pathogens
 - Anaerobic bacteria usually associated with sinusitis of dental origin
 - Often difficult to distinguish between viral and bacterial sinusitis
- Diagnosis usually based on medical history and clinical findings
 - Bacterial sinusitis symptoms usually present for >7 days

- Sinus puncture with aspiration of sinus contents the most accurate diagnostic technique
- Radiographic imaging may help confirm the presence of sinus disease
 - Plain films difficult to interpret
 - CT the preferred examination and findings will include thickened mucosa, sinus opacification, or air–fluid levels
 - Nasal endoscopy often demonstrates swelling within middle meatus or sphenoethmoidal recess, with purulent discharge
- Antimicrobial treatment of acute sinusitis includes amoxicillin, amoxicillin-clavulanic acid, cephalosporins, trimethoprim-sulfamethoxazole, macrolides, doxycycline, and quinolones.
 - Can be supplemented with nasal saline irrigation, antihistamines, decongestants, and intranasal steroids
 - If not treated, may be complicated by development of several orbital and intracranial complications, particularly when the infection involves the ethmoid, frontal, or sphenoid sinuses (Table 74.2).

Chronic Bacterial Rhinosinusitis

- Diagnosed when symptoms present for at least 12 weeks
- Symptoms similar to acute infection, with nasal congestion and purulent discharge predominating, sometimes associated with facial pressure, aural fullness, and anosmia
- Nasal endoscopy may reveal nasal polyps, edema, or purulent discharge
- CT findings show mucosal thickening, sinus opacification, polyps, or air–fluid levels
- Predisposing factors include smoking, inhalant allergies, obstruction of ostiomeatal complex, immune deficiency, and genetic factors.
- Pathogens are similar to those found in acute infections, greater predominance of staphylococcus, *Pseudomonas*, and possibly anaerobes.
 - Most common anaerobic bacteria include *Peptostreptococcus* species, *Fusobacterium* species, *Prevotella* and *Porphyromonas* species
- In cases of *P. aeruginosa*, aminoglycosides, fourth-generation cephalosporins, or fluoroquinolones used

TABLE 74.2

POTENTIAL COMPLICATIONS OF SINUSITIS

Acute sinusitis	
Orbital	
Periorbital cellulitis	
Orbital cellulitis	
Subperiosteal abscess	
Orbital abscess	
Optic neuritis	
Cavernous sinus thrombosis	
Intracranial	
Meningitis	
Epidural abscess	
Subdural empyema	
Brain abscess	
Chronic sinusitis	
Mucocele	
Osteitis/osteomyelitis	

- More prolonged course of antibiotic therapy may be required, from 3 to 6 weeks
- Adjunctive therapy including decongestants, mucolytics, and steroids may be helpful
- Nonresponders to medical therapy are considered for surgical drainage

Viral Rhinosinusitis

- Viral rhinosinusitis more common than bacterial
- Most common pathogens are rhinovirus, influenza viruses, adenoviruses, parainfluenza viruses, and respiratory syncytial virus
- Inflammatory symptoms of viral rhinosinusitis thought due to host response to virus
- Present with symptoms of common cold such as nasal congestion, nasal discharge, sneezing, cough, fever, malaise, and muscle ache
- Usually self-limited
- Antiviral therapy may be used for specific viruses
- Nasal saline irrigation and anti-inflammatories may aid with symptomatic relief

Fungal Rhinosinusitis

- **Acute Necrotizing Fungal Rhinosinusitis.** A fulminant invasive infection often life threatening
 - Usually affects immunocompromised patients
 - Diabetics, immunodeficiency disorders, undergoing chemotherapy, or requiring prolonged stays in intensive care unit
 - Present with acute onset of fever, headache, cough, mucosal ulcerations, and epistaxis
 - Examination shows nasal eschar spreading through mucosa, soft tissue, and bone
 - Histopathology shows necrosis and inflammatory infiltrate with giant cells, lymphocytes, and neutrophils
 - Gomori methenamine silver or periodic acid-Schiff histologic fungal stains demonstrate tissue and vascular invasion by fungal hyphae
 - Common pathogens are *Aspergillus*, *Rhizopus*, and *Mucor* species
 - Treatment involves emergent surgical debridement, intravenous antifungals such as amphotericin B, and treatment of the underlying immunocompromising disorder.
 - If not treated may lead to rapid dissemination and death
- **Chronic Invasive Fungal Rhinosinusitis.** A chronic, more indolent, and slowly invasive fungal infection
 - Usually affects immunocompromised patients
 - Also been reported in otherwise healthy individuals
 - Present with orbital apex syndrome due to the extension of the infection into orbit
 - Decreased vision, ocular immobility, and proptosis
 - Erosion may also occur into infratemporal fossa, anterior cranial fossa, or premaxillary region
 - Histopathology reveals a dense accumulation of hyphae, with a chronic inflammatory infiltrate of lymphocytes, giant cells, and necrotizing granulomas
 - Untreated may invade cerebral blood vessels, leading to ischemic injury or directly invade the brain
 - Treatment involves repeated surgical debridement and antifungal drugs

ORAL CAVITY

Gingivitis

- Affects 50% to 90% of adult population
 - Caused by oral microflora in accumulating dental plaque
 - Usually contains both aerobic and anaerobic bacteria
- A reversible disease
 - Chronic gingivitis leads to bleeding of gums during tooth brushing
 - May progress to periodontitis, leading to loss of supporting connective tissue and alveolar bone
 - This is nonreversible and may lead to loss of involved teeth
- Treatment involves good oral hygiene and mechanical removal of plaque and calculus

Acute Necrotizing Ulcerative Gingivitis (Trench Mouth)

- A rare periodontal disease characterized by gingival necrosis, ulceration, pain, and bleeding
- Most commonly seen in young adults with sudden onset of gingival inflammation
- Gingival lacerations covered with gray membranes and gingival bleeding noted
- Causative organisms are fusospirochetal bacteria, pathogenic with compromised immune system function
 - *Bacteroides* and *Selenomonas* species also implicated
- Diagnosis is based on clinical findings
- Risk factors include dental crowding, physical fatigue, increased stress, low socioeconomic status, immunosuppression, smoking, and poor oral hygiene
- Treatment includes eliminating precipitating factors, treatment of underlying immunosuppression, oral hygiene, mechanical debridement of affected areas, and antibiotics
 - Penicillin or metronidazole is recommended for antibiotic treatment

Herpetic Gingival Stomatitis

- An infection due to herpes simplex virus
 - Most commonly manifests in children between the ages of 2 and 5 years
 - Present with fever and irritability, oropharyngeal pain, mucosal edema, and erythema
 - Vesicular lesions appear on mobile or nonkeratinized mucosal surfaces (buccal, labial) and attached or keratinized surfaces (gingiva, hard palate).
 - Usually rupture within 24 hours, leaving small ulcers with an elevated margin
- Diagnosis confirmed by viral studies and biopsy
- Treatment usually supportive, although acyclovir may shorten severity and duration

Herpangina

- Disease that commonly occurs in children
 - Coxsackie A virus most common causative organism
 - Present with fever, malaise, and sore throat
 - On examination oropharyngeal erythema noted

- Vesicles and small ulcers present on the posterior pharynx, often on the uvula and soft palate
- Course usually self-limiting

Candidiasis

- Caused by overgrowth of *Candida albicans*
- Often patient predisposed, with a history of immunosuppression, radiation, or altered microflora following long-term broad-spectrum antibiotic use
 - Pseudomembranous form, yellow-white plaques are present likened to milk curds
 - Erythematous form, these plaques have disappeared
 - Diagnosis confirmed with potassium hydroxide staining revealing fungal hyphae
- Initial therapy usually consists of oral hygiene and topical treatment
 - Oral nystatin preparations, amphotericin lozenges, and clotrimazole troches
 - Ketoconazole, fluconazole, or itraconazole used for systemic treatment if indicated

Odontogenic Infections

- Originate from infected pulp and may spread to fascial spaces of head and neck where abscess may form
 - Most common causative organisms *S. aureus*, group A streptococci, and anaerobic bacteria
- Treatment with broad-spectrum antibiotics recommended

Ludwig's Angina

- Infection involving left and right sublingual and submandibular spaces
 - Most often seen in adults with poor dentition, usually from infection involving second or third molar
 - Other sources include inflammation of tongue or floor of mouth and lingual tonsillitis
- Present with submandibular swelling but not fluctuance
 - Swelling of floor of mouth pushing tongue upward/backward toward palate
 - In advanced disease, may present in acute distress with fever, difficulty handling secretions, and dyspnea that favors a seated and head forward position
- Can be rapidly progressive, leading to airway compromise
- Anaerobic organisms and streptococci most common causes
- Treatment requires close airway monitoring with prophylactic tracheotomy in most cases for airway protection, administration of antibiotics, and surgical drainage

PHARYNX

Tonsillitis/Pharyngitis

- Common disease characterized by infection of the nasopharynx and oropharynx and associated lymphoid tissue
 - Acute tonsillopharyngitis caused by viral or bacterial infection; virus most common
 - Often difficult to distinguish between a bacterial and viral cause

- Present with fever, malaise, odynophagia, and lymphadenitis
- Examination shows tonsillar enlargement, erythema, and exudate
- Upper respiratory viruses such as rhinovirus, coronavirus, and adenovirus most common
- Most common cause is group A β -hemolytic streptococci (GABHS)
 - Diagnosed by performing a group A streptococcus test
 - Other pathogens associated with disease such as *M. catarrhalis*, *H. influenzae*, *S. aureus*, and *S. pneumoniae*
 - Diphtheria and gonococcal infections should also be considered
- Penicillin, amoxicillin, erythromycin, or first-generation cephalosporins recommended for treatment
 - Recommended to perform group A streptococcus test prior to initiation of antimicrobials
 - Untreated may lead to complications that can be suppurative and nonsuppurative
 - Nonsuppurative include scarlet fever, acute rheumatic fever, and poststreptococcal glomerulonephritis
 - Suppurative complications include peritonsillar, parapharyngeal, and retropharyngeal cellulites and/or abscess
 - Recurrent infections unresponsive to antimicrobials might require tonsillectomy

Peritonsillar Abscess

- The most common deep infection of the head and neck
 - Occurs as complication of bacterial tonsillitis or infrequently infectious mononucleosis
 - Most commonly diagnosed in adults or adolescents
 - Present with increasing pharyngeal pain, dysphagia, trismus, dysarthria, drooling, and muffled voice
 - Clinical examination reveals trismus, peritonsillar bulging that displaces the soft palate medially, and uvular deviation toward opposite side
 - Often see tonsillar exudates and tender cervical lymphadenopathy
 - Usually polymicrobial, with group A streptococci and anaerobes the most common pathogens
 - Diagnosis usually made on physical examination
 - CT scan may help if diagnosis uncertain
 - Treatment involves aspiration or incision and drainage of the abscess along with antibiotic therapy
 - If recurrent, a tonsillectomy indicated
 - Peritonsillar space infection has potential for spreading to parapharyngeal space, manifestations of which may be delayed

Lemierre Syndrome

- Described as presence of oropharyngeal infection, sepsis, internal jugular vein thrombosis, and septic emboli caused by *Fusobacterium necrophorum*
 - A Gram-negative anaerobic organism part of normal human oropharyngeal, gastrointestinal, or genitourinary flora
 - Disease rather uncommon due to the availability of antibiotics

- Most often affects young adults with recent history of oropharyngeal, tonsillar, or peritonsillar infection
- Present with tenderness and swelling of the lateral neck, secondary to thrombophlebitis of the internal jugular vein
- Septic emboli may spread and affect other organs, especially the lungs
- Requires immediate antibiotic treatment with clindamycin, metronidazole, ampicillin-sulbactam, or ticarcillin-clavulanate for period of at least 6 weeks
- In case of abscess formation, surgical drainage might be required
- Rarely ligation or excision of the jugular vein might be indicated

Infectious Mononucleosis

- A systemic disease caused by Epstein-Barr virus (EBV)
 - Most commonly occurs in teenagers and young adults
 - Transmitted through saliva
 - Present with fever, fatigue, malaise, sore throat, generalized nontender lymphadenopathy
 - On examination see inflamed tonsils with exudate
 - Hepatosplenomegaly may also be present
 - Diagnosis confirmed by the presence of atypical lymphocytes on peripheral smear, a positive monospot test, and positive EBV titers
- Treatment of mononucleosis supportive
 - Corticosteroids used to decrease inflammation, particularly where airway obstruction a concern
 - In severe cases of airway obstruction, a secure airway indicated
 - Patients develop a rash if treated with amoxicillin for presumed bacterial tonsillitis; thus administration of amoxicillin should be avoided

LARYNX/AIRWAY

Supraglottitis/Epiglottitis

- An infectious disease of epiglottitis and supraglottitis, most commonly bacterial in origin
 - Usually sudden onset, with high fever, pain with swallowing, drooling due to difficulty handling secretions, and respiratory distress
 - On presentation patient often found sitting in hunched-forward position with extended neck and open mouth (sniffing position)
 - Lateral neck film, edema of epiglottitis and a ballooning of the hypopharynx (thumb sign) noted (Fig. 74.1)
 - Epiglottitis will appear erythematous (cherry-red) and swollen on direct examination
 - Airway manipulation may quickly precipitate complete airway obstruction
 - *H. influenzae* type b used to be most common causative agent
 - With the vaccine incidence of *H. influenzae*-related epiglottitis significantly decreased
 - Currently *S. pneumoniae*, group A β -hemolytic streptococci the most common causative agents

FIGURE 74.1. Lateral plain neck radiograph demonstrating edema of the epiglottis associated with epiglottitis.

- Considered emergency as it has potential for rapid complete airway obstruction, particularly in children
- When diagnosed, a secure airway should be established via endotracheal intubation or tracheostomy.
- Decision to extubate or decannulate based on clinical improvement
- Treatment with intravenous ceftriaxone or ampicillin/sulbactam, and steroids
- Adults may present with supraglottitis where epiglottitis not involved
 - Here the airway can be managed conservatively, although close in-hospital observation required

Laryngitis

- Acutely most often occurs as part of upper respiratory infection, usually caused by rhinovirus
- Laryngoscopy reveals diffuse laryngeal erythema and edema
- Treatment often supportive: voice rest, humidification, and anti-inflammatory medications

Croup

- An inflammatory disease of subglottic airway
- Almost always associated with parainfluenza and influenza viruses
- Most commonly occurs in pediatric population between the ages of 1 and 3 years
- Present with fever, tachypnea, inspiratory stridor, hoarseness, and a barking cough
- History often includes a preceding upper respiratory infection

- Patients require close observation and sometimes establishment of a secure airway
- Glucocorticoids recommended to decrease airway inflammation
 - Racemic epinephrine treatments often helpful
- When recurrent, airway evaluation with laryngoscopy and bronchoscopy recommended to assess for anatomic abnormalities

Diphtheria

- An infectious disease of the upper airway
- Caused by *Corynebacterium diphtheriae*
- Rather rare due to widespread immunization
- Present with fever and malaise
 - Bloody nasal discharge and pseudomembranes in nose, oropharynx, and larynx noted on examination
 - Membranes may lead to airway obstruction and respiratory failure
- Exotoxins produced by bacteria may affect heart, liver, kidney, and brain
- Diagnosis confirmed by bacterial smear and cultures on Löffler or tellurite media
- Treatment consists of ensuring secure airway, administration of antitoxin, and antibiotics
 - Penicillin or erythromycin recommended

Bacterial Tracheitis

- A rare, potentially life-threatening respiratory infection
- Characterized by presence of thick membranous tracheal secretions that do not readily clear with coughing and may lead to occlusion of airway
- Present with fever, cough, stridor, and generalized malaise
- Does not respond to racemic epinephrine treatment
- Radiographically irregular tracheal margins with a normal-appearing epiglottis
- Diagnosis made with direct visualization of thick membranous tracheal secretions or the presence of purulent tracheal secretions in glottis and subglottis
- Most commonly isolated pathogen is *S. aureus*
 - Other pathogens include *H. influenzae*, *S. pneumoniae*, *Streptococcus pyogenes*, *M. catarrhalis*, *Klebsiella*, and *Pseudomonas* species
- Treatment consists of securing airway, endoscopically removing tracheal membranes, and administration of antibiotics

NECK

Salivary Gland Infections

Viral Infections

- **Mumps.** A viral infection caused by paramyxovirus; the most common viral infection involving salivary glands
- Other viruses that infect salivary glands are coxsackie A, echovirus, choriomeningitis, parainfluenza type 1 and 3, and cytomegalovirus
- Patients display signs of fever and malaise

- Painful parotid swelling occurs within 24 hours; is often bilateral
 - May experience pain with salivation
- 10% of patients have submandibular gland involvement
- 25% of affected adolescent or adult males develop orchitis
 - 5% of females present with oophoritis
- Mastitis, pancreatitis, and central nervous system involvement may also occur in affected individuals.
- Mumps infection can also lead to sensorineural hearing loss.
- Treatment usually supportive
- In children the disease has a less severe course than in adults

Bacterial Infections

- Often develop following salivary stasis, secondary to ductal obstruction by a stone or mass, or a decrease of salivary flow secondary to dehydration
- Most common causative pathogens are *S. aureus* and *Streptococcus viridans*
- Parotid gland affected more often, likely due to lower bacteriostatic activity of saliva from this gland compared to submandibular or sublingual glands
- Present with pain, swelling, and erythema in the region of the salivary gland
 - Exacerbated by eating
- Also have fever, malaise, and an elevated white blood cell count
- Treatment involves hydration to increase salivary flow, massaging affected gland, sialogogues, and administration of anti-staphylococcal antibiotics
 - Chronic/recurrent disease, removal of obstruction or excision of gland recommended

Lymphadenitis

- An inflammatory process involving lymph nodes
- Pediatric group more commonly affected
 - Upper respiratory viral infections the most common cause of cervical lymphadenopathy
 - Condition is self-limited and usually does not require treatment
- Bacterial lymphadenitis occurs as complication of skin or respiratory infection
 - Most common causative organisms are *S. aureus* and group A streptococci
 - Present with tender lymphadenopathy, may progress to abscess formation
 - Treatment with β -lactamase-resistant antibiotics is recommended
 - With progression to abscess formation, incision and drainage indicated

Catscratch Disease

- Usually presents with subacute solitary or regional lymphadenopathy in patients with a previous contact with a kitten or cat
 - Primarily caused by *Bartonella henselae*
 - Cases of *Bartonella clarridgeiae* and *Bartonella elizabethae* reported
- Lymphadenopathy occurs 1 to 3 weeks after a scratch, bite, or other contact
 - Small red-brown nontender papules develop at inoculation site 3 to 30 days after contact

- Lymph nodes draining affected site gradually enlarge; are moderately tender
 - Overlying skin appearing warm and erythematous
- Up to 10% of lesions may require surgical drainage
- Indirect fluorescent antibody test and enzyme immunoassay are used for detection of specific serum antibody to *B. henselae*

Mycobacterium

- Nontuberculous mycobacterial infection a rare cause of lymphadenitis
 - Presents as a slowly enlarging, nontender cervical mass
- Can affect adults; most commonly found in children younger than 5 years of age
- Often diagnosed after failure to respond to treatment with antibiotics
- Most common causative pathogen is *Mycobacterium avium-intracellulare*
 - Other reported pathogens are *M. scrofulaceum*, *M. kansasii*, *M. fortuitum*, and *M. malmoense*
- Intradermal purified protein derivative (PPD) test aids in diagnosis of nontuberculous lymphadenitis
 - Positive cultures more definitive
 - Complete surgical resection of infected tissues the gold standard for treatment
 - Treatment with antituberculous medications, such as macrolides (clarithromycin), shown to be effective in some cases
 - Antibiotic therapeutic trial prior to surgical excision or as an adjunct to surgical excision appropriate

Actinomycosis

- Infection caused by *Actinomyces israelii*, a Gram-positive anaerobic bacterium
 - Has multiple presentations and often misdiagnosed
- Most infections occur in head and neck region (>50%)
 - Most often entering the tissue through an area of prior trauma
 - As infection develops, patients noted to have a woody induration
 - Eventually leads to central abscess formation
 - Abscess generally tracks to mucosal surface or externally to skin, forming sinus or fistulous tract
 - Suppurative drainage contains so-called sulfur granules, yellow flecks containing the bacterial colonies
 - Diagnosis best made by culture
 - But may have to rely on the clinical picture and histology
 - Organisms stain best with Gram and Gomori methenamine silver stains
 - Treatment is drainage and debridement of infected area with administration of penicillin.

Deep Neck Space Infections

Retropharyngeal Space Abscess

- Infection usually develops from infected retropharyngeal lymph nodes
 - More common in children
 - Trauma is another common cause

- Present with fever, pain with swallowing, decreased oral intake, drooling, malaise, and torticollis
 - Trismus and neck swelling often present
 - Most common causative organisms are *S. pyogenes* and anaerobic bacteria
 - Lateral radiographic images of neck in extension show thickened prevertebral soft tissue
 - CT aids in determining presence of an abscess
 - Therapy involves administration of intravenous antibiotics and drainage of abscess
 - Transoral drainage recommended unless extension lateral to great vessels (i.e., the carotid artery)
 - Untreated, spontaneous rupture of abscess may lead to aspiration of infectious material
 - Spreading to parapharyngeal and prevertebral spaces, leading to mediastinitis, or involve the great vessels

Parapharyngeal Space Abscess

- Pharyngeal infections, molar tooth infections, gingivitis, mastoiditis may spread to parapharyngeal space
- Untreated, infection may spread to retropharyngeal space, mediastinum, and involve great vessels causing internal jugular thrombosis and erosion of internal carotid artery
- Present with a prior history of a sore throat or tooth infection
 - Initial symptoms are fever and pain with swallowing
 - Tender, erythematous swelling at angle of mandible and parotid typically found
 - Does not appear fluctuant even if abscess present
 - Examination of pharynx often shows medial displacement of ipsilateral tonsil
 - Trismus may develop; torticollis toward opposite side often results from inflammation of lymph nodes under sternocleidomastoid muscle
 - Patients may also complain of otalgia; airway compromise may occur
- Most common causative pathogens are *S. aureus*, *S. pyogenes*, and anaerobic bacteria
 - CT aids in evaluation of site and extent of infection, distinguishing between cellulitis and abscess
- Require immediate treatment with intravenous antibiotics and surgical drainage if abscess present

CHAPTER 75 ■ CATHETER-RELATED BLOODSTREAM INFECTIONS (CRBSI)

- Intravascular devices are a ready conduit for bacterial and fungal invasion, resulting in catheter-related bloodstream infections (CRBSI). (Table 75.1)
- Can be complicated by:
 - Septic thrombophlebitis
 - Infective endocarditis
 - Other metastatic infections, such as lung abscess, brain abscess, and endophthalmitis
- The most common cause of hospital-acquired infections in the critically ill.
 - >80,000 CRBSIs are estimated to occur annually in ICUs in the United States.
 - Attributable mortality ranging from 12% to 25%
 - 9,600 to 20,000 patients die from CRBSI in ICUs annually.
 - Added cost ranges from \$28,690 to \$56,167 per individual episode in ICU patients.
 - Immunocompromised hosts with central venous catheters (CVCs) in place are also at significant risk.
- Organisms migrate along catheter's external surface, through the subcutaneous layers, and infect the catheter tip.
- For long-term catheters—the cuffed, tunneled, silicone catheters, Hickman or Broviac—or implantable devices
 - Lumen of the hub or belt of the port is primary source of entry.
- Microorganisms are introduced via the hands of medical personnel while manipulating the hub during, for example, flushing and drawing of blood.
- Colonization is universal after insertion of a CVC, can occur as early as 1 day after insertion, **and is quantitatively independent of a catheter-related infection.**
- These sources explain the prevalence of primary organisms causing CRBSI:
 - *Staphylococcus aureus*
 - Coagulase-negative *Staphylococcus* (CNS)
 - Enterococci
 - Nonenteric hospital-acquired gram-negative bacilli
 - *Stenotrophomonas maltophilia*
 - *Pseudomonas aeruginosa*
 - *Acinetobacter* spp.
 - Mycobacteria
 - *Candida* spp.
- Secondary seeding of the CVC
 - Whereby organisms become bloodborne and colonize the catheter, has been suggested

PATHOGENESIS

- First step in primary infection is the colonization of the CVC.
 - For short-term, nontunneled, noncuffed, multilumen catheters—which make up 90% of CRBSIs—the skin insertion site is the source of the colonization.

TABLE 75.1

DEFINITIONS OF CATHETER-RELATED BLOODSTREAM INFECTIONS

PROBABLE CRBSI

- Clinical manifestations of infection (fever $>38^{\circ}\text{C}$, chills/rigors, or hypotension)
- No apparent source of the sepsis/bloodstream infection other than the catheter
- Common skin organisms (e.g., coagulase-negative staphylococci) isolated from two blood cultures from patients with intravascular device or a known pathogen (*Staphylococcus aureus* or *Candida*) isolated from a single blood culture

DEFINITE CRBSI

Probable CRBSI criteria outlined above with any of the following:

- Differential quantitative blood cultures with 5:1 ratio of the same organism isolated from blood drawn simultaneously from the central venous catheter (CVC) and peripheral vein

OR

- Differential positivity time (positive result of culture from a CVC is obtained at least 2 h earlier than positive result of culture from peripheral blood)

OR

- Positive quantitative skin culture whereby the organism isolated from an infected insertion site is identical to that isolated from blood

OR

- Isolation of the same organisms from the peripheral blood and from a quantitative or semiquantitative culture of a catheter segment or tip

- To the point of recommending treatment of urinary tract infections *prior* to CVC insertion to prevent a potential CRBSI
- Role in CRBSI has not been documented.
- Contamination of the infusate or additives, such as contaminated heparin flush, is a rare cause of colonization and infection of the vascular devices.
- Nationwide outbreaks of *Enterobacter agglomerans* and *Enterobacter cloacae* in 1971 led to widespread changes and surveillance.
- Nutritional components present in the total parenteral nutrition promote the growth of certain fungi such as *Candida parapsilosis* and *Malassezia furfur*, as well as bacteria such as *Klebsiella pneumoniae* and *E. cloacae*
- Second step in the pathogenesis of CRBSI
 - Ability of some microbes to form a biofilm of extracellular, polysaccharide-rich, slimy material
 - Promotes adhesiveness of bacteria to the surface of CVC
 - Form on the external surface of short-term catheters and the internal surface of long-term catheters—that is, those with a dwell time of at least 30 days
 - Enables bacteria not only to adhere to the surface of the catheter, but also to resist antibiotics, such that “chronic” biofilm eradication becomes a difficult task
 - Another factor promoting adherence is thrombin layer that covers both surfaces of a catheter during its insertion.

- Composition of the host’s blood components enables *S. aureus*, for example, to adhere to fibrinogen, coagulase-negative *Staphylococcus* (CNS) to fibronectin, and *Candida* spp. to fibrin

- Other factors could also potentiate the risk for a CRBSI, including:

- Femoral catheterization
 - Associated with a higher rate of infections and thrombotic complications when compared to subclavian catheterization in a prospective randomized, controlled trial involving ICU patients
- Transparent occlusive dressings associated with significantly increased rates of insertion site colonization ($p < 0.001$) in patients having CVCs for more than 3 days when compared to gauze dressing
- Explained by the warm atmosphere created by occlusive dressings, which promoted microbial growth

CLINICAL MANIFESTATIONS

- Clinical manifestations of CRBSIs can be divided into two categories: local and systemic.

- Local manifestations include:

- Erythema
- Edema
- Tenderness
- Purulent discharge
- These are neither sensitive nor specific, and cannot be relied on to identify catheter colonization or CVC-related bloodstream infection
- Peripherally inserted central catheters (inserted in the basilic or cephalic veins) are associated with a 26% rate of sterile local exit site inflammation secondary to irritation of small veins
- CNS, the most frequent pathogen involved, incites little local or systemic inflammation
- The Centers for Disease Control and Prevention suggested the following definitions:
 - **Exit-site infection:** Purulent drainage from the catheter exit site, or erythema, tenderness, and swelling within 2 cm of the catheter exit site, and colonization of the catheter if removed
 - **Port-pocket infection:** Erythema and/or necrosis of the skin or subcutaneous tissues either over or around the reservoir of an implanted catheter, and colonization of the catheter if removed
 - **Tunnel infection:** Erythema, tenderness, and induration of the tissues above the catheter and more than 2 cm from the exit site, and colonization of the catheter if removed

- The systemic features of CRBSIs:

- Generally indistinguishable from those of secondary bloodstream infections arising from other foci of infection
- Include
 - Fever and chills
 - May be accompanied by:
 - Hypotension
 - Hyperventilation
 - Altered mental status
 - Nonspecific gastrointestinal manifestations such as:
 - Nausea
 - Vomiting

- Abdominal pain
- Diarrhea
- Deep-seated infections such as endocarditis, osteomyelitis, retinitis, and organ abscess may complicate CRBSIs
 - Caused by some virulent organisms such as *S. aureus*, *P. aeruginosa*, and *Candida albicans*.

DIAGNOSIS

- Clinical diagnosis of CRBSI is frequently inaccurate
- Removal of the CVC had previously been mandatory to prove the CRBSI
- Microbiologic methods requiring removal of the CVC were studied with semiquantitative roll plate catheter cultures
 - Considered the gold standard
- Majority of the catheters were removed unnecessarily
 - There are different methods used for the microbiologic diagnosis of CRBSI (Table 75.2)

Catheter-sparing Diagnostic Methods

Simultaneous Quantitative Blood Cultures

- Consists of obtaining paired quantitative blood cultures (QBCs) simultaneously from the CVL and peripheral vein
- Both samples drawn <10 minutes apart **with the same volume of blood**
- Hypothesis is that higher load of organisms on the internal lumen of CVL signifying CRBSI would translate into a colony count from CVL greater by manyfold than the peripheral stick.

TABLE 75.2

SENSITIVITY AND SPECIFICITY OF TESTS USED IN THE DIAGNOSIS OF CRBSI^a

Diagnostic tests	Sensitivity	Specificity
Paired quantitative blood cultures	75%–93%	97%–100%
Differential time to positivity		
Short-term CVCs	89%	87%
Long-term CVCs	90%	72%
Acridine orange leukocyte cytopsin technique	87%	94%
Semiquantitative culture of catheter tip (roll-plate technique)		
Short-term CVCs	84%	85%
Long-term CVCs	45%	75%
Quantitative catheter culture		
Short-term CVCs	82%	89%
Long-term CVCs	83%	97%

CRBSI, catheter-related bloodstream infection; CVC, central venous catheter.

^aThe data on the sensitivities and specificities are based on a meta-analysis of diagnostic methods by Safdar N, Fine JP, Maki DG. Meta-analysis: methods for diagnosing intravascular device-related bloodstream infection. *Ann Intern Med.* 2005;142[6]:451–466.

- CVL/peripheral ratio of CFU/mL of 5:1 has been chosen by the Infectious Diseases Society of America to represent true infection—this is what we use.
- Multiple cutoffs have been used, including 2:1, 3:1, 4:1, 5:1, and 10:1.
- Meta-analysis found that quantitative blood culture is the most accurate.
 - Sensitivity of 75% to 93%
 - Specificity of 97% to 100%
 - Recommended culturing *only* if CRBSI is suspected clinically
- Method is limited by the fact that it is expensive and labor intensive, in addition to the difficulty in obtaining samples through the catheter in some cases.

Differential Time to Positivity

- Differential time to positivity (DTP) of qualitative paired CVC and peripheral blood culture is a more practical test for centers that lack the logistics for QBCs.
- Hypothesis suggests that time to positivity of a culture is closely related to the inoculum size of microorganisms.
- Technique involves measuring the difference between the time required for culture positivity in simultaneously drawn samples of catheter blood and peripheral blood.
- DTP of 120 minutes was associated with:
 - 81% sensitivity and 92% specificity for short-term catheters
 - 93% sensitivity and 75% specificity for long-term catheters
- Meta-analysis showed that the DTP of 120 minutes predicts CRBSI
 - Sensitivity and specificity of 89% and 87% for short-term catheters
 - Sensitivity and specificity of 90% and 72% for long-term catheters
- Technique also demands a simultaneous blood draw (within 10 minutes) from CVL and peripheral vein **with the same amount of blood**.
- Limitation is that sensitivity could be compromised when antibiotics are given intraluminally at the time of drawing the blood cultures through the catheters.

Acridine Orange Cytopsin Technique

- Test involves 1 mL of ethylenediaminetetraacetic acid (EDTA) blood aspirated through CVL.
 - The sample is added to 10% formalin saline solution for 2 minutes.
 - Then centrifuged, supernatant decanted, and the cellular deposit homogenized and cytocentrifuged
 - Monolayer is stained with 1 in 10,000 acridine orange staining and viewed by ultraviolet light.
 - Positive test is indicated by the presence of any bacteria.
- Method is expensive but takes 30 minutes.
 - Sensitivity of 87% and specificity of 94%
 - Technique only tested by a small group of investigators and is not easy to perform

Catheter-drawn Quantitative Blood Culture

- Method includes a single quantitative blood culture drawn through CVL.
 - Cutoff of 100 CFU/mL establishes the diagnosis.
 - Sensitivity of 81% to 86%, specificity of 85% to 96%
 - In pediatric cancer population, the technique showed a sensitivity of 75% and a specificity of 69%.

- Positive predictive value of 79%
- Likelihood ratio of 2.44
 - Odds of having a true CRBSI with the >100 CFU/mL cutoff increase by 2.44 when compared to <100 CFU/mL.
- Major drawback to technique is that it cannot distinguish between CRBSI and high-grade bacteremia, especially in immunocompromised patients.

Diagnostic Methods Requiring Catheter Removal

Semiquantitative Roll-plate Catheter Culture

- Described by Maki in 1977 and remains the international reference diagnostic method
- Consists of rolling a 3- to 5-cm section of the distal tip of the CVL at least four times back and forth over an agar plate surface and leaving it to incubate overnight
- Cutoff of ≥ 15 CFU defines catheter colonization.
- If at the same time a peripheral culture grows with same organism, CRBSI is diagnosed.
- Method does not sample the internal lumen of CVL.
 - Source of the infection in long-term catheters
- Nevertheless, pooled sensitivity and specificity in 14 trials involving short-term catheters was 84% and 85%, respectively.
 - Decreased to 45% and 75%, respectively, with long-term CVLs
 - Those with more than 30 days of dwell time

Quantitative Catheter Cultures

- Involves flushing or sonicating a catheter segment in broth with the target of retrieving organisms from both surfaces of CVL
- Threshold of $\geq 1,000$ CFU correlated best with colonization.
- CRBSI defined by same cutoff
 - Accompanied by high clinical suspicion and absence of evidence of other sites of infection
- Sonication method had a higher sensitivity than the roll-plate method for long-term CVLs
- Both sonication and vortexing had the same sensitivity and specificity of the roll-plate method for short-term CVLs.
 - Meta-analysis revealed:
 - Sensitivity and specificity of 82% and 89% for short-term catheters
 - Sensitivity and specificity of 83% and 97% for long-term catheters

Stain and Microscopy Rapid Diagnostic Techniques

- Method suggests staining of the removed catheter segments and subsequent microscopy testing.
 - Cutoff value of 1 organism per 20 oil immersion fields indicates catheter is colonized.
 - Reported 100% sensitivity, 97% specificity
 - Positive predictive value of 84%, and a negative predictive value of 100%
 - Not reproduced in another study
- In a similar technique, acridine orange staining has been used for diagnosis, in which fluorescence is indicative of positivity.
 - Sensitivity of 84% and a specificity of 99%

- Acridine orange staining is more easily performed than Gram staining.

PREVENTIVE STRATEGIES

- CVLs should only be used when medically necessary, and they should be removed as soon as possible to prevent potential complications.
- Reviewing 1,981 ICU months of data, collective antiseptic measures consisting of:
 - Hand washing
 - Maximal sterile barriers during insertion
 - Cutaneous antisepsis with Chlorhexidine
 - Avoidance of femoral site
 - Removal of CVCs determined to be unnecessary were associated with a significant decrease in CRBSI rate
 - From 7.7 per 1,000 catheter-days to 1.4 per 1,000 catheter-days ($p < 0.001$) over 18 months of follow-up
- When CVLs or pulmonary artery catheters were changed/exchanged over guidewire every 3 days
 - Former procedure resulted actually in an increase in the risk of mechanical complications
 - Latter technique increased the risk of bloodstream infection
- Preventive strategies to decrease colonization risk of CVLs are noted in Table 75.3.
- Novel strategies aiming at controlling all factors that could lead to colonization of CVL, and hence decreasing the rate of CRBSI have been reviewed and are noted in the following text.

Cutaneous Antiseptics

- Guidelines recommend with level 1A evidence usage of 2% chlorhexidine (CHX)-based preparation
- Prospectively randomized study of 68 ICU patients to 10% povidone-iodine, 70% alcohol, or 2% aqueous chlorhexidine to disinfect the site before insertion of CVCs and for site care every other day thereafter
 - 2% aqueous chlorhexidine preparation tended to decrease rate of CRBSI.

TABLE 75.3

PREVENTIVE MEASURES TO DECREASE THE RISK OF COLONIZATION OF CENTRAL VENOUS LINES

- Hand hygiene
- Avoiding femoral site insertion if possible
- Removing unnecessary catheters
- Cutaneous antiseptic agents (2% chlorhexidine-based preparation)
- Maximal sterile barrier (handwashing, sterile gloves, large drape, and sterile gown, mask, and cap)
- Antimicrobial catheter lock solutions (a combination of an anticoagulant like heparin or ethylenediaminetetraacetic acid plus an antimicrobial agent, such as vancomycin, minocycline, or ciprofloxacin)
- Antimicrobial coating of catheter (with minocycline/rifampin or chlorhexidine/silver sulfadiazine)

- Lower concentrations of CHX decreased the effectiveness of this method.
 - Tincture of chlorhexidine gluconate 0.5% no more effective in preventing CRBSI or CVL colonization than 10% povidone-iodine,
- Meta-analysis of eight randomized trials found overall reduction of 49% in CRBSIs when disinfectant containing chlorhexidine was used.

Maximal Sterile Barrier

- Involves wearing a sterile gown, gloves, and a cap and using a large drape similar to those used in the operating room during catheter insertion
- As opposed to the regular precautions consisting of sterile gloves and a small drape only
- Healthcare Infection Control Practices Advisory Committee/Centers for Disease Control and Infection guidelines recommend this technique while inserting CVLs, PICC lines, and pulmonary artery catheters (category 1A).
- Prospective study with long-term, nontunneled silicone CVLs and PICC lines in a cancer patient population demonstrated:
 - Reduction of CRBSIs ($p = 0.03$)
 - Practice was cost effective
- Another prospective study with pulmonary artery catheters found less stringent barrier precautions associated with significantly increased risk of CRBSI (relative risk = 2.1, $p = 0.03$).
- Technique failed to reduce arterial catheter-related colonization.

Antimicrobial Catheter Lock Solutions

- Antimicrobial catheter lock involves flushing catheter lumen and then filling with 2 to 3 mL of a combination of an anticoagulant plus an antimicrobial agent.
- Dwell (lock) time varies between clinicians, but 20 to 24 hours is the most preferred.
 - Might not be possible if catheter has to be used
- Intervention often used in CVLs that remain in place longer than 30 days
 - Combination of vancomycin and heparin, with or without ciprofloxacin, was equivalent
 - Each was superior to heparin alone.
 - Heparin prevents formation of fibrin sheath on inner surface of line
- Four of six studies revealed a significant reduction in CRBSI with the above lock solution; two demonstrated no benefit.
- Vancomycin-heparin lock solutions did not promote vancomycin resistance.
 - Risk of superinfection with gram-negative bacilli and *Candida* is present because vancomycin spectrum is limited to gram-positive bacteria.
 - Meta-analysis concluded that the use of vancomycin lock solution in high-risk patient populations being treated with long-term central intravascular devices (IVDs) reduces the risk of bloodstream infection with a risk ratio of 0.34 (95% confidence interval [CI], 0.12–0.98; $p = 0.04$).

- Minocycline and EDTA (M-EDTA) was reported in a prospective randomized trial to significantly reduce the risk of catheter colonization and infection when compared with heparin in long-term hemodialysis CVLs,
 - Solution superior in an *in vitro* biofilm model and in an animal model to vancomycin-heparin lock solution
- Study of pediatric cancer populations showed M-EDTA significantly reduces risk of catheter infection and colonization when compared to heparin
- Prospective nonrandomized study of tunneled CVLs in pediatric cancer population:
 - Ethanol used as a lock solution and reduced risk of relapse of CRBSI and was well tolerated
 - Symptoms of fatigue, nausea, dizziness, and headache were reported,
 - Involved filling catheter lumen with 2.3 mL of a 74% ethanol solution for 20 to 24 hours
 - Solution then flushed through to prevent clotting inside the catheter
 - Each port was alternately blocked for 3 days, allowing the unblocked port to be used.
 - Recent study showed M-EDTA in 25% ethanol highly effective in eradicating organisms embedded in biofilm.
 - Even after a short exposure of 15 to 60 minutes
- Prolonged dwell time of more than 8 hours often required for nonalcohol-based antibiotic lock solutions.
 - Makes use limited, particularly in critically ill patients those requiring total parenteral nutrition

Antimicrobial Impregnation of Catheters

- Consists of impregnation of external and/or internal surface of the catheter with antiseptic or antibiotics
- Slow release of antimicrobials would prevent initial bacterial adherence and biofilm formation, with virtually undetectable serum levels.
- Healthcare Infection Control Practices Advisory Committee/Centers for Disease Control and Infection, with a category 1B, recommends use of the coated CVLs.
 - First-generation catheters were impregnated on the external surface with CHX and silver sulfadiazine (CHX/SSD).
 - Technique lowered the rate of CRBSI from 7.6 to 1.6 cases per 1,000 catheter-days ($p = 0.03$)
 - With a decrease in the rate of colonization (relative risk, 0.56 [95% CI, 0.36–0.89]; $p = 0.005$)
 - Estimated cost savings per CVL was \$196.
 - Other studies failed to show that difference.
 - Explained by the fact that short-term catheter infection is due to external colonization
 - Long-term CRBSIs due to internal colonization not prevented by external coating
 - Catheters do not protect if the CVL dwell time is more than 3 weeks, secondary to wearing off of the antimicrobial activity.
 - Second-generation CHX/SSD-coated catheters impregnated on both surfaces
 - Multicenter, randomized double-blind prospective study from 14 French ICUs: Second-generation catheters failed to decrease the rate of CRBSI when compared to non-coated catheters.

- They significantly decreased the rate of colonization (from 11 to 3.6/1,000 catheter-days, $p = 0.01$).
- 1997 polyurethane catheter impregnated on both surfaces with minocycline-rifampin (M/R)
 - Prospective trial comparing M/R catheters with first-generation CHX/SSD-impregnated catheters found that:
 - Former was three times less likely to be colonized ($p < 0.001$).
 - CRBSI was 12-fold more likely to occur in the CHX/SSD catheters ($p < 0.002$).
 - The use of antibiotic-impregnated CVCs in medical and surgical units was associated with a significant decrease in nosocomial bloodstream infections, including vancomycin-resistant enterococci (VRE) bacteremia, catheter-related infections, and length of hospital and ICU stay.
 - M/R-coated catheters saved \$9,600 per each CRBSI and \$81 per each catheter placed when compared to first-generation CHX/SSD.
- Concern for emergence of antibiotic-resistant organisms raised with M/R coated catheters
 - Four prospective studies evaluated skin at catheter insertion site before and after the insertion of antibiotic-coated catheters.
 - Failed to detect any emergence of resistance
 - Retrospective review of M/R-coated CVL experience in bone marrow transplant patients also detected no emergence of resistance of *Staphylococci* to either component
- M/R-coated CVLs are shown to bring risk of CRBSI to a level ≤ 0.3 per 1,000 catheter-days in nontunneled, non-cuffed CVLs.
 - Lower than the 1.4 per 1,000 catheter-days achieved with multiple other aseptic measures applied collectively

Silver-impregnated Catheters

- Other catheters incorporate silver, platinum, and carbon (SPC) into the polyurethane, allowing topical silver ion release.
- A prospective randomized study compared these catheters to the M/R-coated type.
 - The latter was more efficacious in reducing, to a significant degree, CVL colonization with gram-positive and gram-negative bacteria ($p = 0.039$).
 - CRBSI rates were low and similar between the two groups.
- Another prospective, randomized, controlled, open-label, multicenter clinical trial resulted in SPC CVLs failing to show any benefit in reducing CRBSI or colonization.

MANAGEMENT

- Management of CRBSIs involves:
 - Confirming the source of infection
 - Determining the choice of antimicrobials
 - Determining the duration of therapy
 - Deciding whether to remove the catheters
 - Confirmation of the infection is dependent on the diagnostic measures outlined above

- Duration of therapy depends on whether the infection is complicated (i.e., by a septic phlebitis or endocarditis) or uncomplicated

Coagulase-negative *Staphylococcus*

- CNS are the primary organisms involved in CRBSIs, as they are the most common skin organisms.
 - For the same reason, they are most frequent blood contaminants.
 - QBC collected through CVL, with a cutoff point of 15 CFU/mL, could be a useful laboratory criterion, together with positive clinical findings for differentiating true bacteremia from false-positive contaminated blood cultures.
 - Sensitivity of 96%, specificity of 94%, positive predictive value of 86%, and negative predictive value of 98%
- The Infectious Disease Society of America (IDSA) guidelines recommend removing CVL and treating for 5 to 7 days.
 - If CVL is to be retained, duration of treatment should be 10 to 14 days.
 - Antibiotic lock therapy should be considered.
 - Leaving CVL in place carries a risk of recurrence of 20%.
- Lock solutions used included vancomycin plus heparin.
 - Limited activity of vancomycin against *Staphylococcus* embedded in biofilms led other alternatives.
 - M-EDTA, ethanol, or the triple combination was used as an alternative.
- Systemically, vancomycin is the most frequently used glycopeptides.
 - Dalbavancin, a new, long-acting glycopeptide that is dosed weekly
 - Noted to be superior to vancomycin for adult patients with CRBSIs caused by CNS and *S. aureus*, including methicillin-resistant *S. aureus* (MRSA) in a phase 2, open-label, randomized, multicenter study
 - Side effect profile was comparable.
 - Linezolid and daptomycin were also used successfully.

Staphylococcus Aureus

- *S. aureus* CRBSI is associated with high rates of deep-seated infection:
 - Osteomyelitis
 - Septic phlebitis
 - Endocarditis
- Patients whose intravascular device was not removed were 6.5 times more likely to relapse or die of their infection than were those whose device was removed.
- IDSA guidelines recommend removing the CVL.
 - Results in a more rapid response and lower relapse rate
 - Might keep it and initiating systemic and lock solutions in case of thrombocytopenia or lack of other vascular access
 - In 40 CRBSIs—including all 12 cases reported to involve *S. aureus*—the antibiotic lock technique in addition to standard parenteral therapy was used for patients with a hemodialysis catheter-related infection
 - These were cured and the catheter salvaged.
 - Lock solutions most frequently used *in vivo* and *in vitro* are vancomycin plus heparin, or M-EDTA
 - Former combination—with or without ceftazidime, depending on the organism—was associated with a 60% failure rate in hemodialysis MRSA catheter infections.

- Ethanol is another appealing component for use in combination lock solutions.
 - Combination of M-EDTA in 25% ethanol was highly efficacious in eradicating *S. aureus* in biofilm within 60 minutes of dwell time.
- For methicillin-sensitive *S. aureus*, nafcillin or first-generation cephalosporins are first-choice agents.
- Vancomycin, linezolid, daptomycin, and dalbavancin are all appropriate options for MRSA.
- Duration of therapy usually consists of 10 to 14 days of IV if CVL removed.
 - And if no deep-seated infection present
 - If fever or bacteremia persists more than 72 hours after catheter removal, transesophageal echocardiography should be considered to rule out infectious endocarditis, and IV therapy duration should be expanded to at least 4 weeks.

Gram-negative Bacilli

- Gram-negative bacilli (GNB) bacteremia rarely due to CVL
- Generally arises from a visceral source of infection such as:
 - Genitourinary tract
 - Pulmonary system
 - Gastrointestinal tract
- However, CRBSIs caused by such organisms as *K. pneumoniae*, *Enterobacter* spp., *P. aeruginosa* spp., *Acinetobacter* spp., and *Stenotrophomonas maltophilia* have been reported.
 - 15-year experience of 149 episodes of septicemia caused by *Xanthomonas maltophilia* and *Pseudomonas* spp. in cancer patients where CVL was the most common source
 - Catheter removal within 72 hours of onset of catheter-related GNB is the only independent protective factor against the relapse of infection (odds ratio, 0.13; 95% confidence interval, 0.02–0.75; $p = 0.02$)
- IDSA guidelines recommend removing nontunneled CVLs and treating for 10 to 14 days.

- No data to guide the use of IV versus oral antibiotics.
- Appropriate to try CVL salvage in certain situations using systemic and lock solution therapies
 - When unable to access other vascular sites due to anatomic challenges
 - If there is a high risk of hemorrhagic complications because of thrombocytopenia or elevated prothrombin time
 - However, lock therapy for GNB CRBSIs is anecdotal.
 - Successful cases salvaged using gentamicin, amikacin, or ceftazidime.

Candida

- Five large prospective studies of *Candida* CRBSI proved catheter retention associated with:
 - Increased mortality
 - Increase in the mean duration of candidemia
 - Higher severity scores, nonremoval of the catheter, persistent candidemia, and lack of antifungal therapy adversely affect outcome
- Retrospective study of 404 patients with candidemia and indwelling CVL, using a multivariate analysis:
 - Demonstrated that catheter removal 72 hours or sooner after onset of candidemia improved the response to antifungal therapy exclusively in patients with catheter-related candidemia ($p = 0.04$)
- IDSA guidelines recommend removing CVL and treating for 14 days after last positive blood culture in uncomplicated cases.
 - Endophthalmitis merits 6 weeks of therapy.
 - Further studies are needed to define the role of antifungal lock solution in these cases.
 - Fluconazole and caspofungin were equivalent to amphotericin B in candidemia, but with a better safety profile
 - Therefore, fluconazole or caspofungin should be considered in documented cases of catheter-related candidemia.
 - If rates of fluconazole-resistant *Candida glabrata* and *Candida krusei* in hospital are high
 - An echinocandin—caspofungin, micafungin, or anidulafungin—the best alternative to amphotericin B

CHAPTER 76 ■ RESPIRATORY INFECTIONS IN THE ICU

PNEUMONIA

- Pneumonia is differentiated as being either community or hospital acquired.
 - *Community-acquired pneumonia* (CAP) begins while the patient is in an outpatient setting.
 - *Hospital-acquired pneumonia* (HAP) occurs while the patient is in an inpatient setting.
- Pneumonia is defined as hospital acquired when it occurs 48 hours or more after admission.
- This dichotomous classification scheme insufficient to characterize all patients suffering from pneumonia
 - Among HAPs, those occurring during mechanical ventilation (VAP) must be distinguished from others.
 - Significant number of VAPs occur within 48 hours of hospital admission.

- Consequently, the 48-hour HAP threshold no longer appropriate.
- It does remain adequate for HAP occurring apart from mechanical ventilation.
- Outpatients benefit from health care services such as dialysis, chemotherapy, or ambulatory surgery.
- Pneumonia developing in such patients is now defined as a *health care–associated pneumonia*.
- Thus, four classes of pneumonia can be distinguished:
 - Community-acquired pneumonia (CAP)
 - Ventilator-associated pneumonia (VAP)
 - Hospital-acquired pneumonia (HAP)
 - Health care–associated pneumonia (HCAP)

Severe CAP

Immediate Concerns

- CAP is a common infectious disease affecting about 1 per 1,000 of the adult population per year.
- ICU admission for severe CAP is required for 2% of patients.
- Most frequent pathogen is *Streptococcus pneumoniae*
- Despite progress in antibiotic therapy and ICU management, the mortality of pneumococcal pneumonia remains elevated.

Diagnosis of CAP

- CAP suspected on the basis of clinical symptoms:
 - Cough
 - Dyspnea
 - Sputum production
 - Pleuritic chest pain
 - Elevated body temperature
- Symptoms can be absent or moderated in older patients.
- Signs are not specific of pneumonia.
 - Chest radiograph (CXR) or computed tomography (CT) scan revealing a new infiltrate is required to document a pneumonia diagnosis.
 - CXR might offer insights into the etiologic diagnosis
 - Intracellular pathogens typically presenting with interstitial pneumonia
 - *S. pneumoniae* resulting in lobar pneumonia
 - However, none of these findings is specific.
 - CXR allows for staging of severity according to localization and number of involved lobes.
 - Helpful to detect complications:
 - Pleural effusion
 - Cavitation
 - Acute respiratory distress syndrome (ARDS)
 - CT scan used to show evocative patterns, particularly in immunosuppressed patients:
 - Halo or crescent signs in pulmonary aspergillosis of neutropenic patients
 - Cavitation in tuberculosis

Definition of Severe CAP and Decision for Admission to the ICU

- No gold standard to define severe CAP; criteria do exist.
- According American Thoracic Society (ATS) guidelines, CAP is considered severe when any one of the following criteria present:

- Respiratory frequency >30 breaths/minute on admission
- Severe respiratory failure ($\text{PaO}_2/\text{FiO}_2 < 250$ mm Hg)
- Requirement for mechanical ventilation
- Bilateral or multilobar or extensive ($\geq 50\%$ within 48 hours of admission) involvement of the CXR
- Shock (SBP <90 mm Hg or DBP <60 mm Hg)
- Requirement for vasopressors for more than 4 hours
- Low urine output (<20 mL/hour or 80 mL/4 hours) or acute renal failure requiring dialysis
- New definition of severe CAP adopted by the ATS in 2001
- Diagnosis of CAP is considered severe and requiring ICU admission for patients exhibiting either:
 - One of two major criteria (need for mechanical ventilation, septic shock) or
 - Two of three minor criteria (SBP ≤ 90 mm Hg, multilobar involvement on CXR, or $\text{PaO}_2/\text{FiO}_2 < 250$ mm Hg)
- In 2001, the British Thoracic Society (BTS) proposed assessing the severity of CAP utilizing three groups of adverse prognostic features:
 - Four “core” factors (CURB score):
 - Confusion
 - Blood Urea nitrogen >19 mg/dL [7 mmol/L]
 - Respiratory rate ≥ 30 breaths/minute
 - Low Blood pressure—SBP <90 mm Hg and/or DBP ≤ 60 mm Hg)
 - Two “additional” factors:
 - Hypoxemia— $\text{SpO}_2 < 92\%$ or $\text{PaO}_2 < 60$ mm Hg (8 kPa)
 - Bilateral or multilobar involvement on chest radiograph
 - Two “pre-existing” factors:
 - Age 50 years or older
 - Presence of coexisting disease
 - CAP was considered and treated as severe in patients having two or more core adverse prognostic features.
 - Patients exhibiting only one of these core factors had decision based on clinical judgment.
 - Assisted by taking into account pre-existing and additional factors

Diagnostic Studies

- Evaluation for etiologic diagnosis is helpful to confirm infectious origin of pneumonia and allow adequate antimicrobial therapy (including secondary deescalation therapy).
- Methods available for microbiologic diagnosis of pneumonia:
 - Sputum stains and cultures necessitate rigorous interpretation criteria.
 - Presence of >25 PMNs and <10 squamous epithelial cells per HPF required to interpret sample
 - A single predominant organism on Gram stain suggests etiology.
 - Other stains can be used according to particular clinical context and may allow for a positive diagnosis without any sample validation (*Mycobacterium tuberculosis*, *Legionella pneumophila*, *Pneumocystis jirovecii*).
 - More invasive sampling methods (endotracheal aspiration, protected specimen brush, bronchoalveolar lavage, transtracheal aspiration) are discussed in the VAP section but can also be used to diagnose CAP.
 - Blood cultures drawn before antibiotic therapy rarely positive (6%–20% of cases)
 - When positive, are most often for *S. pneumoniae*, *Staphylococcus aureus*, and gram-negative bacilli

TABLE 76.1

MICROORGANISMS CAUSING SEVERE CAP REQUIRING ADMISSION TO AN ICU^a

References	Yoshimoto et al. ^b	Leroy et al. ^c	Shorr et al. ^d
Number of patients	72	308	199
Unknown pathogen	55.6%	45%–45.9%	43.7%

- Rapid diagnostic tests recently introduced
 - Urinary antigen test highly sensitive for diagnosis of *L. pneumophila* type 1
 - Urinary antigen test has been introduced for the diagnosis of pneumococcal pneumonia
 - In the ICU, patients with severe CAP displayed sensitivity, specificity, and positive and negative predictive values of 72%, 90%, 68%, and 92%, respectively.
 - Rapid diagnosis is available for influenza A.
 - Available tests can detect influenza viruses in 30 minutes.
 - Types of specimens acceptable for use (i.e., throat, nasopharyngeal, or nasal; and aspirates, swabs, or washes) vary by test.
 - Specificity and, in particular, the sensitivity of rapid tests are lower than for viral culture and vary by test.
- Serologic testing is less useful for rapid diagnosis.
 - Presence of IgM with a titer ≥ 6 generally indicates recent infection.
 - Rarely observed in the initial phase of infection when antibiotic therapy must be chosen.
 - Fourfold rise in antibody titer requiring samples drawn 2 weeks apart indicates, retrospectively, infection.
 - Serologic diagnosis can be useful for some pathogens:
 - *Mycoplasma pneumoniae*
 - *Chlamydia pneumoniae* and *Chlamydophila psittaci*
 - *Legionella* spp.
 - *Coxiella burnetii*
 - Adenovirus, parainfluenza viruses, and influenza A virus
- Polymerase chain reaction (PCR) testing is a promising future field.
 - Cannot be recommended routinely, as questions concerning sensitivity, specificity, and clinical relevance remain

Etiology of Severe CAP

- Despite intensive microbiologic testing, definitive diagnosis obtained in about 50% of cases.

• Organisms causing CAP in hospitalized patients requiring ICU admission:

- The epidemiology of CAP patients admitted to the ICU does not appear to be different from other hospitalized individuals with CAP.
- Most frequent pathogen isolated in ICU-hospitalized CAP patients is *S. pneumoniae* (Table 76.1).
 - Other pathogens responsible for severe CAP include:
 - *L. pneumophila*
 - *S. aureus*
 - *Pseudomonas aeruginosa*
 - *Aspergillus* spp.
 - Influenza
- Drug-resistant pathogens
 - Major challenge is emergence and dissemination of drug-resistant microorganisms
 - Major concerns are caused by penicillin-resistant pneumococci (PRP) and methicillin-resistant staphylococci
 - For *S. pneumoniae*, macrolide resistance is above 20% in the United States and higher than 50% in some European or Asian-Pacific countries.
 - Decreased susceptibility or resistance to penicillin was observed in 30% to 50% of strains.
 - Fluoroquinolone resistance is increasing, and fluoroquinolone-prescribing habits may affect resistance rates.
 - Resistance reaches 5.6% in Italy.
 - Community-acquired MRSA is a new challenge.
 - MRSA strain carrying Panton-Valentine leukocidin (PVL) genes was recently described in the community.
 - Primarily causes skin and soft tissue infections but can be responsible for rapidly progressing necrotizing pneumonia.
 - *P. aeruginosa* are naturally resistant to numerous antibiotics and can elevate to a high-level resistance under treatment.
 - Risk of *P. aeruginosa* is increased in patients presenting with a previous chronic pulmonary disease such as chronic obstructive pulmonary disorder (COPD) or cystic fibrosis,

recent antibiotic therapy, or a stay in the hospital, especially the ICU.

• Specific etiologies in immunosuppressed patients

- Immunosuppressed patients have an increased risk of severe CAP.
- All have more frequent bacterial pneumonia, particularly due to *S. pneumoniae* or *P. aeruginosa*.
- Different types of immunodeficiency can also result in different epidemiology.
 - HIV-infected patients used to have a 25-fold higher risk of developing bacterial pneumonia.
 - In developed countries, risk has been tremendously decreased with the use of newer antiretroviral drugs.
 - Incidence of bacterial pneumonia in a French cohort was 0.8 per 100 patient-years, little difference from the general population.
 - *P. jiroveci* pneumonia remains a frequent AIDS-defining diagnosis.
 - Less frequent causes of severe pneumonias include cytomegalovirus (CMV), toxoplasma, and mycobacteria.
 - Patients with severe, prolonged chemotherapy-induced neutropenia (<500 neutrophils/ μL and >10 days)
 - Have an increased risk of invasive pulmonary aspergillosis and severe bacterial pneumonia
 - Risk also exists with targeted monoclonal antibody therapies, which increase the risk of CMV and *P. jiroveci* pneumonia.
 - Patients with solid organ transplant have increased risk of severe CAP.
 - Usual bacterial pathogens, as well as *P. jiroveci* and *Aspergillus*, have been described.
 - Patients treated by anti-tumor necrosis factor (TNF)- α monoclonal antibodies have an increased risk of infection, including severe pneumonia.
 - Bacterial, viral, and fungal pneumonia have been described.

Treatment of Severe CAP

• Antibiotic therapy

- Ideal antibiotic
 - Should have a “kill spectrum” to cover all pathogens responsible for severe CAP
 - Factors such as cost-effectiveness and selective pressure need to be assessed, so the choice of antimicrobial regimen usually results in a compromise.
 - Most frequent and/or most severe pathogens (*S. pneumoniae*, *Haemophilus influenzae*, *L. pneumophila*) should be covered by initial antimicrobial regimen.
 - Initial coverage of other pathogens (i.e., *S. aureus*, *P. aeruginosa*, opportunistic agents) evaluated on case-by-case basis according to patient history and presentation.
- Timing of initial therapy
 - IDSA guidelines recommend initial antibiotics administration within 4 hours of admission.
 - Reduced mortality (adjusted odds ratio, 0.85, 95% confidence interval [CI] 0.76–0.95) observed in patients with early therapy.
 - However, time to first antibiotic dose may be a marker of disease severity rather than an indicator of prognosis.
- Antimicrobial choices
 - Drug choice depends on numerous factors:

- Pharmacodynamics/pharmacokinetics
- Spectrum
- Dosing schedule
- Adverse events
- Costs
- Availability
- Antimicrobial should have sufficient diffusion in pulmonary tissues
 - β -Lactam antibiotics have a good extracellular diffusion but are ineffective on intracellular organisms.
 - Concentration in the alveolar lining fluid (ALF) reached 10% to 20% of the serum concentration after a single administration.
 - Macrolides, on the other hand, have a variable intracellular distribution—low for erythromycin and elevated for the newer macrolides (clarithromycin, azithromycin).
 - Fluoroquinolones have an excellent intracellular and ALF diffusion.
- Little data are available on best antimicrobial regimen for CAP.
 - Retrospective studies suggested combination regimens, including a macrolide, might be superior to β -lactam monotherapy for CAP.
 - Particularly for bacteremic pneumococcal pneumonia
 - Similar results were reported with a β -lactam–fluoroquinolone combination.
 - Impact of combination therapy on prognosis of pneumococcal bacteremia confirmed
 - Lower mortality associated with combination therapy for **critically ill patients** (14-day mortality, 23.4% vs. 55.3%; $p = 0.0015$), but **not for all patients** receiving combination versus monotherapy (10.4% vs. 11.5%, $p = \text{NS}$)
 - All combinations using a β -lactam had enhanced response
- Recommendations
 - Guidelines published by North American and European medical societies mostly recommend the utilization of a β -lactam with a macrolide or a fluoroquinolone (Table 76.2).
- Duration of therapy
 - Usually based on the pathogen, response to treatment, comorbid illness, and complications
 - For pneumonia caused by *S. pneumoniae* should continue, at least, until patient has been afebrile for 72 hours
 - Bacteria causing necrosis of the pulmonary parenchyma (e.g., *S. aureus*, *P. aeruginosa*, *Klebsiella*, and anaerobes) should probably be treated for no less than 2 weeks.
 - Pneumonia caused by intracellular organisms should probably be treated for at least 2 weeks.
- Nonantimicrobial therapy
 - Activated protein C
 - Severe sepsis is associated with a generalized inflammation and procoagulant response to infection.
 - Activated protein C is an important endogenous modulator of response.
 - Activation of protein C impaired during sepsis
 - Reduced levels of activated protein C in most patients with severe sepsis
 - Drotrecogin- α an activated, recombinant form of human activated protein C (r-aPC)

TABLE 76.2

INITIAL EMPIRIC ANTIBIOTIC THERAPY IN PATIENTS ADMITTED TO AN ICU FOR SEVERE CAP

Clinical characteristics	Recommended antibiotics
No <i>Pseudomonas</i> or methicillin-resistant <i>Staphylococcus aureus</i> (MRSA) or penicillin allergy	A β -lactam (cefotaxime, ceftriaxone, ampicillin/sulbactam) plus azithromycin or a respiratory fluoroquinolone ^a
Patients with penicillin allergy	A respiratory fluoroquinolone, with azithromycin
Suspected <i>Pseudomonas</i> infection	An antipseudomonal β -lactam ^b Plus ciprofloxacin or levofloxacin ^a Or plus an aminoglycoside and an antipneumococcal fluoroquinolone ^a
Suspected community-acquired MRSA	Addition of vancomycin or linezolid

^aDosage of levofloxacin should be 750 mg daily.

^bAntipseudomonal agents include piperacillin-tazobactam, imipenem, meropenem, or ceftazidime. Azithromycin can be substituted for penicillin allergy. Adapted from Mandell LA, Wunderink RG, Anzueto A, et al. Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults. *Clin Infect Dis*. 2007;44(Suppl 2):S27.

- Exhibits profibrinolytic, antithrombotic, and anti-inflammatory characteristics
- Randomized, double-blind, placebo-controlled, multicenter study (PROWESS) composed of 1,690 patients demonstrated that treatment with r-aPC significantly decreased 28-day and hospital discharge mortality rates in patients with severe sepsis
 - Retrospective analysis of these 1,690 patients included in the PROWESS trial identified 602 patients (r-aPC, $n = 324$; placebo, $n = 278$) classified as exhibiting severe CAP
 - Compared with placebo, r-aPC provided a relative risk reduction in a 28-day mortality of 28%.
 - Survival benefit even more pronounced in patients with severe pneumococcal CAP and in patients with a high risk of death assessed by an Acute Physiology and Chronic Health Evaluation (APACHE) II score of at least 25, or a Pneumonia Severity Index score ≥ 4
- Conversely, in patients with severe sepsis but a low risk of death defined by an APACHE II score < 25 or a single organ failure, r-aPC compared with placebo provided no beneficial effect and was associated with an increased incidence of bleeding events.
- Use of r-aPC should be limited in severe CAP, as in other severe infections, to patients at high risk of death.
 - APACHE II score ≥ 25 or multiple organ failure must be present
- Corticosteroids
 - Preliminary randomized trial, hydrocortisone (200 mg IV bolus followed by infusion at a rate of 10 mg/hour for 7 days) compared with placebo in 46 patients
 - On day 8, hydrocortisone treatment was associated with a significant improvement in $\text{PaO}_2/\text{FiO}_2$ and chest radiograph score, as well as a significant decrease in C-reactive protein levels and Multiple Organ Dysfunction Syndrome score, and a lower incidence of delayed septic shock.
 - Moreover, length of hospital stay and mortality were decreased.
 - Results as yet insufficient to propose the systematic use of hydrocortisone in severe CAP

• Expected clinical course

- Evaluation on day 3
 - Generally, a decrease in fever and oxygenation requirements is not observed in responding patients prior to day 3 or 4.
 - Absent rapid clinical deterioration, initial therapy should not be changed prior to completion of 48 to 72 hours of the initial therapy.
 - Day 3 usually sees the return of microbiologic exams, including cultures and antimicrobial sensitivity.
 - Can allow for treatment adaptation (de-escalation or treatment for a pathogen not covered by first-line therapy)
 - For example, negative results of urinary antigen test combined with blood cultures positive for *S. pneumoniae* make it possible to simplify therapy to target *S. pneumoniae* with an aminopenicillin.
- Complications and failure to improve
 - Poor clinical response by day 3 is usually a sign of treatment failure.
 - In the ICU, other diagnoses such as pulmonary embolism or cardiac failure should be considered.
 - Treatment failure can be due to an organism not covered by the first-line antimicrobial therapy, thus demanding a change or addition to the previous treatment regimen.
 - Other causes of treatment failure can include complications despite adequate antimicrobial therapy, including:
 - Lung abscess
 - Necrosis
 - Meningitis
 - Endocarditis
 - Superinfection

Prognosis of Severe CAP

- Mortality in patients with severe CAP requiring admission to the ICU remains high, ranging in the literature from 18% to 46%.
- A meta-analysis of 788 evaluable ICU patients found a mean mortality rate of 36.5%.
- 11 independent prognostic factors associated with a mortality of CAP:

- Male gender (odds ratio [OR] = 1.3)
- Pleuritic chest pain (OR = 0.5)
- Hypothermia (OR = 5.0)
- Systolic hypotension (OR = 4.8)
- Tachypnea (OR = 2.9)
- Diabetes mellitus (OR = 1.3)
- Neoplastic disease (OR = 2.8)
- Neurologic disease (OR = 4.6)
- Bacteremia (OR = 2.8)
- Leukopenia (OR = 2.5)
- Multilobar pulmonary involvement (OR = 3.1)
- Prognosis of patients admitted to the ICU for severe CAP depends on preadmission health status of patient, the initial severity of illness, and the evolution during ICU stay (Table 76.3).

TABLE 76.3**INDEPENDENT PROGNOSTIC FACTORS ASSOCIATED WITH MORTALITY OF PATIENTS WITH SEVERE CAP****Preadmission Health Status**

- Age older than 70 yr
- Immunosuppression
- Comorbidities with anticipated death within 5 yr

Initial Severity of Illness

- Antibiotic administration prior to hospital presentation
- Simplified Acute Physiologic Score (SAPS) I >12 or SAPS II >45
- Septic shock
- Requirement for mechanical ventilation
- Acute renal failure
- Bilateral or multilobar pulmonary involvement
- *K. pneumonia* or *P. aeruginosa* as etiologic agent
- Bacteremia
- Nonaspiration pneumonia

Evolution during ICU Stay

- Radiographic spread of pneumonia
- Number of nonpulmonary organs that failed
- Increase in Logistic Organ Dysfunction score from D1 to D3
- Delay in hospital antibiotic administration of more than 4 h
- Ineffective initial antimicrobial therapy
- Occurrence of non-pneumonia-related complications
- Increase of procalcitonin level in serum from D1 to D3

Data from Pachon J, Prados MD, Capote F, et al. Severe community-acquired pneumonia. Etiology, prognosis, and treatment *Am Rev Respir Dis*. 1990;142:369; Almirall J, Mesalles E, Klamburg J, et al. Prognostic factors of pneumonia requiring admission to the intensive care unit. *Chest*. 1995;107:511; Leroy O, Santré C, Beuscart C, et al. Prognosis factors and outcome of community-acquired pneumonia needing mechanical ventilation. *J Crit Care*. 2005;20:230; Boussekey N, Leroy O, Alfandari S, et al. Procalcitonin kinetics in the prognosis of severe community-acquired pneumonia. *Intensive Care Med*. 2006;32:469; Torres A, Serra-Batlles J, Ferrer A, et al. Severe community-acquired pneumonia. Epidemiology and prognostic factors. *Am Rev Respir Dis*. 1991;144:312; Leroy O, Devos P, Guery B, et al. Simplified prediction rule for prognosis of patients with severe community-acquired pneumonia in ICUs. *Chest*. 1999;116:157; Wilson PA, Ferguson J. Severe community-acquired pneumonia: an Australian perspective. *Intern Med J*. 2005;35:699.

- Initial empiric treatment must be instituted as soon as possible (<4 hours after hospital admission) and must be adequate to be as effective as possible.
- Non-pneumonia-related complications—such as upper gastrointestinal bleeding, catheter-related infection, deep venous thrombosis, and pulmonary embolism—and complications attributed only to underlying medical conditions must be prevented during the ICU stay.
- Mortality risk scores specific to CAP have been elaborated.
 - Pneumonia Severity Index (PSI) and stratifies risk using a two-step approach
 - First, patients with a low risk (class I) are identified by age younger than 50 years and the absence of comorbidities and vital sign abnormalities.
 - For remaining patients, the score is determined by adding points assigned to age and different variables, taking into account comorbid conditions, physical examination findings, and laboratory and radiographic abnormalities (Table 76.4).
 - According to the value of this score, patients are classified into:
 - Class II (≤ 70 points)
 - Class III (71–90 points)
 - Class IV (91–130 points)
 - Class V (> 130 points)
 - From class I to class V, mortality rates observed in the validation cohort were 0.1%, 0.6%, 2.8%, 8.2%, and 29.2%, respectively.
 - A specific prediction rule for mortality of patients with severe CAP admitted to an ICU has been proposed.
 - Rule takes into account data on prognostic factors, emphasizing that the prognosis of severe CAP depends on both *initial* baseline characteristics of the patient and *evolution* during the ICU stay, and is based on two successive steps.
 - On ICU admission, an initial risk score based on six independent variables associated with the prognosis is established. These variables and their respective point value are:
 - Age 40 years or older (+1 point)
 - Anticipated death within 5 years (+1 point)
 - Nonaspiration pneumonia (+1 point)
 - Chest radiograph involvement greater than one lobe (+1 point)
 - Acute respiratory failure requiring mechanical ventilation (+1 point)
 - Septic shock (+3 points)
 - The initial risk score, obtained by summing up these points, allows inclusion of each patient into one of the three risk classes of increasing mortality
 - Class I (0–2 points) mortality risk is low (<5%)
 - Class II (3–5 points), mortality risk is intermediate (25%)
 - Class III (6–8 points), mortality risk is high (>50%)
 - Risk score based on three independent factors identified **during** ICU stay allows definite evaluation of final prognosis
 - These three independent factors and their point scoring are:
 - Hospital-acquired, lower respiratory tract superinfections (+1 point)

TABLE 76.4

CRITERIA AND POINT SCORING SYSTEM USED IN THE PNEUMONIA SEVERITY INDEX (STEP 2; CLASSES II–V)

Variables	Points	Variables	Points
Age	Age (yr)	Vital sign abnormality	
Female gender	–10	Altered mental status	+20
Nursing home resident	+10	Respiratory rate >30 breaths/min	+20
		Systolic blood pressure <90 mm Hg	+20
		Temperature <35°C or ≥40°C	+15
		Tachycardia >125 breaths/min	+10
Comorbidity		Laboratory and radiographic data	
Neoplastic disease	+30	Arterial pH <7.35	+30
Liver disease	+20	Blood urea nitrogen ≥30 mg/dL	+20
Congestive heart failure	+10	Sodium <130 mmol/L	+20
Cerebrovascular disease	+10	Glucose ≥250 mg/dL	+10
Renal disease	+10	Hematocrit <30%	+10
		PaO ₂ <60 mm Hg	+10
		Pleural effusion	+10

Adapted from Fine MJ, Auble TE, Yealy DM, et al. A prediction rule to identify low-risk patients with community-acquired pneumonia. *N Engl J Med.* 1997;336:243.

- Nonspecific CAP-related complications (+2 points)
- Sepsis-related complications (+4 points) occurring during the ICU stay
- This risk score appears particularly useful for patients in the intermediate-risk class II on ICU admission

Prevention of CAP

- Many factors associated with increase in CAP risk (tobacco use, malnutrition, chronic pulmonary disease, diabetes, liver disease, older age, confinement to a nursing home) are not amenable to prevention.
- Immunization remains the most significant method of prevention.
 - Two vaccines are available for preventing pneumococcal disease.
 - Pneumococcal polysaccharide vaccine is recommended for persons 65 or more years of age, and for persons 2 or more years of age who are immunocompetent but at increased risk for illness and death associated with pneumococcal disease because of chronic illness, with functional or anatomic asplenia, who live in environments in which the risk for disease is high, or are immunosuppressed and at high risk for infection.
 - Pneumococcal conjugate vaccine is recommended only for children
 - The Advisory Committee on Immunization Practices (ACIP) recommends the inactivated influenza A vaccine for all persons older than 50 years of age, those at risk for influenza complications, and household contacts of high-risk persons (including health care workers).

- Usual guidelines suggest a delay of 48 to 72 hours between the beginning of MV and occurrence of pneumonia to qualify for this diagnosis; recent data suggest that a pneumonia acquired earlier than the 48th hour of mechanical ventilation could also be considered a VAP.
- VAP represents 80% of pneumonia acquired during hospitalization.
- VAP is the most frequent hospital-acquired infection in ICUs.

Immediate Concerns

- The major dilemmas regarding VAP at present are following:
 - Prevention remains a challenge.
 - No gold standard for diagnosis.
 - Rate of multidrug-resistant causative pathogens has dramatically increased during recent years.
 - Prompt initiation of an adequate antibiotic therapy essential.

Incidence

- The exact incidence of VAP is difficult to assess for a number of reasons:
 - Study populations vary greatly from one study to another.
 - Criteria used to diagnose VAP can be quite different (i.e., clinical vs. bacteriologic diagnosis).
 - Overlap between VAP and other hospital-acquired lower respiratory tract infections such as nosocomial tracheobronchitis exists.
 - With this in mind, one must carefully analyze the extant studies, which show an incidence varying from 5.6% to 82.4% (Table 76.5).
- In a U.S. inpatient database composed of 9,080 patients mechanically ventilated for more than 24 hours, the incidence of VAP was 9.3%.
 - The percentages of episodes of VAP occurring during the first 2 days of hospitalization, between days 3 and 6, and after hospital day 6 were 45.2%, 29.1%, and 25.7%, respectively.

VAP

- VAP defined as pneumonia occurring in intubated or tracheotomized patients undergoing mechanical ventilation (MV).

TABLE 76.5

INCIDENCE OF VAP IN THE ICU

References	No. of patients	Characteristics of patients	Diagnostic criteria	Incidence of VAP

- Most episodes of VAP (63.2%) developed within 48 hours of mechanical ventilation.
 - Thereafter, 16% occurred between 48 hours and 96 hours of mechanical ventilation, and 20.8% after 96 hours of mechanical ventilation.
- In a cohort of 1,014 patients ventilated for 48 hours or more, the overall incidence of VAP was 14.8 cases per 1,000 ventilator-days.
- The daily risk for developing VAP is highest in the early course of hospital stay.
 - Estimated to be 3% per day at day 5
 - 2% at day 10
 - 1% at day 15

Pathogenesis

- Pneumonia occurs resultant to the entry of bacteria into the normally sterile lower respiratory tract.
 - Leading to colonization and subsequently to infection when bacteria overwhelm host defenses secondary to a large bacterial inoculum, a virulent pathogen, or a defect in the local host defenses
- Bacteria can reach the lower respiratory tract by four different pathogenic mechanisms:
 - Contiguous spread
 - Hematogenous spread
 - Inhalation
 - Aspiration
- First two mechanisms of invasion are infrequent.
 - Inhalation of gastric material or direct inoculation of bacteria into the lower respiratory tract through contami-

nated “devices” (aerosol, bronchoscopes, ventilator circuit, nebulizer, tracheal suctioning) is rarely associated with VAP.

- Aspiration of bacteria colonizing the oropharynx is the main route of entry into the lower respiratory tract.
 - Colonization of oropharyngeal airways by pathogenic microorganisms occurs during first hospital week in most critically ill patients.
 - Microorganisms that replace normal microflora of oropharynx can be either endogenous (enteric gram-negative bacteria) or exogenous *via* a cross-contamination from other ICU patients.
 - Stomach, sinuses, and dental plaque may be potential reservoirs for pathogens colonizing oropharynx.
 - Exact contribution still remains controversial.
 - The endotracheal tube (ETT) compromises the natural barrier between the oropharynx and lower respiratory tract.
 - Leakage of contaminated secretions around ETT cuff allows bacterial entry into trachea.

Risk Factors

- Many risk factors for VAP are host related and, thus, not accessible to intervention.
- Patient-related risk factors include:
 - Male gender
 - Pre-existing pulmonary disease
 - Coma
 - AIDS
 - Head trauma

TABLE 76.6

MICRO-ORGANISMS CAUSING VAP^a

References	Trouillet et al. ^b	Leroy et al. ^c	Rello et al. ^d
Number of episodes of VAP	135	124	290

Variations in etiology of ventilator-associated pneumonia across four treatment sites: implications for antimicrobial prescribing practices. *Am J Respir Crit Care Med.* 1999;160:608.

- Age older than 60 years
- Neurosurgical procedures
- Multiorgan system failure
- Among accessible risk factors, most important is the presence of MV, which associated with a 3- to 21-fold risk.
- ETT:
 - Limits draining of secretions that leak around the cuff
 - Favors bacterial multiplication
 - Offers a focus for bacterial adherence and colonization
 - Impairs ciliary clearance and cough
- MV patient requires other devices such as nebulizers or humidifiers, which can be a source of microorganisms.
- Risk of infection is highest during the first 8 to 10 days of MV and increases with MV duration.
- Accidental extubation, rather than reintubation, increases the risk of VAP.
 - Likely due to nonexistent preparation for extubation
 - Enteral nutrition administered *via* NG—rather than a postpyloric—tube also increases risk of VAP.
 - NG tube might increase the risk of reflux and subsequent colonization of the airways.
 - Use of H₂ blockers or antacids favors gastric colonization and may contribute to VAP.
 - Other factors facilitating inhalation of oropharyngeal secretions favor VAP:
 - Supine position
 - Patient transportation out of the ICU
 - Sedation
 - Failed subglottic aspiration

- Intracuff pressure <20 cm H₂O
- Tracheostomy
- Aerosol treatment

Etiology

- VAP may be caused by a wide spectrum of bacteria and is often polymicrobial (Table 76.6).
- Gram-negative enteric bacilli, *P. aeruginosa*, and *S. aureus* are the leading etiologies.
- However, microorganisms responsible for VAP may differ according to patient groups, unit types, hospitals, and countries.
- Main epidemiologic patterns—principally the susceptibility patterns of causative pathogens—may also vary in a given unit over the course of time.
- Presence of altered level of consciousness, admission into a medical ICU, and a high Simplified Acute Physiologic Score are independent factors associated with the development of VAP caused by anaerobes.
- In trauma patients, VAP due to *Stenotrophomonas maltophilia* are independently associated with prior exposure to cefepime and tracheostomy.
- Cytotoxic chemotherapy and use of corticosteroids are independent factors predisposing to the development of nosocomial pneumonia due to *L. pneumophila*.
- Neurosurgery, ARDS, head trauma, and large-volume pulmonary aspiration are independent risk factors for VAP due to *Acinetobacter baumannii*.

- COPD, prior use of antibiotics, and duration of mechanical ventilation longer than 8 days are independently associated with VAP due to *P. aeruginosa*.
- Coma is an independent risk factor for VAP caused by *S. aureus*.
- Even if such factors are important to consider, there is major overlap between these different factors and, consequently, they are not sufficiently discriminant.
- The time of onset of VAP influences the etiology of VAP, making it useful to distinguish early-onset VAP from late-onset VAP.
 - Early-onset VAP, the main causative pathogens are:
 - *S. pneumoniae*
 - Methicillin-susceptible *S. aureus*
 - *H. influenzae*
 - Susceptible gram-negative enteric bacilli
 - In late-onset VAP the main causative organisms are:
 - MRSA
 - *P. aeruginosa*
 - *A. baumannii*
 - *S. maltophilia*
- Distinction between early- and late-onset VAP useful, but no consensus on number of days considered that separate VAP types
 - According to the literature, threshold varies from 3 to 7 days.
 - Unclear whether threshold refers to number of days in hospital or to number of days of mechanical ventilation.
 - Recent ATS/IDSA guidelines note the duration of hospitalization fewer than, or more than, 5 days, respectively, separates early- from late-onset VAP.
- Rate of multidrug-resistant (MDR) pathogens dramatically increased recently.
 - Numerous factors associated with emergence of resistant strains (Table 76.7)
- VAP due to fungi such as *Candida* species and *Aspergillus* species or to viruses such as influenza, parainfluenza, measles, adenovirus, and respiratory syncytial virus is uncommon in immunocompetent patients.

Diagnostic Strategies and Diagnostic Testing

- In the ICU, the diagnosis of VAP remains a challenge.
 - No gold standard for diagnosis
 - Usually, the diagnostic approach is based on two successive steps:
 - Diagnosis of pneumonia must be established.
 - Etiologic pathogen(s) of pulmonary parenchymal infection must be identified.
 - Pneumonia is suspected when current signs of infection present:
 - Fever or hypothermia
 - Leukocytosis or leucopenia
 - Tachycardia
 - Purulent sputum, a decline in oxygenation, and pulmonary infiltrates on CXR suggestive of pulmonary involvement
 - Among these signs and symptoms, none is specific for pneumonia.
 - Presence of a new or progressive radiographic infiltrate associated with at least two of three major clinical findings (fever >38°C, purulent tracheal secretions, and leukocytosis or leucopenia) considered most accurate combination.

TABLE 76.7

RISK FACTORS FOR MDR PATHOGENS AS CAUSATIVE ORGANISMS IN VAP

- Admission from a nursing home or an extended-care facility
- History of regular visits to an infusion or dialysis center
- Prior antimicrobial treatment in the preceding 90 days
- Prior use of broad-spectrum antibiotics
- Prior hospitalization in the preceding 90 days
- Current hospitalization for ≥ 5 days
- Duration of mechanical ventilation ≥ 7 days
- Immunosuppression
- High level of antibiotic resistance in the community or in local intensive care unit

Data from American Thoracic Society, Infectious Diseases Society of America. Guidelines for the management of adults with hospital-acquired, ventilator-associated, and healthcare-associated pneumonia. *Am J Respir Crit Care Med.* 2005;171:388; Trouillet JL, Chastre J, Vuagnat A, et al. - Numerous techniques have been proposed to identify causative organism(s) of VAP:
 - Blood cultures are rarely positive.
 - Positive pleural effusion culture is generally considered as a specific result.
 - However, spread of infection to pleural space is a rare event.
 - Analysis of lower respiratory secretions the most frequently used technique to identify causative organism(s) of VAP.
 - Microscopy and qualitative culture of expectorated sputum or endotracheal aspirates associated with a high percentage of false-positive results because of colonization of the upper respiratory tract and/or tracheobronchial tree.
 - However, initial empiric antimicrobial treatment of VAP could be guided by a reliable tracheal aspirate Gram stain.
 - Quantitative cultures with a threshold of 10^6 colony-forming units (CFU)/mL to differentiate colonization from lung infection provide a diagnostic accuracy nearly similar to that of quantitative cultures from samples obtained by bronchoscopic techniques.
 - When culture of endotracheal secretions is sterile in a patient with no recent (<72 hours) change in antimicrobial therapy, diagnosis of VAP can be ruled out with a high probability
 - Negative predictive value is >90%.
 - Extrapulmonary infectious process must be investigated.

- Protected specimen brush (PSB) allows uncontaminated specimens from the infected pulmonary area to be collected.
 - Threshold set at 10^3 CFU/mL is the most adequate for quantitative cultures.
 - False-positive results are infrequent.
 - False-negative results are observed when sampling is performed at an early stage of infection, in a technically incorrect (unaffected pulmonary area) manner, in a patient where a new antimicrobial treatment has been initiated, and/or if specimens are incorrectly processed.
- Bronchoalveolar lavage (BAL) explores larger lung area than PSB.
 - Quantitative cultures of BAL fluid, with a threshold set at 10^4 CFU/mL seem to provide results similar to those obtained by PSB.
 - Possible microscopic examination of BAL fluid immediately after the procedure a clear advantage
 - The detection with Gram or Giemsa staining of BAL cells containing intracellular bacteria allows for a rapid diagnosis and guides initial antibiotic treatment.
- Arguments favoring these bronchoscopic techniques are:
 - Ability to confirm diagnosis of VAP by identifying causative organism(s) and guide antimicrobial treatment
 - When cultures are negative, they can point to an alternative diagnosis.
 - When cultures are positive, a more targeted antimicrobial treatment plan is possible, and selective pressure for antibiotic resistance may be reduced.
 - Having accurate microbiologic diagnosis may reduce VAP mortality.
- Major limitations of bronchoscopic techniques are:
 - Questionable accuracy in patients in whom a new antimicrobial treatment has been introduced before sampling
 - Significant cost
 - Possible occurrence of complications (i.e., hypoxemia)
 - Low impact on therapeutic decisions since physicians are often reluctant to modify (or discontinue) an effective treatment
- ATS/IDSA guidelines propose a “mixed” diagnostic strategy as follows:
 - Diagnosis of VAP suspected in presence of a new or progressive pulmonary infiltrate associated with at least two of the following three infectious signs:
 - Fever $>38^\circ\text{C}$
 - Leukocytosis or leucopenia
 - And/or purulent secretions
 - For patients with ARDS, radiographic changes are difficult to analyze; consequently, hemodynamic instability and/or deterioration of blood gases could be considered sufficient to suspect VAP.
 - When diagnosis suspected, lower respiratory tract samples are obtained for microscopy, and quantitative or semiquantitative cultures and empiric antimicrobial therapy are started unless there is both a low-clinical suspicion for VAP and a negative microscopy of the respiratory sample.
 - On days 2 and 3, the results of cultures should be available, and the clinical response is assessed.

– According to whether the clinical picture is improving or worsening and the results of cultures:

- Antimicrobial therapy will be stopped, de-escalated, or adjusted, and an investigation for other pathogens, other diagnoses, other sites of infection, or complications is performed.
- Quantitative cultures of respiratory samples appear more accurate than qualitative or semiquantitative cultures for diagnosis of VAP.

Antibiotic Treatment

● Principles of initial empiric treatment

- Prompt initiation of adequate antimicrobial treatment is a cornerstone of therapy, as inadequate initial antibiotic treatment is associated with significantly increased VAP mortality.
- Timing of adequate antibiotic treatment is an important determinant of outcome.
 - Delayed appropriate antibiotic treatment—defined as a period ≥ 24 hours between time VAP was suspected and administration of adequate treatment—resulted in significantly higher mortality than those receiving nondelayed treatment (69.7% vs. 28.4%; $p < 0.001$).
 - Patients with delayed treatment received antibiotics, on average, only 16 hours later than patients without delay.
 - Once bacteriologic and susceptibility data become available, it does not reduce the excess mortality induced by inadequate treatment given initially.
 - Adequate antibiotic therapy could be defined as the administration, at an appropriate dose, of at least one antibiotic with good penetration into lung tissues and to which all causative pathogens are susceptible *in vitro*.
 - Although inappropriate doses and/or choice of agents with poor lung penetration could explain inadequacy of treatment, the most common reason is resistance of causative pathogen(s).
 - Consequently, antibiotics must be selected according to presence or absence of risk factors for MDR pathogens (see Table 76.7) and the local microbiologic patterns of VAP.

● Guidelines for initial empiric antibiotic therapy

- On basis of time of onset of VAP and presence or absence of risks for MDR pathogens, ATS/IDSA guidelines propose two different schemes for initial empiric antibiotic therapy
 - With no risk factors for MDR pathogens and an early-onset VAP (duration of hospitalization < 5 days), limited-spectrum antibiotic therapy based on monotherapy seems appropriate (Table 76.8).
 - In patients with late-onset VAP (≥ 5 days) or exhibiting risk factors for MDR pathogens, a broad-spectrum antibiotic regimen based on two or three combined antibiotics is usually required (see Table 76.8).
- Initial choice should take into account:
 - Patient characteristics (underlying diseases associated with contraindications to specific antibiotic agents or classes)
 - Class of antibiotic to which the patient was recently exposed
 - Local microbiologic data (resistance patterns)
 - Recent exposure to one antibiotic could lead to resistance to entire class.

TABLE 76.8

INITIAL EMPIRIC ANTIBIOTIC THERAPY IN PATIENTS WITH VAP

Characteristics of patient	Recommended antibiotics and recommended dosages ^a
Early-onset VAP and no risk factors for MDR pathogens	<ul style="list-style-type: none"> • Ceftriaxone (1–2 g/24 h) • <i>or</i> • Levofloxacin (750 mg/24 h), moxifloxacin (400 mg/24 h), or ciprofloxacin (400 mg/8 h) <i>Or</i> • Ampicillin (1–2 g) plus sulbactam (0.5–1 g)/6 h • <i>or</i> • Ertapenem (1 g/24 h)
Late-onset VAP or risk factors for MDR pathogens	<ul style="list-style-type: none"> • Antipseudomonal cephalosporin: Cefepime (1–2 g/8–12 h) or ceftazidime (2 g/8 h) <i>Or</i> • Antipseudomonal carbapenem: Imipenem (500 mg/6 h or 1 g/8 h) or meropenem (1 g/8 h) <i>Or</i> • β-Lactam/β-lactamase inhibitor: Piperacillin-tazobactam (4.5 g/6 h) <i>plus</i> • Antipseudomonal fluoroquinolone: Levofloxacin (750 mg/24 h) or ciprofloxacin (400 mg/8 h) <i>Or</i> • Aminoglycoside^b: Gentamicin (7 mg/kg/24 h) or tobramycin (7 mg/kg/24 h) or amikacin (20 mg/kg/24 h) <i>Plus</i> • Vancomycin (15 mg/kg/12 h)^c <i>Or</i> • Linezolid (600 mg/12 h)

Adapted from American Thoracic Society, Infectious Diseases Society of America. Guidelines for the management of adults with hospital-acquired, ventilator-associated, and health care-associated pneumonia. *Am J Respir Crit Care Med.* 2005;171:388.

^aDosages are based on normal hepatic and renal function.

^bTrough levels for gentamicin and tobramycin should be <1 mg/L and for amikacin should be <4–5 mg/L.

^cTrough levels for vancomycin should be <15–20 mg/L.

- If patients develop VAP shortly after, or during, antibiotic treatment, it is recommended that an antibiotic be chosen from a different antimicrobial class for empiric treatment.
- Local epidemiologic patterns (predominant pathogens and local antibiotic susceptibility) must lead to the implementation of specific institutional guidelines for the treatment of VAP, which are of particular importance.
- In 95% of cases, routine quantitative cultures of endotracheal aspirates obtained twice a week in mechanically ventilated patients before onset of VAP identified the same microorganisms as BAL cultures are obtained when VAP was suspected.
- Thus, antibiotic choice based on the results of last available quantitative culture of endotracheal aspirate could increase adequacy of initial empiric treatment.
- Although prospective comparative studies are required to validate these results, it is possible to imagine routine cultures of ETT aspirates could also help clinician to choose most appropriate antibiotic(s) among all proposed agents.
- **De-escalation strategy**
 - A therapeutic strategy based on narrow-spectrum initial therapy, followed by a broadened-spectrum therapy once culture results are available, must be avoided.
 - Most patients suffering from VAP exhibited either a late-onset VAP or risk factors for multidrug-resistant pathogens.
- Most patients with VAP are treated with a broad-spectrum antibiotic therapy that combines two or three agents.
- The widespread use of broad-spectrum empiric therapy in the ICU may result in the emergence of MDR pathogens.
 - To preempt this vicious circle, a de-escalating strategy has been proposed.
 - Once the results of blood or respiratory tract cultures become available, strategy recommends change from a broad- to a narrow-spectrum antibiotic to which the isolated organism is sensitive as well as removing an antibiotic from an initial combination when the anticipated organism is not recovered.
 - De-escalation is possible in 31.4% of 115 patients in one study.
 - Strategy was applied to 40.7% of patients with early-onset and 12.5% of patients with late-onset VAP.
 - Obviously, a de-escalation strategy is not possible in patients without cultures.
- **Duration of therapy**
 - Prospective, multicenter, randomized, double-blind trial performed to determine whether 8 versus 15 days of antibiotic treatment equally effective
 - Patients receiving appropriate antimicrobial treatment during 8 days had neither excess mortality nor more recurrent infection than patients treated for 15 days.
 - In patients suffering from VAP due to nonfermenting gram-negative bacilli (mainly *P. aeruginosa* and *A. baumannii*), the outcome was similar in two groups, but there

was a trend to greater rates of pulmonary infection recurrences (relapses and/or superinfection) in short duration of treatment group.

- ATS/IDSA guidelines suggest shortening duration of therapy to 7 days, providing that causative pathogen is neither *P. aeruginosa* nor *A. baumannii*, and patient exhibits a good clinical response.
- Whatever treatment duration, when aminoglycosides are used in combination with other agents, they may be stopped after no more than 5 to 7 days.
- Prompt initiation of empiric antibiotic therapy is a cornerstone of VAP treatment.
- In absence of gold standard, diagnosis of VAP remains difficult.
 - Among all empirically treated patients, some will not have VAP.
 - Empiric antibiotic therapy may be safely discontinued after 72 hours when a noninfectious etiology for the pulmonary infiltrates is discovered or when signs and symptoms of active infections resolve.
 - Sterile culture of lower respiratory tract secretions rules out, absent a new antibiotic in past 72 hours, presence of bacterial pneumonia.
 - In a case such as this, withholding antibiotics is justified.
- **Specific antibiotic regimens**
- *P. aeruginosa*, *A. baumannii*, and MRSA are the main causative pathogens of VAP.
- Combination of antibiotics for *P. aeruginosa* VAP commonly used
 - Aim of combination is to achieve antibiotic synergy and prevent the emergence of resistant strains during therapy
 - While two recent meta-analyses showed that, for septic patients, combination β -lactam plus aminoglycoside compared with β -lactam monotherapy provides no clinical benefit and has no beneficial effect on development of antimicrobial resistance among initially antimicrobial-susceptible isolates, these analyses suffer from limitations that weaken the interpretation.
 - Low number of studies included in analysis
 - Heterogeneity of those studies
 - Outdated aminoglycoside administration schedules
 - These results are not sufficiently strong to justify discontinuing the use of short-term aminoglycoside- β -lactam combination therapy for *P. aeruginosa* VAP.
- Vancomycin remains standard therapy for treatment of serious infections due to MRSA.
 - Linezolid is a recent agent proposed for treatment of these infections.
 - Two multicenter studies demonstrated equivalence between linezolid and vancomycin for treatment of hospital-acquired pneumonia due to MRSA.
 - Linezolid may provide better outcome and a lower mortality than vancomycin.
 - However, results appear conflicting, and a prospective validation of the superiority of linezolid required.
 - Nevertheless, linezolid may be preferred to vancomycin in patients with or at risk for renal insufficiency.
- *A. baumannii* exhibits native resistance to many classes of antimicrobial agents and has seen the emergence of resistance to carbapenems.
 - Despite reported nephrotoxicity of polymyxins, they may be safely used.

- Safety and efficacy of intravenous colistin in patients with VAP due to *A. baumannii* resistant to carbapenems has been shown.

• Local instillation and aerosolized antibiotics

- Aminoglycosides and polymyxin B have been used for local instillation or aerosolization to treat VAP due to pathogens that are “resistant” to systemic antimicrobial agents.
- There is a lack of large or randomized prospective studies evaluating the value of these administration routes.
- Routine use of local instillation/aerosolized antibiotics not recommended.

Response to Therapy

• Normal pattern of resolution

- Improvement usually apparent only after 48 to 72 hours of adequate antibiotic therapy.
 - Unless rapid clinical deterioration, antimicrobial therapy should not be changed during this period following initiation of therapy.
- Fever and hypoxemia appear to be the best indicators to monitor response to treatment.
 - In patients without ARDS, most respond with a resolution of fever to $<38^{\circ}\text{C}$ and resolution of hypoxemia with a $\text{PaO}_2/\text{FiO}_2$ improving to >250 within first 72 hours of adequate treatment.
- For responding patients with ARDS, hypoxemia resolves more slowly and, consequently, this parameter should not be used to define the resolution of VAP.
 - Although fever takes twice as long to resolve, core temperature appears as most useful indicator of clinical response.
- Monitoring of white blood cell count not accurate to evaluate the response to therapy.
- Similarly, chest radiographs are of limited value for defining clinical improvement in VAP.
 - Initial radiograph deterioration is common.
 - However, quick radiographic resolution suggests that initial diagnosis of VAP could be erroneous.

• Reasons for deterioration or nonresolution

- When a patient fails to improve or exhibits rapid deterioration, several causes may be considered (Table 76.9).
 - When possible, antimicrobial spectrum should be broadened.
 - Careful clinical evaluation to rule out diagnostic possibilities based on differential diagnosis must be performed.
 - Sampling of respiratory tract secretions must be repeated.
 - If cultures reveal a resistant pathogen (inadequate initial empiric choice, development of resistance or superinfection with a resistant strain), an adequate antibiotic therapy must be rapidly instituted, even if such a change has a low prognostic impact.
 - If cultures do not yield a resistant pathogen, one must consider a noninfectious process, another site of infection, or occurrence of complications.
 - Vascular catheters must be removed and cultured, and blood and urine samples must be drawn for culture.
 - Radiographic procedures such as CT scanning of the thorax and, possibly, of extrathoracic sites (sinuses, abdomen) may reveal complications (e.g., lung abscess, empyema) or other infectious sites (e.g., sinusitis).
- Finally, when entire workup remains negative—including the microbiologic and radiographic evaluations for VAP,

TABLE 76.9**CAUSES OF NONRESOLUTION OR DETERIORATION IN PATIENTS WITH VAP**

Factors	Comments
Wrong initial diagnosis of VAP	<p>Many noninfectious processes can mimic VAP:</p> <ul style="list-style-type: none"> • Pulmonary embolism • Congestive heart failure • Lung contusion • Atelectasis • Chemical pneumonitis from aspiration • ARDS • Pulmonary hemorrhage
Host factors	<p>Despite adequate treatment, many conditions are known to be associated with failure:</p> <ul style="list-style-type: none"> • Underlying fatal condition • Age older than 60 yr • Prior pneumonia • Prior antibiotic treatment • Chronic lung diseases
Bacterial factors	<ul style="list-style-type: none"> • Infecting bacteria can be resistant and can acquire resistance during treatment (<i>Pseudomonas aeruginosa</i>) • Infecting pathogen can be a nonbacterial pathogen: <ul style="list-style-type: none"> • Mycobacteria • Virus • Fungus • Some pathogens, even with effective treatment, are difficult to eradicate (<i>P. aeruginosa</i>)
Occurrence of complications	<ul style="list-style-type: none"> • Complications of initial pneumonia: <ul style="list-style-type: none"> • Empyema • Lung abscess • Other sites of infection: <ul style="list-style-type: none"> • Urinary tract infection • Catheter-related infection • Sinusitis • Pseudomembranous enterocolitis • Drug fever, pulmonary embolism, and sepsis with multiple system organ failure

ARDS, acute respiratory distress syndrome.

Adapted from American Thoracic Society, Infectious Diseases Society of America. Guidelines for the management of adults with hospital-acquired, ventilator-associated, and healthcare-associated pneumonia. *Am J Respir Crit Care Med.* 2005;171:388.

with or without resistant pathogens, noninfectious processes mimicking VAP, VAP complications, or an extrapulmonary site of infection, physicians must consider the following:

- Coverage for unusual pathogens (i.e., mycobacteria, fungi)
- Need for an open-lung biopsy
- Initiation of anti-inflammatory therapy such as corticosteroids

- In one review, the main causes of nonresponsiveness were:
 - Inappropriate initial treatment (23%)
 - Superinfections (14%)
 - Another site of infection (27%)
 - Noninfectious process (16%)
 - In 36% of nonresponding patients, no cause of failure was identified.

Prognosis of VAP

- Crude mortality rates associated with VAP vary from 24% to 76%.
- Widely diverging crude mortality rates can be explained by differences both in studied populations and diagnostic criteria used.
- One of the most important concerns about VAP is to know whether it is associated with significant attributable mortality.
 - In some studies, VAP was not associated with any significant attributable mortality.
 - In others, VAP was associated with a significant attributable mortality set around 25%.
- Numerous independent prognostic factors associated with hospital mortality of patients suffering from VAP were identified.
 - Patients' underlying illnesses (malignancy, immunosuppression, anticipated death within 5 years, American Society of Anesthesiology grade 3 or more)
 - Age older than 64 years
 - Severity of disease justifying ICU admission (high APACHE II score, Simplify Acute Physiology Score >37)
 - Initial severity of VAP (chest radiographic involvement of more than one lobe, platelet count <150,000 cells/ μ L, Logistic Organ Dysfunction score >4, time of onset of VAP >3 days, surgery, or hypotension)
 - Initial therapeutic approach (delayed initial appropriate antibiotic treatment)

Prevention of Ventilator-Associated Pneumonia

- Basic infection control techniques are necessary to limit cross-contamination of resistant organisms through health care workers, such as:
 - Hand washing
 - Glove use
 - Sterile equipment
 - Adequate staffing
- Primary intervention to reduce VAP is to minimize intubation frequency and duration.
 - Noninvasive positive pressure ventilation (NIPPV) using a face mask as an alternative ventilation mode in ICU patients.
 - Associated with a relative risk reduction for VAP ranging from 0.67 to 0.87
 - When intubation is necessary, orotracheal route is preferred.
 - Strategies to reduce duration of MV, such as optimized sedation and weaning protocols, are also effective.
 - Continuous aspiration of subglottic secretions associated with relative risk reduction for VAP of 0.45
 - Semirecumbent (45-degree) patient position also reduces VAP, particularly compared to the supine position with enteral nutrition.
 - Stress ulcer prophylaxis has controversial impact on VAP.
 - Benefit offered by decreasing risks of gastric hemorrhage might outweigh increased risk of VAP.

TABLE 76.10

MEASURES RECOMMENDED BY THE CDC TO REDUCE THE INCIDENCE OF VAP

- Changing the breathing circuits of ventilators only when they malfunction or are visibly contaminated
- Preferential use of orotracheal rather than nasotracheal tubes
- Use of noninvasive ventilation
- Use of an endotracheal tube with a dorsal lumen to allow drainage of respiratory secretions

Data from Tablan OC, Anderson LJ, Besser R, et al. Healthcare Infection Control Practices Advisory Committee, Centers for Disease Control and Prevention. Guidelines for preventing health-care-associated pneumonia, 2003: recommendations of the CDC and the Healthcare Infection Control Practices Advisory Committee. *MMWR Recomm Rep*. 2004;53(RR-3):1.

- Enteral nutrition is associated with VAP, but the alternative—parenteral nutrition—carries the risk of catheter-related bacteremia.
 - Postpyloric feeding reported to reduce VAP.
- Ventilator circuit management, transfusion practices, and glycemic control are also issues that may be addressed to reduce VAP.
- The CDC published 2004 guidelines on the prevention of VAP (Table 76.10).
- ICU providers caring for immunosuppressed patients with severe neutropenia and/or allogeneic hematopoietic stem cell transplant recipients must take measures to prevent legionellosis or aspergillosis.
- Legionellosis prevention based on control of hot water system.
- Aspergillosis prevention necessitates rooms with high-efficiency particulate air filters and the use of high-efficiency respiratory protection devices (e.g., N95 respirators) by patients when they leave their rooms and/or when dust-generating activities are ongoing in the facility.
- One last highly controversial issue is use of selective digestive decontamination (SDD).
 - The subject of multiple trials using application and ingestion of topical nonabsorbed antimicrobials (usually combining polymyxin, aminoglycoside, and amphotericin B) with or without the addition of a short-duration systemic broad-spectrum antibiotic.
 - Theory is topical agents will eradicate potential pathogens (gram-negative aerobic intestinal bacteria, *S. aureus*, and fungi) but not anaerobic flora.
 - Impressive results have been recently published, with a 20% decrease in ICU mortality.
 - However, methodologic flaws (ward, no patient randomization, and unblinded trials) and an extremely low rate of drug-resistant organisms, including zero MRSA colonization, make generalization of results difficult.
 - Preventive effects of SDD for VAP are lower in ICUs with high endemic levels of antibiotic resistance, and, in such cases, SDD increases the selective antibiotic pressure and can increase incidence of drug-resistant microorganisms.
 - To date, generalized routine use of SDD in ICUs not recommended.
 - Should be decided according to patient population and ICU characteristics

HAP

- HAP defined as pneumonia occurring <2 days from hospital admission, but without any criteria defining VAP.
- Data about HAP acquired outside the ICU, treated outside the ICU, or requiring ICU admission for treatment are scarce.
- Information suggests most patients who acquired HAP in medical wards exhibited severe underlying diseases (i.e., chronic pulmonary diseases, immunosuppression) and developed HAP late during hospital stay.
- Microbiologic data demonstrate major role played by Enterobacteriaceae, *P. aeruginosa*, and MRSA, and variations in local epidemiology (Table 76.11)
- Mortality rate varies from one study to another between 18.8% and 53%.
- ATS/IDSA guidelines suggest that all patients with HAP be managed as if they were VAP cases.

HCAP and Nursing Home Pneumonia

- HCAP includes any patient:
 - Hospitalized in an acute care hospital for 2 or more days within 90 days of infection
 - Resides in nursing home or long-term care facility (LTCF)
 - Received recent intravenous antibiotic therapy, chemotherapy, or wound care within 30 days of current infection
 - Attends a hospital or hemodialysis clinic
- Most pneumonia occurring in hosts with therapeutic immunodeficiency are now classified as HCAP.
- In nursing homes, pneumonia is the leading cause of mortality, morbidity, and transfers to acute care facilities among residents.
 - Pneumonia is second most common infection in LTCFs.
 - Incidence of 0.3 to 4.7 cases per 1,000 resident-days
 - An independent risk factor for death in LTCF patients
 - Mortality in these patients ranges from 5% to 40%.
 - Coincides with mortality seen in community-dwelling patients diagnosed with pneumonia and admitted to an ICU
 - These differ in presentation due to modified host response seen in elderly.
- In older individuals, fever and respiratory signs may be minimal.
 - An altered mental status might be only evident symptom.
- Pneumonia risk factors in nursing home residents include:
 - Decreased functional status
 - Diminished ability to clear airways
 - Underlying comorbidities (such as COPD and heart disease)
 - Swallowing disorders
 - Use of sedatives
- Etiology of nursing home-acquired pneumonia remains controversial.
 - Using strict criteria, *S. pneumoniae* and *H. influenzae* are the major pathogens.
 - Gram-negative bacilli account for 0% to 12% of cases.
- The ATS/IDSA guidelines recommend that, when hospitalized, these patients be managed like those with HAP until an etiologic diagnosis is made.
- Recommendations are summarized in Tables 76.8 and 76.9.

TRACHEOBRONCHITIS

Acute Exacerbations of Chronic Obstructive Pulmonary Disease

- Acute exacerbation of COPD defined by impairment in patient's baseline dyspnea, cough, and/or sputum
- Need for ICU or special care unit admission based on severity of respiratory failure and/or presence of associated organ dysfunction (i.e., shock, hemodynamic instability, neurologic disturbances)
- Therapy in the ICU is based on supplemental oxygen, ventilatory support, bronchodilators, corticosteroids, and antibiotics.
- Role of bacterial infection in acute exacerbation of COPD remains controversial.
 - Even in the absence of symptoms of exacerbation, numerous bacteria colonize lower respiratory tract of COPD patients.
 - Bacteria colonizing lower respiratory tract vary from one patient to another, as COPD patients are heterogeneous.
 - Information provided by sputum culture does not really reflect conditions in distal airways.
 - Only half of episodes of acute exacerbations of COPD are linked to bacterial infection.
 - Animal models are limited by the fact that the most often isolated bacteria (*S. pneumoniae*, *H. influenzae*, *Moraxella catarrhalis*) are exclusively human pathogens.
 - Clinical studies addressing impact of antibiotic therapy during acute exacerbation of COPD suggest that such a treatment provides only a small improvement in the most severely ill patients.

- Despite uncertainties ATS/European Respiratory Society Task Force proposed to institute antibiotic treatment in all patients suffering from a severe acute exacerbation of COPD requiring ICU admission.
- Prospective, randomized, double-blind, placebo-controlled trial assessing effects of ofloxacin.
 - Antibiotic treatment reduced mortality rate, need for additional antibiotics in preventing occurrence of nosocomial pneumonia, and duration of mechanical ventilation and hospital stay.
- An inadequate initial antibiotic treatment increased hospital mortality and was significantly associated with failure of noninvasive ventilation, leading to secondary intubation and invasive MV.
 - Inadequacy of initial empiric treatment mainly occurred when colonizing pathogens not the usual community-acquired pathogens (*S. pneumoniae*, *H. influenzae*, *M. catarrhalis*) but were instead nonfermenting (*P. aeruginosa*) or enteric gram-negative bacilli
- Current recommendations propose an antibiotic therapy based on amoxicillin/clavulanate or respiratory fluoroquinolones (gatifloxacin, levofloxacin, moxifloxacin).
 - If *Pseudomonas* spp. or *Enterobacteriaceae* spp. are suspected, combination therapy should be considered.
 - A wide-spectrum β -lactam combined with an antipseudomonal fluoroquinolone or an aminoglycoside may be of use.
 - Finally, an ongoing study of local microbiology and susceptibility patterns by routine bacteriologic investigation in COPD patients appears the best means to provide initial adequate antibiotic treatment for acute exacerbations of COPD.

Nosocomial Tracheobronchitis

- Only a few studies have addressed nosocomial tracheobronchitis acquired during MV
 - Most recent data has potentially major limitation that studies performed in a single ICU
 - Consequently, the results may not be applicable to other units.
 - Retrospective analysis of 2,128 mechanically ventilated patients more than 48 hours
 - Incidence of nosocomial tracheobronchitis was 10.6%.
 - No significant difference between medical (9.9%; 165 of 1,655) and surgical patients (15.3%; 36 of 234)
 - In patients without underlying chronic respiratory insufficiency, incidence was 8%.
 - Delay between initiation of MV and occurrence of tracheobronchitis was up to 10 days.
 - In medical patients, nosocomial tracheobronchitis significantly associated with:
 - Age younger than 60 years (OR = 1.8)
 - COPD (OR = 1.57)
 - Receiving prior antibiotics within the 2 weeks preceding ICU admission (OR = 1.52)
 - Main pathogens identified in culture of tracheal aspirates were *P. aeruginosa*, *A. baumannii*, and MRSA.
- Impact of nosocomial tracheobronchitis on patient outcome is difficult to assess.
 - Two case-control studies comparing patients with and without nosocomial tracheobronchitis
 - In both COPD patients and in patients without chronic respiratory insufficiency, nosocomial tracheobronchitis was significantly associated with longer durations of mechanical ventilation and ICU stay.
 - Conversely, occurrence of tracheobronchitis had no significant influence on mortality rates.
 - Indications for antibiotic treatment in these patients are still debated.
 - Some physicians consider that antibiotic treatment is not justified, whereas others consider antibiotics to be useful in patients with tracheobronchitis and weaning difficulties.
 - Despite results suggesting that appropriate antibiotic treatment might reduce duration of mechanical ventilation only well-designed prospective studies will answer the question.

LUNG ABSCESS

- Can be associated with aspiration pneumonia, poor dental hygiene, alcohol consumption, or chronic lung disease
- Relatively uncommon in developed countries
 - Where it occurs mostly in immunosuppressed patients or as a postobstructive complication
- Risk factors and underlying diseases are presented in (Table 76.12).

Bacteriology of Lung Abscesses

- Predominant pathogens are considered to be anaerobes
 - Account for 60% to 80% of cases

TABLE 76.12

RISK FACTORS AND UNDERLYING DISEASES OF ADULT PATIENTS WITH COMMUNITY-ACQUIRED LUNG ABSCESS^a

References	Hammond et al. ^b	Wang et al. ^c
Number of patients	34	90
Characteristic (%)		
Smoking	ND	57%
Chronic lung disease	29%	37%
Diabetes mellitus	ND	31%
Previous aspiration pneumonia	29%	32%
Malignancy	3%	19%
Alcohol abuse	38%	14%
Dental caries	26%	ND
CNS disease	9%	11%
Chronic liver disease	ND	11%
Steroid use/SLE	9%	6%
None	12%	18%

ND, no data; CNS, central nervous system; SLE, systemic lupus erythematosus.

^aData are presented as number or percentage.

^bHammond JM, Potgieter PD, Hanslo D, et al. Etiology and antimicrobial susceptibility patterns of micro organisms in acute community-acquired lung abscess. *Chest*. 1995;108:937.

^cWang JL, Chen KY, Fang CT, et al. Changing bacteriology of adult community-acquired lung abscess in Taiwan: *Klebsiella pneumoniae* versus anaerobes. *Clin Infect Dis*. 2005;40:915.

- In a study of 34 patients with community-acquired lung abscess
 - 2.3 bacterial species per episode
 - Anaerobes were identified in 75% of cases.
 - Infection due to an aerobe observed in only 19% of cases.
- More recent studies reveal a more mixed pattern
 - Study of 90 patients with lung abscesses in Taiwan observed polymicrobial infection in only 20% of cases.
 - Gram-negative bacilli, mostly *Klebsiella pneumoniae* the most frequently isolated microorganisms (47%)
 - Anaerobes were only isolated in 31%.
 - Main bacteriologic data are reported in (Table 76.13).

Diagnosis

- Blood cultures and sputum examination are rarely positive.
- Methods to obtain a specimen uncontaminated with colonizing bacteria from upper airway preferred.
 - Percutaneous aspiration, transtracheal aspiration, or thoracocentesis from empyema fluid make isolation of both aerobic and anaerobic bacteria possible.

Treatment

- A severe disease
- Historically, death in one-third of cases when surgical resection or drainage was only available tool.

Antimicrobial Therapy

- Generally treated successfully with prolonged systemic antibiotic therapy

TABLE 76.13**PATHOGENS ISOLATED FROM ADULT PATIENTS WITH COMMUNITY-ACQUIRED LUNG ABSCESS^a**

References	Hammond et al. ^b	Wang et al. ^c
Number of patients	34	90
Number of bacteria identified	79	118
Anaerobes	59 (75%)	40 (34%)
Microaerophilic streptococci	7 (20%)	11 (12%)
<i>Prevotella</i>	17 (50%)	8 (9%)
<i>Bacteroides</i>	4 (12%)	6 (7%)
<i>Fusobacterium</i>	4 (12%)	3 (3%)
<i>Porphyromonas</i>	7 (20%)	1 (1%)
Gram-negative bacilli	3 (9%)	42 (47%)
<i>Klebsiella pneumoniae</i>	2 (6%)	30 (33%)
Gram-positive cocci	12 (35%)	30 (33%)
<i>Streptococcus milleri</i>	ND	19 (21%)
<i>Staphylococcus aureus</i>	5 (15%)	2 (2%)
<i>Viridans streptococci</i>	7 (20%)	5 (5%)
Other	5 (15%)	5 (5%)

^aData are presented as number and (percentage).^bHammond JM, Potgieter PD, Hanslo D, et al. Etiology and antimicrobial susceptibility patterns of micro organisms in acute community-acquired lung abscess. *Chest*. 1995;108:937.^cWang JL, Chen KY, Fang CT, et al. Changing bacteriology of adult community-acquired lung abscess in Taiwan: *Klebsiella pneumoniae* versus anaerobes. *Clin Infect Dis*. 2005;40:915.

- Preferred antimicrobial therapy, based on high frequency of anaerobes was clindamycin
- β -lactamase inhibitor/aminopenicillin also effective
- Both regimens obtain cure rates between 60% and 70% with a 3-week course.

Other Therapies

- Lack of improvement may necessitate drainage procedures in 10% to 20% of patients who remain symptomatic and eventually require other therapy.
- Percutaneous radiographic-guided drainage is effective in only a selected subgroup of patients.
- Reported catheter drainage times averaged 9.8 to 20.1 days.
- With range of 4 to 59 days
 - Procedure may be difficult in patients with hemostatic abnormalities.
 - Risk of soiling pleural space with abscess contents
 - Surgical resection of the diseased lung and abscess might be necessary.
 - Endoscopic drainage could be useful in patients who have an airway connection to the abscess or an endobronchial obstruction preventing drainage.

PLEURAL EMPYEMA**Pathophysiology of Pleural Infection**

- Pleural space is normally sterile.
- Pleural effusion favored by an increase in hydrostatic pressure, a decrease of oncotic pressure, or alterations of pleural permeability.

- Infection follows colonization of pleural fluid.
- Formation of an empyema arbitrarily divided into three phases:
 - An exudative phase with accumulation of pus
 - A fibropurulent phase with fibrin deposition and loculation of pleural exudate,
 - An organization phase with fibroblast proliferation leading to scar formation and lung entrapment
- In up to half of cases, empyema is a complication of pneumonia.
 - Approximately one-fourth of empyemas are due to a traumatic or iatrogenic injury (surgery, thoracentesis, chest tube placement).
 - In remaining cases, pleural infection is due to a contiguous infection (i.e., mediastinum, esophagus, subdiaphragmatic areas) extending to the pleura.

Bacteriology of Pleural Infection

- Bacterial etiology of empyema depends on underlying mechanism leading to pleural colonization.
- Three-fourths of empyemas develop as complication of pneumonia or traumatic or iatrogenic injury.
- The most isolated aerobic organisms are:
 - *Streptococcus* species
 - *S. pneumoniae*
 - *S. aureus*
- The main isolated aerobic gram-negative organisms are:
 - *Klebsiella* species
 - *P. Aeruginosa*
 - *H. Influenzae*
 - *Escherichia coli*
 - These are commonly part of mixed growths with anaerobes.
 - Anaerobic isolates are identified in 12% to 34% of cultures.
 - Can cause empyema without aerobic copathogens in about 15% of cases

Management of Patients with Pleural Infection**Identification of Pleural Effusion**

- In empyema, clinical symptoms may be nonspecific.
 - Fever
 - Chills
 - Chest pain
 - Night sweats
- Physical examination alterations may be limited to:
 - Diminished breath sounds
 - Basilar dullness to percussion
 - Pleural friction rub
 - In mechanically ventilated patients, these signs and symptoms may be less relevant.
- CXR remains the most important clue for diagnosis of pleural effusion.
 - With a volume of pleural fluid exceeding 200 mL, blunting of posterior costodiaphragmatic sulcus occurs.

- CXR can reveal a pulmonary infiltrate, which suggests possibility of a parapneumonic collection.
- Ultrasonography is particularly useful in unstable or critically ill patients, since devices are at bedside.
 - Precisely locates fluid collection and allows for a guided diagnostic aspiration
 - Some ultrasonographic characteristics (i.e., echogenicity, septations) may help distinguish empyema from transudative pleural effusion and solid mass, and may detect the presence of loculated collections.
- When diagnosis difficult, contrast-enhanced CT scan is useful to:
 - Differentiate pleural empyema from a lung abscess.
 - Detect complications of pleural infection.
 - Identify an intra- or extrathoracic focus of infection that extends to the pleura.

Indication of Pleural Fluid Sampling

- Management of pleural effusion guided by biologic characteristics of pleural fluid
- Diagnostic pleural fluid sampling is recommended in all patients exhibiting pleural effusion in association with pneumonia, recent chest surgery or trauma, or an infectious process contiguous to pleura.
- In the ICU, numerous patients develop pleural effusion without any relationship to pleural infection (i.e., hypoalbuminemia, heart failure, and atelectasis).
 - In patients at low risk of infection, pleural fluid sampling is not immediately useful in the absence of sepsis.
- Gross appearance and chemical, physical, and microscopic characteristics of pleural fluid must be determined.
 - pH, lactic dehydrogenase (LDH) and glucose levels, and white blood cell count must be measured.
 - An appropriate microscopic examination of stained smears and cultures of pleural fluid must be performed.
 - Empyema usually has:
 - A pH value <7.0
 - An LDH level >1,000 IU/L
 - A glucose level <40 mg/dL
 - Positive Gram stain and/or culture
- In patients with parapneumonic pleural effusions, gross appearance and biologic characteristics of pleural fluid can differentiate simple parapneumonic from complicated parapneumonic effusion and empyema, and guide management
 - In simple parapneumonic effusion:
 - Macroscopic appearance reveals a clear fluid
 - pH is >7.2.
 - LDH level is <1,000 IU/L.
 - Glucose level is >40 mg/dL.
 - No organism is identified on Gram stain and culture.
 - In complicated parapneumonic effusion:
 - Pleural fluid is clear, cloudy, or turbid.
 - pH is <7.2.
 - LDH level is >1,000 IU/L.
 - Glucose level is >40 mg/dL.
 - Gram stain and/or culture are positive
 - In empyema, macroscopic examination reveals frank pus exhibiting biologic characteristics described earlier.
- **Antibiotics:** As soon as pleural infection is diagnosed, antibiotic treatment must be started.
 - When pleural fluid cultures are positive, antibiotics must be chosen according to organisms identified and sensitivities.
 - Penicillins and cephalosporins exhibit good penetration into pleural space.
 - Drugs of choice for treating empyemas due to *Streptococcus* sp. and *S. pneumoniae*.
 - Nafcillin is the drug of choice for MRSA infection.
 - Third-generation cephalosporins and carbapenems are preferred choices in case of empyema due to gram-negative aerobic bacilli.
 - Infections due to MRSA and penicillin- and cephalosporin-resistant *S. pneumoniae* are treated with vancomycin.
 - Aminoglycosides are avoided, as penetration into pleural space is poor and they lose their activity in acid pleural fluid.
 - When anaerobic organisms are causative pathogens, a β -lactam combined with a β -lactamase inhibitor, imipenem, metronidazole, and clindamycin are drugs of choice.
 - When cultures are negative, antibiotics must be chosen according to likely causative organisms.
 - Choice depends on mechanism of empyema.
 - Origin of infection (community acquired *versus* hospital acquired)
 - Local hospital policy
 - BTS guidelines suggest following empirical antibiotic regimens:
 - In community-acquired infection, second- and third-generation cephalosporins, amoxicillin, β -lactam- β -lactamase inhibitor combination, meropenem, clindamycin, and benzyl penicillin combined with quinolone may be proposed.
 - In hospital-acquired infection, such as empyema following a nosocomial pneumonia or recent chest surgery, antibiotics should cover both gram-positive and gram-negative aerobes and anaerobes.
 - Antipseudomonal penicillins (piperacillin-tazobactam, ticarcillin-clavulanic acid), carbapenems, and third-generation cephalosporins combined with vancomycin may be used.
 - Duration of antibiotic treatment remains controversial because specific clinical trials are absent.
 - Recent BTS guidelines suggest duration of 3 weeks is probably appropriate.
- **Chest tube drainage:** Prompt chest tube drainage is indicated in patients with frankly purulent or turbid/cloudy pleural fluid on sampling.
 - Pleural fluid pH <7.2 and the presence of pathogens identified by Gram stain or culture of nonpurulent pleural fluid require prompt chest tube drainage.
 - If despite appropriate antibiotic treatment, clinical improvement is poor or when radiologic investigations demonstrate the presence of a loculated pleural collection, chest tube drainage may be suggested.
 - No consensus about the optimal size of chest tube or about efficacy of intrapleural fibrinolytic drugs
 - Randomized, double-blind trial compared intrapleural streptokinase (250,000 IU twice daily for 3 days) to placebo among 427 patients.

Treatment

- Treatment of empyema requires adequate antimicrobial therapy, drainage of pus, and re-expansion of the lung.

- Streptokinase did not reduce mortality, need for drainage surgery, or duration of hospital stay, and it did not improve radiographic and spirometric outcomes.
- Meta-analysis does not support routine use of fibrinolytic treatment for patients requiring chest tube drainage for empyema or complicated parapneumonic effusion.
- **Surgical treatment:** Must be considered in all patients exhibiting persisting sepsis associated with continuous pleural col-

lection despite being appropriately treated with antibiotics and chest tube drainage

- Choice between video-assisted thoracoscopic surgery, open thoracic drainage, or thoracotomy with decortication depends on:
 - Patient status (age, comorbidity)
 - Surgical preferences
 - Anatomy of pleural effusion assessed by recent thoracic CT scanning

CHAPTER 77 ■ ADULT GASTROINTESTINAL INFECTIONS IN THE ICU

- Diarrhea occurs in close to one occurrence per person per year in the United States.
- Varies from short-lasting mild illness to various more serious enteric syndromes
 - Include watery diarrhea with dehydration, febrile dysentery, and gastroenteritis with sepsis
- Usually acquired by exposure to contaminated food, water, or the environment
 - Foodborne enteric diseases estimated to cause:
 - Approximately 76 million cases of illness
 - 325,000 hospitalizations
 - 5,000 deaths in the United States
 - Known pathogens account for:
 - Estimated 14 million cases of illnesses
 - 60,000 hospitalizations
 - 1,800 deaths
- Diarrhea has two important definitions:
 - Increase in normal frequency of stools associated with decrease in form
 - Progressing from formed stools to those showing a watery or loose (soft) consistency
 - Passage of more than 200 g/day of unformed stool in an adult on standard Western diet
- Divided into three stages based on duration:
 - *Acute* (≤ 14 days)
 - *Persistent* (≥ 14 days)
 - *Chronic* (≥ 30 days)
 - Cause of the illness is different in the three groups
 - Viruses, bacteria, and toxins explain most acute episodes (Table 77.1)
 - Parasitic agents more involved in persistent cases (Table 77.1)
 - Noninfectious causes characteristically associated with chronic diarrhea
 - Severity of diarrhea determined according to a functional definition:

- Mild—requires no change in activities
- Moderate—requires a change in activities but doesn't disable
- Severe—disables, usually confining affected person to bed; usually leads to hospitalization

ETIOLOGY OF ACUTE DIARRHEA IN THE UNITED STATES

- Community-acquired, acute infectious diarrhea is caused by various organisms (see Table 77.1).
- Bacterial causes include various *Escherichia coli* species.
 - Enterotoxigenic (ETEC)
 - Enteropathogenic (EPEC)
 - Shigatoxin-producing (STEC) including *E. coli* O157:H7
 - Enteroinvasive (EIEC)
- In the community, most common causes of diarrhea are viral.
 - Noroviruses being most important
 - Usually mild and require no specific treatment
 - Varies with season
 - More viral cases in spring and winter
 - More bacterial cases in summer and spring
- Etiology of diarrheal cases presenting to a hospital and hospital-acquired diarrhea different from community-based diarrhea
 - More severe compared to community diarrhea
 - Causative agent may be a bacterial (most common), parasitic, or viral (rarely)
 - May be due to bacteria (*Clostridium difficile* or *Salmonella*), viruses (rotavirus, noroviruses), or fungi (*Candida albicans*), or most commonly to noninfectious agents

TABLE 77.1
POTENTIAL ETIOLOGIC AGENTS IN PATIENTS WITH ACUTE DIARRHEA

Viral	Bacterial	Protozoal
Noroviruses	<i>Shigella</i> sp.	<i>Entamoeba histolytica</i>
Rotavirus	<i>Salmonella</i> sp.	<i>Giardia lamblia</i>
Cytomegalovirus	<i>Vibrio cholerae</i>	<i>Cryptosporidium</i>
	<i>Clostridium difficile</i>	<i>Cyclospora</i>
	<i>Campylobacter jejuni</i>	<i>Isospora</i>
	<i>Staphylococcus aureus</i>	<i>Microsporidia</i>
	<i>Bacillus cereus</i>	
	Shigatoxin-producing <i>E. coli</i> (STEC)	
	Enteropathogenic <i>E. coli</i> (EPEC)	
	Enteraggregative <i>E. coli</i> (EAEC)	
	Enterotoxigenic <i>E. coli</i> (ETEC)	
	<i>Aeromonas</i>	
	<i>Plesiomonas</i>	
	<i>Yersinia</i> sp.	
	<i>Clostridium perfringens</i>	
	Non-cholera <i>Vibrio</i>	

EVALUATION OF THE PATIENT WITH SEVERE DIARRHEA

Emergency Department

- First priority is to evaluate vital signs and hydration status of patient.
- Second, electrolyte disturbances need to be sought and corrected.
- Primary concern to immediately reverse circulatory or organ failure resulting from loss of fluid and salt
- Diagnostic investigations for identifying causative agent done simultaneously or after stabilization of patient.
 - Epidemiologic history and clinical features may provide clues to diagnosis.
 - Travel to an economically developing country suggests a bacterial cause.
 - A person receiving antibacterial or chemotherapeutic drugs may have *C. difficile*.
 - Proctitis in a male with history of having gay sex suggests sexually transmitted pathogens including *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, herpes simplex, or *Treponema pallidum*.
 - Figure 77.1 provides an algorithm to identify steps in patient workup.
- Laboratory studies will help establish the diagnosis.
 - Fecal leukocytes indicates patient has diffuse colonic inflammation.
 - Occult blood in stool supports inflammatory type of diarrhea.
 - Gross blood passed in stool may indicate dysenteric pathogen including:
 - *Shigella*
 - *Campylobacter*
 - Shigatoxin-producing *E. coli* (often *E. coli* O157:H7)
 - *C. difficile*
 - Stool cultures, parasite examination, or toxin test for *C. difficile* may help define cause of illness.

- Characteristics requiring aggressive and thorough laboratory workup are fever >102°F with systemic findings suggesting presence of sepsis.
- Useful to categorize diarrhea into one of two physiologic classifications
 - Noninflammatory and inflammatory (Table 77.2)
 - Subcategory of inflammatory is hemorrhagic or dysenteric diarrhea

Hospital-Acquired Diarrhea

- Diarrhea developing 3 days or longer after admission considered health care associated.
 - Between 10% and 30% of nosocomial diarrhea due to *C. difficile*
 - Other important causes of nosocomial diarrhea include antibiotics, chemotherapeutic agents, proton pump inhibitors, tube feedings, laxatives, other drugs, and various iatrogenic and idiopathic conditions.
 - Always appropriate in hospital-associated diarrheas, when patient receiving antibacterial treatment, to consider *C. difficile* as causative agent.
 - Empiric treatment advisable in more severe cases while laboratory tests pending
 - Other pathogens rarely found in hospital-associated diarrhea.
 - Including rotaviruses in pediatric wards, noroviruses, and *Salmonella* spp.

The International Traveler

- Incidence of traveler's diarrhea (TD) ranges from 13.6% to 54.6% in high-risk regions and approximately 4% in low-risk regions.
- Various parts of world classified into three different groups: low, intermediate, and high risk, based on the frequency of TD in the traveling public

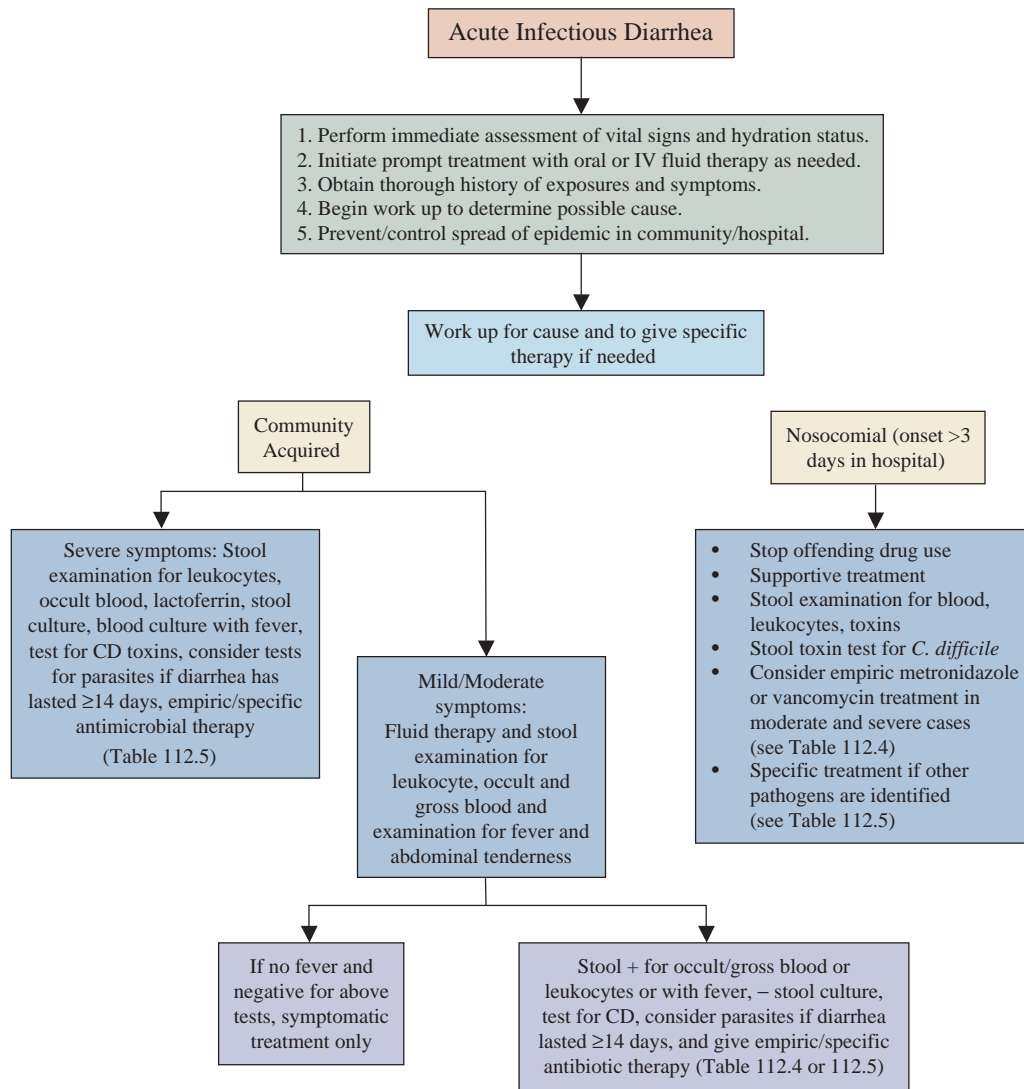

FIGURE 77.1. Flow chart showing approach to a patient with acute infectious diarrhea.

- Important causes of TD are ETEC, EAEC, noroviruses, *Campylobacter*, *Shigella*, and *Salmonella*
- Less commonly, parasitic agents cause TD and should be suspected in persistent illness.
 - Important parasitic pathogens in persistent TD include *Giardia*, *Cryptosporidium*, and *Cyclospora*.

The Immunosuppressed Patient

- Patient with congenital or acquired immunodeficiency, HIV/AIDS, or receiving immunosuppressive or cancer chemotherapy drugs will have increased susceptibility to diarrhea.

TABLE 77.2

CLASSIFICATION OF ACUTE DIARRHEA BASED ON FINDINGS OF FECAL MARKERS OF INFLAMMATION (LEUKOCYTES OR LACTOFERRIN) OR PRESENCE OF GROSS FECAL BLOOD

Types of diarrhea	Possible causes	Measures to be taken
Noninflammatory (negative for inflammatory markers or dysentery)	Toxin-mediated, viral, noninvasive pathogens like <i>Vibrio cholerae</i> , ETEC	Oral/IV fluid replacement and empiric therapy if required
Invasive, cytotoxic, or enterohemorrhagic (positive for inflammatory markers or presence of dysentery)	<i>Shigella</i> , <i>Salmonella</i> , STEC, <i>Entamoeba histolytica</i> , <i>Giardia</i> , <i>Campylobacter</i> , <i>Clostridium difficile</i>	Oral/IV fluid therapy based on hydration status and thorough laboratory investigations with specific antibiotic therapy if indicated ^a

ETEC, enterotoxigenic *E. coli*; STEC, Shigatoxin-producing *E. coli*.

^aSpecific therapies are listed in Table 77.5

- Etiology of diarrheal diseases in immunocompromised hosts different from other populations in that they are at risk of developing infections from various opportunistic organisms in addition to routine diarrheal pathogens
- Use of various chemotherapy drugs or immunomodulators such as cyclosporine, mycophenolate mofetil, tacrolimus, or sirolimus results in drug-induced diarrhea
- Diarrhea in transplant recipients can also be due to graft-versus-host disease (GVHD)
- Various organisms to consider as causes of diarrhea in this group of patients include *Clostridium difficile*, *Salmonella enterica*, noroviruses, *Cryptosporidium*, *Isospora*, *Cyclospora*, cytomegalovirus, and *Mycobacterium avium intracellulare* complex.
- Rapid diagnostic tests include:
 - Direct stool examination for ova, cysts, and parasites
 - Stool test for *C. difficile* toxin
 - Polymerase chain reaction (PCR) for cytomegalovirus or herpesvirus
 - Stool and blood cultures
- If aforementioned tests do not provide specific diagnosis, endoscopy and mucosal biopsy are pursued to establish etiologic diagnosis.

The Patient with Extraintestinal Disease

- Blood cultures, computed tomography of abdomen, and serology (for *Entamoeba histolytica*) may help determine primary cause of disease.
- In sepsis, blood cultures and stool studies may provide diagnosis.
- Systemic complications often seen with invasive bacterial and parasitic infections
 - Systemic complications of enteric infection include:
 - Hemolytic uremic syndrome (HUS) or thrombotic thrombocytopenic purpura (TTP)
 - Guillain-Barré syndrome
 - Sepsis
 - Infective endocarditis
 - Abdominal abscesses or localized abscess elsewhere
 - Pyogenic arthritis
- In immunocompromised patients with diarrhea, systemic complications can occur with any etiologic agent

- Antimotility drugs **should not** be used in inflammatory diarrhea.
- Amoebiasis—uncommon in the United States—shows extended spectrum of extraintestinal complications including liver abscess and disseminated infection.

MANAGEMENT OF ACUTE DIARRHEA

Dehydration

- Defined as excess loss of body fluids resulting in fluid and electrolyte abnormalities
- Classifications of dehydration are provided in Table 77.3.
- Dry skin and mucous membranes, sunken eyes, decreased urine output, loss of skin turgor, dizziness/light-headedness all manifestations of moderate to severe dehydration
- The most common serious complication of diarrhea and should be promptly recognized and managed
- Routine testing of electrolytes in patients with severe diarrhea of proven value
- Rehydration done, depending on severity of dehydration, either by oral or IV route
 - Oral rehydration salt (ORS) solution used in mild or moderate dehydration
 - Also for maintenance of hydration after IV fluid administration in severe dehydration
 - Standard or reduced osmolarity (low-salt) ORS formulations preferable where available
 - When due to cholera, reduced-osmolarity ORS may lead to subclinical reduction of body electrolytes, making standard ORS preferable here
 - In the United States, ORS is not readily available, but Pedialyte or Ricelyte is used to maintain hydration and treat minor degrees of dehydration.
 - Specific fluid replacement strategies based on severity are described in Table 77.3.

Dysentery

- Diagnosis when subjects are passing grossly bloody stools
- Historically classified as bacillary dysentery (shigellosis) versus amoebic dysentery

TABLE 77.3

CLASSIFICATION OF DEHYDRATION IN A PATIENT WITH ACUTE DIARRHEA

Dehydration	Symptoms	Suggested management
Mild dehydration	3%–5% loss in body weight	Increased thirst and slightly dry mucous membranes
Moderate dehydration	6%–9% loss in body weight	Loss of skin turgor, dry mucous membranes, tenting of skin
Severe dehydration	≥10% loss in body weight	Lethargy, altered consciousness, prolonged skin retraction time, cool extremities, decreased capillary refill
		Oral rehydration solution (ORS) 50 mL/kg over first 2–4 h ORS 100 mL/kg over first 2–4 h Immediate IV fluid replacement with 20 mL/kg of lactated Ringer solution to restore perfusion and mental status. Continue with 100 mL/kg ORS or IV 5% dextrose and 0.45% saline solution at two times the maintenance rate.

From Duggan C, Santosham M, Glass RI. The management of acute diarrhea in children: oral rehydration, maintenance, and nutritional therapy. Centers for Disease Control and Prevention. *MMWR Recomm Rep.* 1992;41(RR-16):1–20; and King CK, Glass R, Bresee JS, et al. Managing acute gastroenteritis among children: oral rehydration, maintenance, and nutritional therapy. *MMWR Recomm Rep.* 2003;52(RR-16):1–16, with permission.

TABLE 77.4

EMPIRIC ANTIMICROBIAL THERAPY OF ACUTE DIARRHEA

Indication	Recommended therapy
Febrile dysentery: Fever (temperature >100.2°F [>38°C]) plus dysentery (passage of grossly bloody stools)	Azithromycin, 500 mg PO daily for 3 days
Moderate to severe traveler's diarrhea with fever and dysentery	Azithromycin, 500 mg PO daily for 3 days
Moderate to severe traveler's diarrhea without fever and dysentery	Rifaximin, 200 mg tid for 3 days; ciprofloxacin, 500 mg bid for 3 days; or levofloxacin, 500 mg once a day for 3 days; or azithromycin, 500 mg once a day for 3 days
Severe hospital-acquired diarrhea in a patient with comorbidity and prior receipt of antibacterial therapy	Oral metronidazole, 500 mg tid for 10 days; or vancomycin, 125–500 mg qid for 10 days
bid, twice a day; PO, orally; qid, four times a day; tid, three times a day.	

- Bacillary dysentery is also caused by several invasive pathogens in addition to *Shigella* spp. including *Campylobacter*, *Clostridium difficile*, STEC, and *Salmonella*.
- Specific cause should be established followed by specific treatment.
 - Empiric and specific antibiotic treatments are provided in Tables 77.4 and 77.5.

***Clostridium difficile* (CD) Diarrhea and Colitis**

- CD first identified as causative agent of antibiotic-associated diarrhea in early 1970s
 - Then was associated with clindamycin use
 - A gram-positive, spore-forming anaerobic bacteria producing enterotoxin known as toxin A and a cytotoxin called toxin B

TABLE 77.5

SPECIFIC THERAPY FOR PATHOGEN-SPECIFIC DIARRHEA, ONCE ETIOLOGIC DIAGNOSIS IS ESTABLISHED

Identified pathogen	Suggested antimicrobial therapy
<i>Clostridium difficile</i>	Oral metronidazole, 500 mg tid for 10 days; or vancomycin, 125–500 mg qid for 10 days (newer therapies being evaluated including nitazoxanide, rifaximin, and <i>Saccharomyces</i>)
<i>Salmonella</i> sp. (treat only for suspected sepsis based on presence of high-risk host*)	For high-risk host ^a : Fluoroquinolones: ciprofloxacin, 500 mg bid; or levofloxacin, 500 mg once a day for 7 to 10 days
<i>Shigella</i>	Fluoroquinolones, dose as in <i>Salmonella</i> above, give for 3 days
<i>Campylobacter</i>	Azithromycin, 500 mg once a day for 3 days; or erythromycin, 500 mg bid for 5 days
Shigatoxin-producing <i>E. coli</i> (STEC)	No antimotility drugs, antibiotic treatment not usually given as they may increase the risk of occurrence of hemolytic uremic syndrome (HUS)
Enterotoxigenic <i>E. coli</i> (ETEC)	Rifaximin, 200 mg tid for 3 days; fluoroquinolone in above dose for 3 days; or azithromycin, 500 mg once a day for 3 days.
Enteropathogenic <i>E. coli</i> (EPEC)	Same as <i>Shigella</i>
Enteraggregative <i>E. coli</i> (EAEC)	Same as ETEC
Enteroinvasive <i>E. coli</i> (EIEC)	Same as <i>Shigella</i>
<i>Vibrio</i> spp. (<i>Vibrio cholerae</i> or noncholera <i>Vibrios</i>)	Tetracycline, 500 mg qid for 3 days; or 300 mg doxycycline, single 100 mg dose for adults
<i>Aeromonas/Plesiomonas</i>	Same as <i>Shigella</i>
<i>Yersinia</i>	Same as <i>Shigella</i>
<i>Entamoeba histolytica</i>	Metronidazole, 750 mg tid for 5–10 days and diloxanide furoate, 500 mg tid for 10 days; or paromomycin, 500 mg tid for 10 days
<i>Giardia</i>	Metronidazole, 250–750 mg tid for 7–10 days; tinidazole, 2 g as a single dose
<i>Cryptosporidium</i>	Nitazoxanide, 500 mg bid for 3 days; in HIV/AIDS or immunosuppressed patients nitazoxanide, 500/1,000 mg bid for 14 days or more. Paromomycin, 500 mg qid for 7–14 days; or spiramycin, 3 g/day for up to 1 week
<i>Cyclospora</i>	TMP–SMX, 160 and 800 mg, respectively, bid for 7 days; in AIDS patients, TMP–SMX treatment is given for 14 days followed by 3 times weekly for up to 10 weeks
<i>Isospora</i>	TMP–SMX, 160 and 800 mg, respectively, bid for 7 days; in AIDS patients, treatment is followed by thrice weekly TMP–SMX for up to 10 weeks
<i>Microsporidium</i>	Albendazole, 400 mg bid for 7 days and for 4 weeks in immunocompromised patients
<i>Cytomegalovirus</i>	In immunocompromised patient, ganciclovir, 5 mg/kg bid for 14 days

bid, twice a day; ETEC, enterotoxigenic *E. coli*; qid, four times a day; tid, three times a day; TMP–SMZ, trimethoprim-sulfamethoxazole.

^aHigh-risk patients for *Salmonella* enterica species (nontyphoid *Salmonella*): Any subject who is toxic with fever >102°F (39°C), age <3 months or 65 years of age or greater, and subjects with malignancy or AIDS, on steroids, with inflammatory bowel disease or renal failure, or undergoing hemodialysis, with hemoglobinopathy such as sickle cell disease. Patients with simple gastroenteritis are best not given antibacterial drugs.

- A third type of toxin produced, called binary toxin, which is an actin-specific ADP ribosylating toxin
- Toxin A causes necrosis, increased intestinal permeability, and inhibition of protein synthesis
- Toxin B thought to become effective once gut wall damaged
- Increased virulence of CD strains presumably associated with higher levels of toxin production by a fluoroquinolone-resistant CD strain variably classified as PCR ribotype 027, pulsed-field gel electrophoresis (PFGE) type NAP1, restriction endonuclease analysis (REA) type BI, and toxin type III
- Incidence of CD acute diarrhea (CDAD) rising due to excess use of antibiotics and emergence of resistant and more virulent strains
- Nosocomial CDAD increasing in ICUs of large and hospital-wide in smaller hospitals
- Rise nearly doubled from the years 1996 to 2003.
- Disproportionately increased in elderly population
- Conservative estimate of cost of disease in the United States is \$1.1 billion per year.
 - With 54% increase in individual adjusted hospital costs
 - Extension of hospital stay by 3.6 days for each affected person
 - Normal hospital surveillance of CDAD identifies half of affected patients.
 - Real burden of CDAD seems to be much more than estimated.
- Major risk factors for CDAD include:
 - Antimicrobial use
 - Age older than 65 years
 - Severity of existing health condition
 - Use of other drugs such as chemotherapeutic agents and proton pump inhibitors
 - Renal insufficiency
 - Gastrointestinal surgery
 - In CDAD, advanced age and comorbidity, plus severity of underlying impairment, predict frequency of infection and outcome
- Associated risk factors for CDAD should be considered
 - Low albumin level (<2.5 g/dL)
 - Recent admission to a health care institution
 - Use of proton pump inhibitors
 - In nonhospitalized patients with other predisposing conditions such as cancer, prolonged antibiotic use is a recognized risk factor for CDAD.
 - Especially with first-generation cephalosporins, fluoroquinolones, or clindamycin
- Recurrence very common in CDAD
- Estimated that 15% to 30% of patients have recurrent illness after initial treatment
 - Include both reinfections with new strains and relapse of original infecting strain
 - 56% of recurrences due to reinfection
 - Risk factors for early recurrence of CDAD are:
 - Renal failure
 - White blood cell counts >15,000 cells/ μ L with the initial episode
 - Community-acquired CDAD with first episode
 - Failure to mount a serum antibody response to toxin A during an initial episode of CDAD
- Diagnosis of CDAD based on clinical and laboratory findings
 - Customary way to make diagnosis is to recover a toxigenic strain of CD through microbiologic culture or to detect

one or both of the known CD toxins, A and B, in stool samples

- Stool toxin studies include commercial tissue culture cytotoxin assay for toxin B or an enzyme immunoassay (EIA) for one or both of toxins
- In a highly probable clinical case with severe disease or fragile clinical picture often advisable to initiate prompt empiric treatment
- Colonoscopy considered in patients in whom diagnosis not obvious, after initial screening, when there are extraintestinal complications, and in those not responding to empiric treatment

Treatment

- Prompt diagnosis and treatment important to management of CDAD (see Table 77.5)
 - Cessation of causative antibiotic use if possible
 - Initiation of either oral metronidazole (first-line therapy) or oral vancomycin for 10 days is standard practice.
 - Vancomycin may be slightly more effective than metronidazole.
 - Both metronidazole and vancomycin used in treatment of recurrent CD diarrhea
 - Independent predictors of second recurrence are age and duration of hospitalization after first recurrence.
 - Strategies for treating recurrent CD diarrhea or colitis include:
 - Repeating antibiotics either with metronidazole or vancomycin, with tapering of antibiotic dose after a 10-day standard and administering the drug for 2 months or longer
 - Use of probiotics (*Saccharomyces boulardii*) along with high-dose (500 mg four times a day) vancomycin
 - *Saccharomyces* reduces risk of recurrence by 50%
 - Use of IVIG
 - If more than one recurrence, various drugs used for prolonged therapy including:
 - Vancomycin
 - Rifaximin
 - *Saccharomyces*
 - Other useful approaches include the restoration of normal colonic flora by fecal enema or by nasogastric tube administration
 - Surgical management of CDAD done after failure of medical therapy or if life-threatening complications occur, including colonic perforation, peritonitis, or bowel infarction

Diarrhea Epidemics in the Hospital

- Early identification and controlling spread of rare hospital epidemics of enteric disease keys to successful management
 - Universal protocols of isolation and personal hygiene measures important
 - Putting infected persons in contiguous areas away from uninfected persons
 - Using dedicated hospital personnel for their care an important strategy
 - Judicious use of antibiotics in hospital and prompt discontinuation of possible inciting drugs also helpful
 - Agents showing potential for epidemics in hospitals are:
 - *C. difficile*
 - *Salmonella* spp.

- *Shigella*
- *Campylobacter*
- *Vibrio*
- *Aeromonas*
- *Yersinia*
- Noroviruses, and rotavirus
- Early therapy of treatable enteric pathogens should occur (see Table 77.5).

Prevention of Diarrhea in the Hospital

- Appropriate use of antibiotics in hospitalized patients
 - With use of narrowest-spectrum antibiotics safely possible to minimize disruption of gut flora should prevent cases of CDAD

- Additionally *Saccharomyces* has been used to prevent CDAD
- Enteric isolation practices for patients with enteric infection in hospital helps prevent spread of diarrhea and lowers incidence
- Effective and widespread hand washing with soap and water
 - Note that alcohol-based hand cleaners not effective against *C. difficile*.
- Meticulous environmental cleaning with chlorine-based bleach products in clinical settings where *C. difficile*-infected patients have been housed proven to prevent spread of infections in hospital

CHAPTER 78 ■ CATHETER-ASSOCIATED URINARY TRACT INFECTIONS IN THE ICU: IMPLICATIONS FOR CLINICAL PRACTICE

- ICUs represent a meeting point between:
 - Most seriously ill patients receiving aggressive therapy
 - Most resistant pathogens that are selected by the use of broad-spectrum antimicrobial therapy
 - Most patients in ICUs receive an indwelling urinary catheter to monitor urine output
 - Urinary tract infection (UTI) remains a leading cause of nosocomial infections with significant morbidity, mortality, and, hence, additional hospital costs.
- UTIs represents 30% to 40% of nosocomial infections.
 - Prevalence in patients admitted to the ICU is approximately 20%.
 - UTIs are the third most common cause of nosocomial infections in the ICU.
 - Incidence of urosepsis:
 - Defined as an inflammation of upper urinary tract that causes sepsis
 - Occurs in approximately 16% of the ICU patient population

DEFINITIONS

- CDC definitions of symptomatic UTIs and asymptomatic UTIs are collected in Tables 78.1 through 78.3
- In the ICU, UTI is consequence of placement of an indwelling catheter.
 - This results in the concept of *catheter-associated UTI*.
 - Definition of which is restricted to the presence of bacteria in the bladder of a patient with an indwelling catheter

- Bacteriuria is defined as the detection of $\geq 10^5$ microorganisms per milliliter of urine with no more than two species of organisms.
- Contrary to non-ICU-acquired UTIs, this definition does not take into account the clinical symptoms.

PATHOPHYSIOLOGY

- Except for the distal urethra, the urinary tract is normally sterile.
- Resistance to UTI is influenced by:
 - Exposure to uropathogenic bacteria
 - Age
 - Hormonal status
 - Urine flow
- Insertion of a catheter allows organisms to gain access to bladder.
 - Catheter induces an inflammation of the urethra.
 - Allows bacteria to ascend into bladder in space between urethral mucosa and catheter
 - Catheter-associated UTI usually follows the formation of biofilm.
 - Consists of adherent microorganisms, their extracellular products, and host components deposited on both the internal and external catheter surfaces
 - Biofilm protects organisms from antimicrobials and host immune response.
 - Ascending route of infection is predominant in women.
 - Owing to their short urethra and contamination with anal flora

TABLE 78.1

DEFINITIONS FOR SYMPTOMATIC UTIs

At least one of the following criteria:

Criterion 1

Patient has at least one of the following signs or symptoms with no other recognized cause: fever ($>38^{\circ}\text{C}$), urgency, frequency, dysuria, or suprapubic tenderness, *and* patient has a positive urine culture with $\geq 10^5$ microorganisms/mL of urine with no more than two species of microorganisms.

Criterion 2

Patient has at least one of the following signs or symptoms with no other recognized cause: fever ($>38^{\circ}\text{C}$), urgency, frequency, dysuria, or suprapubic tenderness *and at least one of the following*: (a) positive dipstick for leukocyte esterase and/or nitrate; (b) pyuria (urine specimen with 10 white blood cells (WBC)/ μL or ≥ 3 WBC/high-power field of unspun urine); (c) organisms seen on Gram stain of unspun urine; (d) at least two urine cultures with repeated isolation of the same uropathogen (gram-negative bacteria or *Staphylococcus saprophyticus*) with $\geq 10^2$ colonies/mL in nonvoided specimens; (e) $\leq 10^5$ colonies/mL of a single uropathogen (gram-negative bacteria or *S. saprophyticus*) in a patient being treated with an effective antimicrobial agent for a urinary tract infection; (f) physician diagnosis of a urinary tract infection; or (g) physician institutes appropriate therapy for a urinary tract infection.

Criterion 3

Patient ≤ 1 year of age with *at least one of the following signs or symptoms with no other recognized cause*: fever ($>38^{\circ}\text{C}$), hypothermia ($<37^{\circ}\text{C}$), apnea, bradycardia, dysuria, lethargy, or vomiting *and* positive urine culture with $\geq 10^5$ microorganisms/mL of urine with no more than two species of microorganisms.

Criterion 4

Patient ≤ 1 year of age with *at least one of the following signs or symptoms with no other recognized cause*: fever ($>38^{\circ}\text{C}$), hypothermia ($<37^{\circ}\text{C}$), apnea, bradycardia, dysuria, lethargy, or vomiting *and* (a) positive dipstick for leukocyte esterase and/or nitrate; (b) pyuria (urine specimen with 10 WBC/ μL or ≥ 3 WBC/high-power field of unspun urine); (c) organisms seen on Gram stain of unspun urine; (d) at least two urine cultures with repeated isolation of the same uropathogen (gram-negative bacteria or *S. saprophyticus*) with $\geq 10^2$ colonies/mL in nonvoided specimens; (e) $\leq 10^5$ colonies/mL of a single uropathogen (gram-negative bacteria or *S. saprophyticus*) in a patient being treated with an effective antimicrobial agent for a urinary tract infection; (f) physician diagnosis of a urinary tract infection; or (g) physician institutes appropriate therapy for a urinary tract infection.

From Garner JS, Jarvis WR, Emori TG, et al. CDC definitions for nosocomial infections, 1988. *Am J Infect Control*. 1988;16:128.

- Internal route of contamination (i.e., through lumen of catheter) less frequent
 - Related to reflux of pathogens from drainage system into bladder
 - Occurs when the drainage system fails to close or with contamination of urine in the collection bag

MICROBIOLOGY

- Isolated pathogens in ICU patients with bacteriuria are essentially relatively few (Table 78.4):

- *Escherichia coli*
- *Pseudomonas aeruginosa*
- *Enterococcus* species
- Polymicrobial infections represent a relatively small percentage—5% to 12%—of total infections.
- In nosocomial infections in ICU patients:
 - Gram-negative bacteria caused 71% of UTIs.
 - With stability over a 17-year period of surveillance
 - Resistance to antimicrobials increased during this period.
 - With rates of resistance to third-generation cephalosporins up to 20% for *E. coli*
 - Cross-transmission probably plays a much greater role than suggested at present.

TABLE 78.2

DEFINITIONS FOR ASYMPTOMATIC UTIs

One of the following criteria:

Criterion 1

Patient has had an indwelling urinary catheter within 7 d before the culture *and* patient has a positive urine culture with $\geq 10^5$ microorganisms/mL of urine with no more than two species of microorganisms and patient has no fever ($>38^{\circ}\text{C}$), urgency, frequency, dysuria, or suprapubic tenderness.

Criterion 2

Patient has not had an indwelling urinary catheter within 7 d before the first positive culture and patient has had at least two positive urine cultures with $\geq 10^5$ microorganisms/mL with repeated isolation of the same microorganism and no more than two species of microorganisms and patient has no fever ($>38^{\circ}\text{C}$), urgency, frequency, dysuria, or suprapubic tenderness.

From Garner JS, Jarvis WR, Emori TG, et al. CDC definitions for nosocomial infections, 1988. *Am J Infect Control*. 1988;16:128.

TABLE 78.3

OTHER UTIs

One of the following criteria:

Criterion 1

Patient has organisms isolated from culture of fluid (other than urine) or tissue from affected site.

Criterion 2

Patient has an abscess or other evidence of infection seen on direct examination, during surgical operation, or during a histopathologic examination.

Criterion 3

Patient has at least two of the following signs or symptoms with no other recognized cause: fever ($>38^{\circ}\text{C}$), localized pain, or tenderness at the involved site *and at least one of the following*: (a) purulent drainage from affected site; (b) organisms cultured from blood that are compatible with suspected site of infection; (c) radiographic evidence of infection (e.g., abnormal ultrasound, computed tomography [CT] scan, magnetic resonance imaging [MRI], or radiolabel scan); (d) physician diagnosis of infection of the kidney, ureter, bladder, urethra, or tissues surrounding the retroperitoneal or perinephric space; or (e) physician institutes appropriate therapy for an infection of the kidney, ureter, bladder, urethra, or tissues surrounding the retroperitoneal or perinephric space.

Criterion 4

Patient ≤ 1 year of age with at least one of the following signs or symptoms with no other recognized cause: fever ($>38^{\circ}\text{C}$), hypothermia ($<37^{\circ}\text{C}$), apnea, bradycardia, dysuria, lethargy, or vomiting *and at least one of the following*: (a) purulent drainage from affected site; (b) organisms cultured from blood that are compatible with suspected site of infection; (c) radiographic evidence of infection (e.g., abnormal ultrasound, CT scan, MRI, or radiolabel scan); (d) physician diagnosis of infection of the kidney, ureter, bladder, urethra, or tissues surrounding the retroperitoneal or perinephric space; or (e) physician institutes appropriate therapy for an infection of the kidney, ureter, bladder, urethra, or tissues surrounding the retroperitoneal or perinephric space.

From Garner JS, Jarvis WR, Emori TG, et al. CDC definitions for nosocomial infections, 1988. *Am J Infect Control*. 1988;16:128.

RISK FACTORS

- In ICU patients, UTIs are associated with the presence of indwelling catheters.
- The first step of prevention is to highlight the risk factors of catheter-associated UTI in this specific population.

- In assessing risk factors for bacteriuria in 553 patients with a urinary catheter for more than 48 hours and hospitalized in an ICU, independent risk factors were:
 - Female gender
 - Length of ICU stay
 - Prior use of antibiotics

TABLE 78.4

PERCENTAGE OF PATHOGENS ASSOCIATED WITH NOSOCOMIAL UTIs

Pathogens	Percentage of isolates		
	Leone et al. ^a (n = 53)	Laupland et al. ^b (n = 290)	Gaynes et al. ^c (n = 4,109)
Gram negative

- Severity score on admission
- Duration of catheterization
- Reducing duration of catheterization the most important clinical step identified for prevention
 - In 21% of 202 patients, the initial indication for the placement of a urinary catheter was unjustified.
 - In a medical ICU, excessive duration of urinary catheter use for monitoring urine output resulted in 64% of the total of unjustified patient-days.

IMPACT OF UTIs in the ICU

- The real impact of ICU-acquired UTIs on outcome remains unclear.
 - In a general hospital population, nosocomial UTIs were associated with significant attributable mortality.
 - Picture probably different in a specific ICU population
 - Even after controlling for many risk factors, UTIs have a higher incidence in ICUs as compared to other wards.
 - Though the urinary tract is source of sepsis in only 10% to 14% of the cases
 - Far less than the lung—44% to 68% (Table 78.5)
 - Development of ICU-acquired UTIs associated with:
 - Increase in the length of ICU stay
 - Increased crude rate of mortality
 - Adequately powered studies demonstrate that UTIs are not dependent factors for mortality
- *Urosepsis* is defined as inflammation of the upper urinary tract that causes seeding of the blood with bacteria, resulting in local and distant destruction of tissue.
- 126 trauma patients with a urinary catheter were evaluated for sepsis.
 - Twenty (16%) were diagnosed with urosepsis.
 - Correlated with:
 - Age older than 60 years
 - Extended length of stay in the ICU and/or hospital
 - Duration of catheterization
- Mortality rates (15%) of the patients without urosepsis and with urosepsis did not differ.
- A prospective, cohort study of 235 catheter-acquired infections among 1,497 patients, 90% of whom were asymptomatic, reported only one (0.42%) secondary bloodstream infection.

TABLE 78.5
RATES OF SEPSIS ACCORDING TO EACH SITE

Sites	Percentages of patients	
	Vincent et al. ^a (n = 1,177)	Angus et al. ^b (n = 192,980)
Lung	68%	44.0%
Abdomen	22%	8.6%
Blood	20%	17.3%
Urine	14%	9.1%

- Finally, UTIs can incur significant additional cost.
 - Episode of symptomatic nosocomial UTI in a hospitalized patient is expected to result in an average of \$676 in additional cost.
 - In a study calculating the daily antibiotic costs per infected ICU patient, UTIs had the lowest daily antibiotic cost per infected patient (\$52).

DIAGNOSTIC TOOLS IN THE ICU

- Urosepsis should be suspected any time a patient has a febrile episode.
 - Routine daily bacteriologic monitoring of urine from all catheterized patients is not an effective way to decrease the incidence of symptomatic, catheter-associated UTI and is not recommended.
 - Three clinical trials have assessed the effectiveness of urinary dipsticks (leukocyte esterase and nitrite) for screening patients instead of quantitative urine culture in the ICU (Table 78.6).
 - Leukocyte esterase activity is an indicator of pyuria.
 - Urinary nitrite production is an indicator of bacteriuria.
 - Our best sense of these data is that the use of dipsticks—instead of quantitative urine culture—cannot be recommended for symptomatic UTIs in ICU patients.
 - The Infectious Diseases Society of America guidelines recommend that asymptomatic bacteriuria or funguria not be screened in patients with an indwelling urethral catheter.
 - In symptomatic patients, quantitative urine culture with Gram stain examination is recommended to obtain rapid identification of the pathogen.

PREVENTION

- The best prevention of ICU-acquired UTIs is to reduce the use of indwelling urethral catheters.
 - In a medical ICU, 64% of the total unjustified patient-days with urethral catheter resulted from its prolonged use for monitoring urine output.

TABLE 78.6
ASSESSING URINARY REAGENT STRIPS IN THE ICU

^dBologna RA, Tu LM, Polansky M, et al. Hydrogel/silver ion-coated urinary catheter reduces nosocomial urinary tract infection rates in intensive care unit patients: a multicenter study. *Urology*. 1999;54:982.

- Each member of the critical care medicine team should attempt to reduce the length of urethral catheterization.
- This evaluation should occur during daily rounds.
- Other measures can be useful only in units with a restrictive policy of catheterization (Table 78.7).

Urinary Drainage System

- To prevent infection, maintenance of a closed sterile drainage system is recommended as the most successful method.
- Closed drainage system described for the first time in 1928
 - Subgroup analysis of a randomized study, in which analyzed patients did not receive antibiotic treatment, showed a reduction in mortality in the group using the closed system.
 - “Open systems” were large, uncapped glass bottles.
 - Drainage catheters were inserted into the glass bottles, often below the level of urine.
 - Urine was stagnant, and bacteria could easily grow and ascend through the drainage catheter.
 - Introduction of closed drainage systems was a major improvement, and use has greatly reduced the rate of bacteriuria.
 - In the modern era, several studies have failed to confirm the benefit of complex closed systems compared with simple devices.
- Two studies in the literature specifically focused on ICU patients and comparing a two-chamber, open drainage system with a complex closed drainage system.
 - Performed by the same team of investigators
 - Found similar results, although one of these studies was not randomized
 - In randomized and prospective trial, 311 patients requiring an indwelling urinary catheter for longer than 48 hours

were assigned to the two-chamber drainage system group or to the complex closed drainage system group to compare the rates of bacteriuria.

- Rates of UTIs were 12.1 and 12.8 episodes per 1,000 days of catheterization, respectively.
- Data extracted from recent literature do not support use of complex closed drainage systems in ICU patients in view of the increased cost.
- Owing to the lack of specific ICU studies, the guidelines for the management of drainage systems should be viewed as recommendations at best. The following are reasonable suggestions:
 - Only those with the proper technique of aseptic insertion and maintenance of catheter should handle catheters.
 - Hospital personnel should be given periodic in-service training stressing the proper techniques and potential complications of urinary catheterization.
 - Hand washing should be performed immediately before and after any manipulation of the catheter site or apparatus.
 - If small volumes of fresh urine are needed for examination, the distal end of the catheter, or preferably the sampling port if present, should be cleansed with a disinfectant, and urine then aspirated with a sterile needle and syringe.
 - Larger volumes of urine for special analyses should be obtained aseptically from the drainage bag.
 - Unobstructed flow should be maintained.
 - In order to achieve free flow of urine:
 - Catheter and collection tube should be kept from kinking.
 - Collection bag should be emptied regularly using a separate collecting container for each patient (the draining spigot and nonsterile collection container should never come into contact).
 - Poorly functioning or obstructed catheters should be irrigated or, if necessary, replaced.

- Collection bags should always be kept below the level of the bladder.
- Indwelling catheters should not be changed at arbitrary fixed intervals.

Types of Urethral Catheters

- A large number of articles in the literature stress that the efficacy of antiseptic-impregnated catheters, including silver oxide or silver alloy, and antibiotic-impregnated catheters in hospitalized patients.
- Two meta-analyses clarify some points related to these devices.
 - Silver oxide catheters are not associated with a reduction in bacteriuria in short-term catheterized adults.
 - Silver alloy catheters reduce the incidence of asymptomatic bacteriuria and the risk of symptomatic UTI in catheterized adults.
 - Economic evaluation is required to confirm that the reduction of infection compensates for their increased cost.
- Catheters coated with a combination of minocycline and rifampin or nitrofurazone may also be beneficial in reducing bacteriuria in hospitalized men catheterized <1 week, but this requires further testing.
 - No trials directly compare nitrofurazone-coated and silver alloy-coated catheters.
- A randomized, prospective, double-blind multicenter trial compared catheters coated with hydrogel and silver salt with classic urinary tract catheters in 199 patients requiring urethral catheterization for more than 3 days.
 - Cumulative incidence of UTIs associated with catheterization was 11.1% overall, 11.9% for the control group, and 10% for the coated catheter group.
 - Odds ratio was 0.82 (95% confidence interval [CI] 0.3–2.2).
 - Differences between the two groups were not significant, although the power of the study was more than 90%.
- Prior trial, which included five hospitals selected to participate in a blinded prospective study, exchanged the standard latex Foley catheter for a hydrogel latex Foley catheter with a monolayer of silver metal applied to the inner and outer surfaces of the device.
 - Adjusted catheter-associated infection rate during the baseline and intervention periods was 8.1 and 4.9 infections per 1,000 catheter-days ($p = 0.13$), respectively.

Meatal Care

- Twice-daily cleansing of the urethral meatus with povidone-iodine solution and daily cleansing with soap and water have failed to reduce catheter-associated UTIs.
 - Daily meatal care with either of these two regimens cannot be endorsed.
- A randomized, controlled, prospective clinical trial involving 696 patients hospitalized in medical and surgical units undertaken to determine effectiveness of 1% silver sulfadiazine cream applied twice daily to urethral meatus in preventing transurethral catheter-associated bacteriuria.
 - Overall incidence of bacteriuria was approximately 13% in both groups ($p = 0.56$).

- Absent data from an ICU-specific patient population, the aforementioned guidelines should be followed.
- No data available on the level of sterility required to insert a urinary catheter
 - Experts recommend that catheters should be inserted using an aseptic technique and sterile equipment, including gloves, drapes, and sponges.
- In a prospective study conducted in the operating room, 156 patients underwent preoperative urethral catheterization, randomly allocated to “sterile” or “clean/nonsterile” technique groups.
 - No statistical difference between the two groups with respect to the incidence of UTI, but the cost differed considerably between the two groups.

Vesical Irrigation and Antiseptic in the Drainage System

- Objective of antibiotic irrigation is to clear bacteria from urinary tract.
 - Randomized study compared 89 patients receiving a neomycin-polymyxin irrigation administered through a closed urinary catheter to 98 patients not so irrigated
 - Number of ICU patients was not specified in this clinical study
 - 19 of the 98 (18%) patients not irrigated became infected as compared with 14 out of the 89 (16%) of those who were irrigated.
 - Organisms from the irrigated patients were more resistant.
- Another study was conducted in 264 urology patients, evaluating the effect of povidone-iodine bladder irrigation prior to catheter removal on subsequent bacteriuria.
 - Of 264 patients, 138 received irrigation and 126 were controls.
 - Urine cultures were positive in 22% in the control group and 18% in the study group.
 - Irrigation methods failed to demonstrate efficacy in surgical patients, and its use is not recommended in ICU patients.
- Addition of antimicrobial agents to drainage device has not been studied in the ICU
 - Largest reported clinical trial evaluating the effect of H_2O_2 insertion into the drainage device of 353 patients, and comparing this to 315 control patients, failed to show a benefit in the treatment group.
 - 68% of these patients required an indwelling catheter for hemodynamic monitoring and antimicrobial therapy was prescribed in 75% of the patients, suggesting that these results may apply to ICU patients.
 - Expert opinion recommends that we not use irrigation unless obstruction is anticipated, as might occur with bleeding after prostatic or bladder surgery.

Alternatives to a Urinary Catheter

- For selected patients, other methods of urinary drainage should be considered as alternatives to indwelling urethral catheterization.
 - Condom catheters

- Suprapubic catheterization
- Intermittent urethral catheterization
- Limited ICU data available to assess these alternative devices
 - There is evidence that suprapubic catheterization is advantageous, as compared to indwelling catheters, with respect to bacteriuria, recatheterization, and discomfort.
 - Use of a condom connected to a collection bag has been evaluated in a study comparing 167 patients over two periods of 6 months.
 - Occurrence of bacteriuria was significantly decreased for the period using the condom catheters (26.7 vs. 2.4%).
 - Issue merits further study to determine whether or not this alternative method may actually reduce bacteriuria rates.
 - Use of intermittent catheterization is also associated with a lower risk of bacteriuria than indwelling urethral catheter.
 - Procedure has never been investigated in ICU patients.

Miscellaneous Measures

- Although low risk of bacteremia during urinary catheterization, administration of antimicrobial therapy at the time the device is placed leads to a reduction in bacteriuria.
- Efficacy of antibiotic treatment has been assessed as optimal for catheterization lasting <14 days.
- Prophylactic use of antibiotics in the ICU can be detrimental to the bacterial ecology by increasing the pressure for antimicrobial resistance among bacteria.
- Thus, practice of administration of prophylactic antimicrobials in this manner must be discouraged in our ICUs.
- In most ICU studies, 75% of the patients with an indwelling catheter require antibiotics for reasons unrelated to the urinary catheter.
 - All measures aimed at reducing the burden of nosocomial infections can reduce the rate of UTIs.

TREATMENT AND MANAGEMENT

- Management of catheter-associated UTI has not been evaluated in ICU patients.
- Several nonspecific measures, including hydration, have been advocated in the therapy of UTI.
 - Adequate hydration appears to be important.
 - No evidence that it improves the effectiveness of an appropriate antimicrobial therapy
- Management of complicated UTIs in the ICU may include mechanical intervention.
 - Consequently, appropriate diagnostic tests and urologic consultation should be included in the algorithm of the management of these patients.

Management of Asymptomatic Bacteriuria

- Asymptomatic catheter-associated UTI does not require treatment.
- Antimicrobial treatment may be considered for asymptomatic women with a catheter-acquired UTI that persists 48 hours after catheter removal.

- In an ICU population, 60 patients with an indwelling urethral catheter for longer than 48 hours who developed an asymptomatic positive urine culture were randomized to receive either a 3-day course of antibiotics associated with the replacement of the indwelling urethral catheter 4 hours after the first antibiotic administration or no antibiotics and no catheter replacement.
 - Six patients equally distributed in the two groups developed urosepsis.
 - Profile of bacterial resistance was similar in the two groups.
 - Treating a positive urine culture in an asymptomatic patient with an indwelling urethral catheter does not reduce the occurrence of urosepsis.

Management of Symptomatic UTIs

Choice of Antimicrobial Agents

- Optimal characteristics of agents to treat UTI must include:
 - Activity against the major pathogens involved in these infections
 - Good tissue penetration
 - Minimal side effects
 - High urinary levels should be present for an adequate period to eliminate the organisms
 - Disappearance of bacteriuria correlates with the sensitivity of the pathogen to the concentration of antimicrobial agent achieved in urine.
 - Inhibitory urinary concentrations are achieved after administration of essentially all commonly used antibiotics.
 - An antibiotic that achieves active concentrations in renal tissue is required for infection of renal tissue.
 - Antibiotic concentration in serum or plasma can be used as surrogate markers for the antibiotic concentrations in the renal tissue.
 - Most clinical studies have shown that renal concentrations of cephalosporins remained higher than minimal inhibitory concentration for the most common bacteria during the time interval between the administration of two doses.
 - By contrast, β -lactam antibiotics, which have a low pKa and poor lipid solubility, penetrate poorly into the prostate.
 - Except for some cephalosporins
 - Good to excellent penetration into the prostatic tissue has been demonstrated with many antimicrobial agents:
 - Aminoglycosides
 - Fluoroquinolones
 - Sulfonamides
 - Nitrofurantoin
- Many patients develop renal failure, which is associated with the inability to concentrate antimicrobial agents in the urine.
- Administration of drugs with potential renal toxicity may worsen renal insufficiency.
- There is significant literature demonstrating that the use of fluoroquinolone is associated with the emergence of resistant pathogens.

Cystitis

- Acute uncomplicated cystitis is infrequent in ICU patients.
- *E. coli* is the evident target pathogen.

- IDSA guidelines recommend treatment with trimethoprim-sulfamethoxazole for 3 days as standard therapy for acute uncomplicated cystitis.
- A meta-analysis determined that 3 days of antibiotic therapy is similar to 5 to 10 days in achieving symptomatic cure during uncomplicated UTI treatment, while the longer treatment is more effective in obtaining bacteriologic cure.
- Quinolones are recommended for acute cystitis in regions where the level of resistance to trimethoprim-sulfamethoxazole is high.
- Antibiotic treatment of UTI depends on ability of antibiotic to inhibit growth or kill the bacteria present in urinary tract.
 - This is related to the concentration of antibiotics at the site of infection.
 - Very high concentrations of antibiotics with renal clearance are obtained in urine.
 - Consequently, even in the presence of pathogens exhibiting *in vitro* resistance, the high concentrations of antibiotics in urine inhibit the growth of pathogens, rendering them effective to treat a UTI.

Prostatitis

- For outpatients, bacterial prostatitis is a common diagnosis and a frequent indication for antibiotics.
- Urethral instrumentation and prostatic surgery are known causes of prostatitis.
- Incidence of prostatitis among ICU patients has never been assessed.
- There is only a weak relation between acute and chronic prostatitis.
- Acute prostatitis is an acute infection producing:
 - Local heat
 - Tenderness
 - Fever
 - With the presence of IgA and IgG bacteria-specific immunoglobulins in the prostatic secretions
 - Few symptoms, usually perineal discomfort, are exhibited with prostatitis.
 - Most patients with chronic prostatitis have no history of positive urine or urethral cultures.
- In ICU patients, acute bacterial prostatitis is probably a common infection.
 - The patient presents septic, but without an evident source of infection.
 - There may be a history of urine retention due to bladder outlet obstruction.
 - Rectal examination, a crucial step in the diagnosis, reveals a warm, swollen, and tender prostate.
 - Prostatic fluid contains leukocytes and the pathogen responsible for the infection.
 - Fluoroquinolones are the drugs of choice to treat acute prostatitis because of their excellent penetration in the tissue and excretions.
- Targeted pathogens are:
 - *E. coli*
 - *Proteus* sp.
 - *Klebsiella* sp.
 - *Enterococcus* sp.
 - *Staphylococcus aureus*
 - *Neisseria gonorrhoeae*
 - *Chlamydia trachomatis*
- For acute prostatitis occurring without bacteremia:
 - Antimicrobial treatment consists of oral ofloxacin 200 mg twice per day for 28 days.
 - Ceftriaxone 2 g/day has good prostatic tissue penetration and represents an alternative to ofloxacin.
 - Gentamicin 3 mg/kg/day is added in the presence of positive blood cultures (Table 78.8).
 - Of importance, urethral instrumentation should be discouraged.
 - If acute retention occurs, suprapubic drainage of urine is required.
 - Treatment of chronic prostatitis is based on the oral administration of ofloxacin 200 mg twice per day, or trimethoprim 160 mg–sulfamethoxazole 800 mg twice per day for at least 28 days.

Acute Pyelonephritis

- No specific data available on management of acute pyelonephritis in the ICU.
- The urine of all patients with suspicion of complicated pyelonephritis should be cultured and a Gram stain of the spun urine performed.
- Blood cultures, which are positive in 36% of women not admitted to the ICU, are also required.
- All patients with acute pyelonephritis should have an ultrasound examination or a renal computed tomography scan to evaluate for obstruction and stones.
- For uncomplicated acute pyelonephritis, the IDSA, in 1999, derived two conclusions from the analysis of randomized clinical trials.
 - Trimethoprim-sulfamethoxazole is preferred over ampicillin.
 - There is a relatively high prevalence of organisms causing acute pyelonephritis that are resistant to ampicillin.
 - Second conclusion is that 10 to 14 days of therapy appears to be adequate for the majority of women.
 - 255 outpatients were randomized to oral ciprofloxacin, 500 mg twice per day for 7 days, followed by placebo for 7 days versus trimethoprim-sulfamethoxazole, 160/800 mg twice per day for 14 days.
 - A 7-day ciprofloxacin regimen was associated with greater bacteriologic and clinical cure rates than a 14-day trimethoprim-sulfamethoxazole regimen
 - Gatifloxacin appears to be equivalent to ciprofloxacin for this indication.
- Patients with complicated acute pyelonephritis should be hospitalized and initial administration of broad-spectrum intravenous (IV) antibiotics begun.
- Targeted bacteria are:
 - *Enterobacter* sp.
 - *E. coli*
 - *Proteus* sp.
 - *Enterococcus* sp.
- Ciprofloxacin, 500 mg twice daily, is administered orally for 14 to 21 days.
- Gentamicin, 3 mg/kg/day IV, is added during the first 3 days.
- Oral ciprofloxacin is as effective as the IV regimen in the initial empirical management of complicated pyelonephritis.
- Gatifloxacin is as effective as ciprofloxacin.
- Ceftriaxone, 2 g/day IV, is an alternative choice to ciprofloxacin.

TABLE 78.8

ANTIMICROBIAL TREATMENT OF UTIs^a

Source of infection	Pathogens	Treatment	Duration
Acute prostatitis (without bacteremia)	<i>Escherichia coli</i> , <i>Proteus</i> sp., <i>Klebsiella</i> sp., <i>Enterococcus</i> sp., <i>Staphylococcus aureus</i> , <i>Neisseria gonorrhoeae</i> , <i>Chlamydia trachomatis</i>	Ofloxacin 200 mg twice daily (oral)	28 d
Acute prostatitis (with bacteremia)	<i>E. coli</i> , <i>Proteus</i> sp., <i>Klebsiella</i> sp., <i>Enterococcus</i> sp., <i>S. aureus</i> , <i>N. gonorrhoeae</i> , <i>C. trachomatis</i>	Ofloxacin 200 mg twice daily (oral) or Ceftriaxone 2 g/d And gentamicin 3 mg/kg/d IV	28 d 3 d
Chronic bacterial prostatitis	<i>E. coli</i> , <i>Proteus</i> sp., <i>Klebsiella</i> sp., <i>Enterococcus</i> sp., <i>S. aureus</i> , <i>N. gonorrhoeae</i> , <i>C. trachomatis</i>	Ofloxacin 200 mg twice daily (oral) or Trimethoprim 160 mg/sulfamethoxazole 800 mg twice daily (oral)	28 d
Acute pyelonephritis (uncomplicated)	Enterobacteriaceae, <i>E. coli</i> , <i>Proteus</i> sp., <i>Enterococcus</i> sp.	Ciprofloxacin 500 mg twice daily (oral) If oral route not possible: Ceftriaxone 2 g/d IV	14 d
Acute pyelonephritis (complicated)	Enterobacteriaceae, <i>E. coli</i> , <i>Proteus</i> sp., <i>Enterococcus</i> sp.	Ciprofloxacin 500 mg twice daily (oral) Or Ceftriaxone 2 g/d IV And Gentamicin 3 mg/kg/d	14–21 d 3 d

^aEach empirical treatment must be adapted to the susceptibility testing results.

- Drainage of urine must be urgently performed using bladder catheterization, percutaneous nephrostomy drainage, or definitive surgery.
 - Antimicrobial treatment is administered after urine and blood specimen collection.
- Antibiotic selection is based on the result of the Gram stain of the urine and knowledge of local ecology.
- Antimicrobial treatment should be adapted to the susceptibility testing results as soon as possible.
- De-escalation should be performed in favor of a narrow-spectrum antibiotic.

- Combination of a β -lactam antibiotic with antipseudomonal activity and a fluoroquinolone

Management of Candiduria

- Candiduria represents from 3% to 15% of catheter-associated UTI in the ICU.
 - *Candida albicans* and *Candida (Torulopsis) glabrata* found in 46% and 31% of cases, respectively
 - According to the International Conference for the Development of a Consensus on the Management and Prevention of Severe Candidal Infections, colonized patients without evidence of infection do not require treatment.
 - But contributing cause should be addressed, such as changing or removing the indwelling catheter and discontinuing inappropriate antibiotic therapy
 - Fluconazole may be the best option for treating a candiduria only if the species is *C. albicans*.
 - Voriconazole may be more effective against non-*albicans* species.
- A prospective, randomized trial compared fungal eradication rates among 316 hospitalized patients with candiduria treated with fluconazole (200 mg) or placebo daily for 14 days.
 - Candiduria cleared by day 14 in 50% of the patients receiving fluconazole and 29% of those receiving placebo.
 - Higher eradication rates among patients completing 14 days of therapy
 - Fluconazole initially produced high eradication rates, but cultures at 2 weeks revealed similar candiduria rates among treated and untreated patients.
 - In 41% of the catheterized subjects, candiduria was resolved as the result of catheter removal only.
 - Outcomes of patients were not provided in the results.

Specificities of Complicated UTIs in the ICU

- Little in the literature on the treatment of UTIs in the ICU.
 - One presumes the need for IV antibiotics for these patients because of the possibility of bacteremia or sepsis.
- Guidelines from the Surviving Sepsis Campaign state that:
 - Antibiotic therapy should be started within the first hour of recognition of severe sepsis, after appropriate cultures have been obtained.
 - Initial empirical anti-infective therapy should include one or more drugs that have activity against the likely pathogens and that penetrate the presumed source of sepsis.
 - Monotherapy is as effective as combination therapy with a β -lactam and an aminoglycoside as empiric therapy of patients with severe sepsis or septic shock.
 - For the septic shock patients whose presumed source is urine, we recommend, empirically:

- Bladder irrigation using amphotericin B has been proposed as an alternative technique to clear *Candida* from the urine.
- Comparative and randomized study of 109 elderly patients showed that funguria was eradicated in 96% of the patients treated with amphotericin B and 73% of those treated with fluconazole ($p < 0.05$).
- One month after study enrollment, the mortality rate associated with all causes was greater among patients who

were treated with amphotericin B bladder irrigation than among those who received oral fluconazole therapy (41% vs. 22%, respectively; $p < 0.05$).

- This finding suggests that irrigation therapy could be associated with poorer survival.
- There has only been one study performed in ICU patients developing candiduria, which reached the same conclusions.
- Methodologic issues restrict the interest of this study.

CHAPTER 79 ■ FUNGAL AND VIRAL INFECTIONS

FUNGAL INFECTIONS

Fungal Pathogens

- Medically relevant fungi are classically considered as one of three types of organism:
 - **Yeasts**
 - Grow as smooth colonies on culture plates
 - Microscopically, they are oval or spherical, and they reproduce by budding
 - Most common human yeast pathogens are *Candida* spp. and *Cryptococcus* spp.
 - **Molds**
 - Appear as fuzzy colonies on agar plates
 - Microscopically, they have hyphae.
 - Tubular or filamentous morphologies that grow by branching and longitudinal extension
 - Hyphae can be septated (i.e., with cross walls perpendicular to hyphal cell wall) or aseptated (no cross walls)
 - Most common human pathogens are *Aspergillus* spp. and *Rhizopus* spp.
 - **Dimorphic agents**
 - *Dimorphic fungi* used to describe the endemic fungi
 - Found in distinct geographic locations
 - Grow as filaments in the environment at ambient temperatures and as yeasts at higher body temperatures
 - Three most common pathogens are:
 - *Histoplasma capsulatum*
 - *Coccidioides immitis*
 - *Blastomyces dermatitidis*
 - Term, dimorphic fungi, as commonly used in the medical literature is misleading
 - *Candida albicans*
 - Not grouped with the endemic dimorphic fungi
 - Frequently assumes filamentous morphologies in tissue (pseudohyphae and hyphae)
 - Most fungal pathogens, except for *Candida* spp., are widespread in nature
 - Acquired by inhalation into the lungs

- In immunocompetent hosts, inhaled fungi are generally arrested in lungs by host immune system.
- *Candida* spp., with the exception of *Candida parapsilosis*, are part of the human gastrointestinal flora.
 - Infections with these organisms are usually endogenous in origin.
- Diagnosis of infection (i.e., fungal disease):
 - Often difficult to distinguish from colonization
 - Definitive diagnoses generally require either the presence of the organism at sterile sites or histopathology demonstrating tissue-invasive disease.
 - Many fungi show morphologies that are indistinguishable by histopathology (e.g., *Aspergillus* spp. vs. *Fusarium* spp. and other acute-angle branching, septated molds).
 - Identification of organism from culture is the only means to ascertain etiologic agent.
- In ICU settings, *Candida* spp. and, to a much lesser extent, *Aspergillus* are the major fungal pathogens.

Infections Caused by *Candida* Species (Candidiasis)

- *Candida* spp. cause a wide range of clinical syndromes.
 - Benign cutaneous to fatal deep-seated infections (Table 79.1)
 - Can affect otherwise healthy patients, as well as those with defective immune systems
 - In the ICU, the most common and serious form of disease is invasive candidiasis.
- Invasive candidiasis typically refers to:
 - Candidemia and deep-organ infections resulting from bloodborne dissemination
 - Candidemia is not always detected.
 - Deep-seated organ involvement is frequently the first evidence of candidiasis.

Epidemiology

- In the ICU, *Candida* spp. is the third most common cause of blood stream infections.

TABLE 79.1
MAJOR CLINICAL CANDIDAL SYNDROMES

Type of candidiasis	Specific clinical syndromes	Frequency	Risk factors	Types of hosts	Treatment
Cutaneous: skin, nails		Most common form of candidiasis; Self-limited	Prolonged exposure of skin to moisture	Immunocompetent Immunocompromised	Topical antifungals
Mucocutaneous: Mucous membranes of the mouth, esophagus, vagina	Oropharyngeal	About 2.5% in patients with solid tumors and 60% in patients with hematologic malignancies and/or following bone marrow transplantation; up to 90% in AIDS	Extremes of age, broad-spectrum antibiotics, inhaled or systemic steroids, radiation to the head and neck	Immunocompetent Immunocompromised, especially patients receiving cytotoxic chemotherapy or systemic immunosuppressive therapy, those with AIDS, malignancy, or chronic mucocutaneous candidiasis	Topical or systemic azole agents
	Esophagitis	15%–20% in AIDS	Broad-spectrum antibiotics, acid-suppressive therapy, prior gastric surgery, mucosal barrier injury, inhaled or systemic steroids, esophageal motility disorders	Mostly immunocompromised, especially patients receiving cytotoxic chemotherapy or systemic immunosuppressive therapy, those with AIDS or malignancy	Systemic antifungal agents: oral azole (preferred treatment), parenteral echinocandin or AmB
	Vaginitis	70%–75% of healthy adult women	Pregnancy, diabetes mellitus, and broad-spectrum antibiotics	Immunocompetent Immunocompromised	Topical or systemic azole agents
Disseminated candidiasis			Colonization with <i>Candida</i> , broad-spectrum antibiotics, end-stage renal disease, central venous catheters, critically ill patients, hyperalimentation, GI surgery, burn patients, neonates	Immunocompetent Immunocompromised, especially granulocytopenia, bone marrow or solid organ transplant, chemotherapy, mucositis	Systemic antifungal agents
AIDS, acquired immunodeficiency syndrome; AmB, amphotericin B; GI, gastrointestinal.					

- Account for approximately 10% of cases
- Crude mortality rates range from 40% to 75%.
- Candidemia associated with excess ICU and hospital stays and increased costs of care
- Postmortem studies suggest that mortality rates due to invasive candidiasis may be higher than generally realized because of undiagnosed infections.

Risk Factors

- Leading predisposing factors for invasive candidiasis include:
 - Prolonged ICU stay
 - Previous surgery (especially solid organ transplant and gastrointestinal surgery)
 - Solid organ transplant recipients at highest risk among the surgical patients
 - Small bowel, liver, and pancreas recipients have prevalence of from 9% to 59%
 - Acute renal failure
 - Receipt of antibacterial agents or hyperalimentation
 - Presence of a central venous catheter
 - Although risk factors are well defined
 - Diversity of factors and underlying diseases associated with invasive candidiasis make it difficult to reliably identify large subgroups of patients within the ICU who might merit particular attention or targeted interventions.

Microbiology

- *C. albicans* the most common *Candida* species involved in invasive candidiasis
 - Followed by *C. glabrata*, *C. tropicalis*, and *C. parapsilosis*
 - Other species less common and often associated with underlying malignancy or chemotherapy
 - *C. tropicalis* and *C. glabrata* are found largely in adults
 - *C. parapsilosis* the leading pathogen in neonatal population

- In many tertiary care centers, *C. glabrata* has surpassed *C. albicans* to become the most common *Candida* sp. in invasive candidiasis.
 - Accounting for up to 35% of all candidemias
 - Among non-*albicans* *Candida* species, *C. krusei* and *C. glabrata* are particularly important because of their resistance and decreased susceptibility to fluconazole, respectively.

Clinical Manifestations

- Clinical manifestations are often nonspecific
 - Fever is frequently the first and only sign of invasive candidiasis
 - Other signs that should raise concern for candidemia are:
 - Papulopustular or macronodular skin lesions
 - Ocular involvement such as chorioretinitis or endophthalmitis
 - Deep-seated infections often present, with findings localized to the particular tissue site
- Invasive candidiasis can be divided into four major clinical entities:
 - Catheter-related candidemia
 - Acute disseminated candidiasis
 - Chronic disseminated candidiasis
 - Deep-organ candidiasis (Table 79.2)

Diagnosis

- A challenge due to nonspecific clinical manifestations and the low sensitivity of microbiologic culture techniques
- Blood cultures should be routinely obtained in patients with suggestive signs and symptoms, as well as those at high risk for invasive candidiasis.
- Candidemia is the most common manifestation of invasive candidiasis.
 - Other forms of invasive candidiasis generally originate from bloodborne dissemination.

TABLE 79.2

FORMS OF INVASIVE CANDIDIASIS

Forms	Portal of entry	Characteristics	Blood cultures	Management
Catheter-related candidemia	Intravascular catheter	Frequently self-limited, but can rarely spread to deep-seated organs	Positive for <i>Candida</i> sp.	Systemic antifungal agents and removal of the catheter
Acute disseminated candidiasis	Intravascular catheter or GI tract is most common	Frequently involves deep-seated organ(s)	Can be positive or negative	Systemic antifungal
Chronic disseminated candidiasis (or hepatosplenic candidiasis)	GI tract is the most common portal; intravascular catheter	Almost exclusively seen in neutropenic patients or bone marrow transplant recipients. Typical presentation: Persistent fever, right upper quadrant pain, elevated alkaline phosphatase, lucencies on CT or ultrasound of the liver	Typically negative at the time of the diagnosis	Systemic antifungal
Deep-organ candidiasis	Intravascular catheter or GI tract is most common	Frequently follows an episode of undiagnosed candidemia	Typically negative at the time of the diagnosis	Systemic antifungal

GI, gastrointestinal; CT, computed tomography.

- Deep-seated candidiasis can occur without a positive blood culture.
 - Blood cultures are positive in <50% of patients.
 - Autopsy data demonstrate as few as 15% to 40% of patients with invasive candidiasis have an antemortem diagnosis of the disease.
 - Diagnosis, therefore, should also rely on histopathology and/or fungal cultures obtained by biopsy of sterile sites.
 - *Candida* spp. are common colonizers of humans.
 - Difficult to differentiate between colonization or true infections when organisms are isolated from the urine and nonsterile sites
- Given the potential for antifungal resistance among the non-*albicans* *Candida* spp.
 - Isolates recovered from blood or sterile sites should be identified to the species level
 - Availability of special fungal media (such as CHROMagar) and rapid *in situ* hybridization techniques have significantly shortened the time to speciation
- Nonculture-based diagnostic methods for invasive candidiasis
 - Antibody-based assays have not been useful.
 - Beta D-glucan assay, an antigen test, has recently been approved for the diagnosis of invasive fungal infections.
 - Assay measures [1, 3]-beta-D-glucan levels released from cell wall of most fungi
 - Sensitivity in diagnosing invasive candidiasis 81%
 - Specificity 84%
 - Positive and negative predictive values (PPV and NPV) are 84%, and 75%, respectively.
 - Test is able to detect various *Candida* spp.
 - Potential drawback is its nonspecificity for *Candida*
 - It also detects *Aspergillus*, *Fusarium*, and *Trichosporon*
 - Other factors that can contribute to false-positive tests results include dialysis filters, gauze, and sponges.
- Azole MICs correlate with likelihood of success in treating patients.
 - Antifungal susceptibility testing of *Candida* is currently performed in relatively few clinical laboratories.
 - Not considered the standard of care, unlike antibacterial susceptibility testing
 - Antifungal susceptibility patterns are predictable in most cases based on species and prior exposure to antifungal agents.
 - For this reason, identification of isolates to the species level is usually more important than MIC data in the management of individual patients.
 - *C. krusei* is intrinsically resistant to fluconazole.
 - Significant minority of *C. glabrata* strains develop resistance to fluconazole
 - For other species, the vast majority of bloodstream isolates remain susceptible to fluconazole.
 - Cross-resistance to other azoles is often seen, which limits the utility of this class against fluconazole-resistant isolates.
 - Reports of resistance to echinocandin class of antifungals are beginning to appear.
 - MICs of echinocandins against *C. parapsilosis* are generally higher than against other species, and breakthrough infections among patients receiving these agents have been described.

- Amphotericin B resistance is difficult to document using current testing methods.
 - Resistance among *C. lusitanae* and *C. guilliermondii* isolates is well described but not seen with all isolates.
 - Avoid amphotericin B if elevated MICs are documented.
- At centers where candidiasis is a particular problem and antifungal use is widespread, it is useful to conduct periodic susceptibility testing to generate an institutional antibiogram.
- Clinicians should be aware if such reports exist at their institution, as susceptibility patterns against different species can be used to guide empiric antifungal therapy.

Management

- **Invasive Candidiasis:** The major antifungal agents and their activity are summarized in Table 79.3.
- Current guidelines for management of invasive candidiasis are summarized in Table 79.4.
 - Amphotericin B (conventional or lipid formulations) or caspofungin should be the first-line treatment of critically ill patients with invasive candidiasis.
 - Caspofungin, an echinocandin agent, is better tolerated and has fewer side effects than amphotericin B.
 - Fluconazole can also be considered when resistant species such as *C. krusei* are ruled out.
 - Anidulafungin and micafungin, two newly approved echinocandin agents, are as effective as caspofungin in management.
- All patients with candidemia should have an ophthalmologic exam to rule out retinal involvement.
 - All vascular catheters should be removed if possible.
 - *Candida* spp. tend to form biofilms on catheters, which can render otherwise susceptible isolates resistant to antifungal agents.
- ***Candida* Recovered from Urine or Sputum/Bronchoalveolar Lavage (BAL):** As mentioned earlier, *Candida* spp. are part of endogenous flora and frequent colonizers of mucosal surfaces.
 - In the ICU setting, urine and sputum are two most common sites of colonization
 - *Candida in the Urine.* *Candida* spp. the most common organisms recovered from urine of surgical ICU patients
 - Risk factors include:
 - Urinary catheters
 - Old age
 - Receipt of antibacterial agents
 - Colony counts and urine analysis are not helpful in deciding whether candiduria is of clinical importance.
 - Asymptomatic candiduria in the low-risk patient is of little clinical relevance and should not be treated.
 - In a small subset of patients, candiduria is a marker for invasive candidiasis.
 - Treatment indicated for:
 - Symptomatic patients
 - Those who are neutropenic
 - Have undergone a urologic manipulation
 - Received a kidney transplant
 - Treatment entails removal of the urinary catheter and therapy with a systemic antifungal agent.
 - Fluconazole or amphotericin B for 7 to 14 days
 - In the event that catheter removal is not possible, changing the catheter might be of benefit and should be performed.

TABLE 79.3

CURRENTLY AVAILABLE SYSTEMIC ANTIFUNGAL AGENTS

Class of antifungal	Mechanisms of actions of specific drugs	Routes of administration and daily doses	Spectrum of activity	Side effects and toxicity
Polyene	Potent antifungal agents that act by binding to ergosterol in the fungal cell membrane, leading to leakage and cell death Amphotericin B (AmB), available in 4 formulations: <ul style="list-style-type: none"> • AmB deoxycholate (dAmB; often called conventional AmB) • AmB colloidal dispersion (ABCD) • AmB lipid complex (ABLC) • Liposomal AmB (L-AmB) 	IV for invasive candidiasis Usual daily dosages: dAmB, 0.3–1.5 mg/kg ABCD, 3–6 mg/kg ABLC, 5 mg/kg L-AmB, 3–5 mg/kg	AmB is active (fungicidal) against most pathogenic fungi, except the following: <i>Trichosporon beigelii</i> , <i>Aspergillus terreus</i> , <i>Pseudallescheria boydii</i> , <i>Malassezia furfur</i> , <i>Fusarium</i> spp. Some <i>Candida lusitanae</i> and <i>C. guilliermondii</i> isolates are resistant.	Infusion-related (fever, chills, and myalgia). Nephrotoxicity: Azotemia, electrolyte wasting (potassium, magnesium), renal tubular acidosis. Overall, the lipid formulations of AmB are less nephrotoxic.
Azoles	Inhibition of cytochrome P450 14 α -demethylase, an enzyme involved in the sterol biosynthesis pathway Fluconazole	PO and IV Usual daily dosage: 6 mg/kg. Doses of 12 mg/kg are increasingly used to overcome intermediately susceptible (i.e., dose-dependent) organisms.	Fungistatic agent, active against <i>Candida</i> spp., <i>Cryptococcus</i> spp., and <i>Coccidioides immitis</i> . <i>Candida krusei</i> is intrinsically resistant, and resistance has been reported among isolates of several other <i>Candida</i> spp., especially <i>C. glabrata</i> . No activity against molds. Limited activity against <i>Histoplasma capsulatum</i> , <i>Blastomyces dermatitidis</i> , and <i>Sporothrix schenckii</i> . Active against yeasts, molds, and dimorphic fungi.	In general, well-tolerated. Hepatotoxicity is rare.
	Itraconazole	PO and IV Daily dosage: PO: 100–400 mg (at 400 mg/d doses, better levels are achieved with bid dosing) IV: 200 mg bid for 2 days, followed by 200 mg/d	Limited activity against <i>Fusarium</i> and Zygomycetes. Resistance has been reported among <i>Candida</i> and <i>Aspergillus</i> spp.	Generally benign. Hepatotoxicity is rare.
	Voriconazole	PO and IV Daily dosage: PO: 200 mg bid IV: 3–6 mg/kg every 12 h	Active against yeasts, molds, and dimorphic fungi. Variable activity against <i>Fusarium</i> . Limited activity against Zygomycetes. Resistance has been reported among <i>Candida</i> and <i>Aspergillus</i> spp.	Dose-related, transient visual disturbances, skin rash, and elevated hepatic enzyme levels have been reported.
	Posaconazole	PO Daily dosage: 600–800 mg/d in divided doses with food	Active against yeasts, molds (including Zygomycetes) and dimorphic fungi. Variable activity against <i>Fusarium</i> .	Nausea and headache. Rash, dry skin, nausea, taste disturbance, abdominal pain, dizziness, and flushing can occur. Posaconazole can cause abnormalities in liver function.
Glucan synthesis inhibitors (echinocandins)	Block the synthesis of a major fungal cell wall component, 1–3-beta-D-glucan Caspofungin Anidulafungin Micafungin	IV Caspofungin: 70 mg load, then 50 mg daily Anidulafungin: 200 mg, then 100 mg/d Micafungin: 100 mg/kg	Activity is mainly against <i>Candida</i> spp. and <i>Aspergillus</i> spp. No activity against <i>Cryptococcus</i> or Zygomycetes.	Side-effects are limited Liver toxicity

TABLE 79.4

RECOMMENDED ANTIFUNGAL AGENTS AGAINST INVASIVE CANDIDIASIS

Host	Primary therapy	Alternative therapy	Comments
Nonneutropenic	AmB, 0.6–1 mg/kg/d IV <i>or</i> Fluconazole, 400–800 mg/d IV or PO <i>or</i> Caspofungin, 70 mg IV once, then 50 mg/d IV <i>or</i> Voriconazole, 6 mg/kg IV every 12 h for 2 doses, then 3 mg/kg/d IV every 12 h (can be switched to 200 mg bid PO after 3 days) <i>or</i> Anidulafungin, 200 mg IV for 1 dose, then 100 mg/d IV <i>or</i> Micafungin, 100 mg/d IV	AmB, 0.7 mg/kg IV plus fluconazole, 800 mg IV or PO for 4–7 d, then fluconazole, 800 mg/d	Duration: 14 days after the last positive blood culture and resolution of signs and symptoms Removal of all vascular catheters
Neutropenic	AmB, 0.7–1 mg/kg/d IV <i>or</i> Lipid formulations of AmB, 3–5 mg/kg/d IV <i>or</i> Caspofungin, 70 mg IV for 1 dose, then 50 mg/d IV	Fluconazole, 6 to 12 mg/kg/d	Duration: 14 days after the last positive blood culture, resolution of signs and symptoms, and of neutropenia Removal of vascular catheters if possible (controversial issue)

- *Candida in the Sputum*: Specimens from the airways—sputum, tracheal aspirates, and BAL—are frequently contaminated with oropharyngeal flora, including *Candida* spp.
- *Candida* spp. frequently isolated from the respiratory tree of ICU patients
- Primary *Candida* pneumonia is extremely rare.
- Cases are generally encountered among neutropenic hosts.
 - Diagnosis of *Candida* pneumonia requires evidence of parenchymal invasion by hyphae on a biopsy specimen.
 - Antifungal therapy should not be instituted in response to *Candida* isolates recovered from respiratory samples.
 - Strategies of not identifying or reporting *Candida* spp. in respiratory samples:
 - Decrease length of stay

- Hospital costs
- Unnecessary antifungal therapy
- Without any negative effects on accurate diagnosis of *Candida* pneumonia or patient outcome

Prevention

- Given the nonspecific clinical manifestations, low yield of blood cultures, and high mortality rates of invasive candidiasis, investigators have studied three treatment strategies in the absence of a definitive diagnosis:
 - Prophylactic strategy: Administration of an antifungal agent at a period of high risk to prevent candidiasis
 - Controversial
 - See Table 79.5.

TABLE 79.5

CLINICAL TRIALS DEMONSTRATING A POSITIVE IMPACT OF ANTIFUNGAL PROPHYLAXIS IN NONNEUTROPENIC ICU PATIENTS

Patient population	Intervention	Impact on fungal infections
Surgical patients with recurrent gastrointestinal perforations or anastomotic leakage	Randomized prospective double-blind, placebo-controlled study: fluconazole (400 mg/day IV) ($N = 25$) or placebo ($N = 22$) continued until resolution of the underlying surgical condition	Fluconazole reduced candida colonization by 47% (15% vs. 62%; $p = 0.04$) and <i>Candida</i> peritonitis by 31% (4% vs. 35%; $p = 0.02$) No impact on survival
Medical and surgical adult ICU patients with mechanical ventilation for at least 48 h	Randomized double-blind, placebo-controlled study: fluconazole, 100 mg daily ($N = 103$) or placebo ($N = 101$)	Fluconazole reduced <i>Candida</i> infections by about 10% (5.8% vs. 16%). No impact on survival (mortality rate 39% vs. 41%)
Medical and surgical adult ICU patients in septic shock	Randomized double-blind study: fluconazole, 200 mg IV daily ($N = 32$) or placebo ($N = 39$) during the course of their septic shock	Fluconazole improved 30-day survival by 32% (78% vs. 46%) in patients with intra-abdominal sepsis. No impact on survival in patients with septic shock due to nosocomial pneumonia
Surgical ICU patients with a length of ICU stay of at least 3 days	Randomized placebo-controlled study: fluconazole, 400 mg orally or placebo (total $N = 260$)	Fluconazole reduced the risk of fungal infection by 55%. No impact on survival

- Preemptive strategy: Administration of an antifungal agent to treat suspected invasive candidiasis based on particular warning signs.
 - Based on specific findings on computed tomography (CT) scan or laboratory markers such as galactomannan
 - Popular approach in patients undergoing bone marrow transplantation or those with neutropenia from a hematologic malignancy
 - No good indicators for preemptive approaches in nonneutropenic ICU patients
- Empiric therapy: Administration of an antifungal agent in persistently febrile patients without a known source or with no response to appropriate antibacterial agents
 - Widely used but not validated by clinical trials
 - Mathematical models suggest strategy might be proven effective.
 - Theoretical cost-effectiveness analysis was performed on a target population of ICU patients with fever, hypothermia, or unexplained hypotension who had not responded to 3 days of antibacterial therapy.
 - Assuming that 10% of the target population would have invasive candidiasis, the authors concluded that empiric fluconazole was the most reasonable strategy.
 - Cost: \$12,593 per discounted life-year saved
 - One life saved for 71 patients treated
 - Empiric fluconazole:
 - Estimated to decrease mortality from 44% to 30.4% in patients with invasive candidiasis
 - From 22.4% to 21.0% in the overall target cohort
 - Strategy justifiable if likelihood of invasive candidiasis at least 2.5%
 - Until clinical trials validate empiric strategies within well defined at-risk populations, however, they cannot be broadly recommended

Infections Caused by *Aspergillus* Species (Aspergillosis)

- Less common human pathogens in the ICU than *Candida* spp. but cause greater morbidity and mortality
 - These molds are ubiquitous in the environment.
 - In normal hosts, generally saprophytes that colonize the bronchopulmonary tree
 - Four classical clinical syndromes of pulmonary aspergillosis are discussed in Table 79.6.
 - Focus here on two syndromes most commonly encountered in ICU setting:
 - Chronic necrotizing pulmonary aspergillosis (CNPA)
 - Invasive pulmonary aspergillosis (IPA)
 - In both of these diseases, *Aspergillus* spp. invade tissue and blood vessels, causing necrosis and possibly disseminating to the brain and elsewhere.
 - Entities similar to allergic bronchopulmonary aspergillosis, CNPA, and IPA are also found in the sinuses.

Epidemiology

- IPA is estimated to occur in:
 - 5% to 13% of patients who have undergone bone marrow transplantation
 - 5% to 25% of patients who have received heart or lung transplants
 - 10% to 20% of patients receiving intensive chemotherapy for leukemia
 - Mortality rates are 50% to 90%
 - Not as common in patients with less profound immunosuppression and exceedingly uncommon in immunocompetent hosts
 - In immunocompetent hosts, the rare cases of IPA often follow influenza or other infectious respiratory processes.
 - CNPA is generally a disease of patients with underlying lung disease.

Risk Factors

- Major risk factors predisposing to invasive aspergillosis are summarized in Table 79.7.
 - There are increasing reports of disease among debilitated patients in the ICU.

Microbiology

- Over 100 species of *Aspergillus*
 - Only a few cause diseases in humans.
 - *A. fumigatus* is most common, followed by *A. flavus*
 - Less common pathogens include *A. terreus*, *A. niger*, and *A. clavatus*.
 - Antifungal susceptibility testing against molds not recommended routinely
 - Reproducible testing methodologies have been developed, but interpretive criteria have not been established
 - Nevertheless, elevated MICs to amphotericin B have been documented against a number of *A. terreus* isolates.
 - Elevated MICs of itraconazole against a small percentage of *A. fumigatus* isolates

Clinical Manifestations

- Most *Aspergillus* spp. infections originate from the inhalation of fungal spores into lungs.
 - Cases of direct skin inoculation of *Aspergillus* have been described.
 - Associated with insertion of intravenous (IV) devices or the taping of arm boards to the extremities
 - Patients with severe burns can also develop local burn wound infections, especially if they are rolled in the dirt to extinguish flames.
 - Regardless of the portal of entry, any local form of aspergillosis can disseminate to various sites if host immune function is impaired.
 - Almost any organ may be involved in disseminated aspergillosis, including:
 - Integument (onychomycosis, cutaneous aspergillosis)
 - Ear (otomycosis)
 - Respiratory tract (sinusitis, pneumonia, empyema)
 - Heart (endocarditis, myocarditis)
 - Gastrointestinal (GI, hepatosplenic aspergillosis)
 - Central nervous system (cerebral aspergillosis, meningitis)
 - Eye (endophthalmitis)
 - Bone (osteomyelitis, mediastinitis)
 - Lungs and sinuses are the two most common primary sites of aspergillosis
 - CNS is the most common secondary site.

TABLE 79.6

CLINICAL SPECTRUM OF ASPERGILLOSIS

Clinical syndromes	Description and epidemiology	Predisposing factors	Clinical characteristics	Outcome
Aspergilloma	Fungus ball (a mass of fungal mycelia, inflammatory cells, tissue debris) within a pre-existing lung cavity. Usually, the fungus does not invade the surrounding lung parenchyma or blood vessels. 17% of patients with pre-existing lung cavity have aspergilloma.	Pre-existing lung cavity.	Often asymptomatic. Some develop hemoptysis. Chest radiograph shows a mobile intracavitary mass with an air crescent in the periphery.	Asymptomatic patients: No treatment. Symptomatic patients: Intracavitary AmB or antimold azole agents. Surgical resection: Reserved for patients with massive hemoptysis; carries significant morbidity and mortality.
Allergic Bronchopulmonary aspergillosis (ABPA)	Hypersensitivity reaction to <i>Aspergillus</i> colonization of the tracheobronchial tree. This can occur by itself or in conjunction with aspergillus sinusitis. 7%–10% of patients with steroid-dependent asthma and 7% of patients with cystic fibrosis have ABPA. The incidence is much less among all patients with asthma (<1%).	Patients with asthma or cystic fibrosis.	Typical presentations: fever and pulmonary infiltrates unresponsive to antibacterial therapy; cough with mucous plugs. Suggestive findings: asthma, eosinophilia, a positive skin test result for <i>A. fumigatus</i> , serum IgE level >1,000 IU/dL, fleeting pulmonary infiltrates, central bronchiectasis, mucoid impaction, and positive test results for <i>Aspergillus</i> precipitins.	Systemic corticosteroids (inhaled steroids have no effect). For recurrent ABPA, itraconazole in conjunction with systemic steroids speeds the resolution of symptoms and facilitates steroid taper.
Chronic necrotizing aspergillosis	Chronic, indolent destructive process of the lung due to invasion by <i>Aspergillus</i> . The rate of disease is not known.	Underlying lung disease. Patients with mild immunosuppression, diabetes, poor nutrition, chronic lung diseases (such as COPD, inactive tuberculosis, previous radiation therapy, pneumoconiosis, cystic fibrosis), lung infarction, sarcoidosis. This syndrome can also follow aspergilloma.	Typical presentations: fever, cough, sputum production, and weight loss for several months. Chest radiographs show an infiltrative process with or without a fungal ball. The diagnosis requires confirmation by demonstration of fungal tissue invasion and the growth of <i>Aspergillus</i> species on culture.	Systemic antifungal therapy with voriconazole (or itraconazole) or lipid formulations of AmB. Caspofungin might also be considered. Surgical resection is considered if the disease is focal and refractory to antifungal therapy.
Invasive aspergillosis	Rapidly progressive, often fatal infection. Characterized by fungal invasion of blood vessels. Infection can disseminate to various organs. Epidemiology: refer to discussion in text.	Patients with profound immunosuppression: prolonged neutropenia; recipients of bone marrow transplant or solid organ transplant; advanced AIDS or chronic granulomatous disease; severe burn.	Typical presentations: fever refractory to antibacterial agents, cough, pleuritic chest pain, or hemoptysis. Suggestive chest radiograph findings: pulmonary nodules with or without surrounding halo sign, crescent sign (indicative of cavitation), wedge-shaped or pleural-based nodules or infiltrates.	Systemic antifungal therapy with voriconazole. Itraconazole, lipid formulations of amphotericin B, and caspofungin are alternative treatments.

COPD, chronic obstructive pulmonary disease; AIDS, acquired immunodeficiency syndrome.

TABLE 79.7

PREDISPOSING FACTORS TO INVASIVE ASPERGILLOSIS

Underlying conditions	Notes	Predisposing factors
Allogeneic bone marrow transplant (BMT) recipients	Risk highest for transplantation from an unrelated donor >HLA-mismatched related donor >HLA-matched related donor	Early after BMT: receipt of T-cell-depleted or CD34-selected stem cell products; neutropenia; use of steroids; CMV disease; respiratory viral infections 1–6 mo: defective cellular immunity; use of steroids >6 mo: use of steroids for GVHD; CMV disease
Cord blood transplant	Higher risk of fungal infections than other allograft recipients during the early and late transplant period	Early: slower myeloid engraftment >6 mo: use of steroids for GVHD
Autologous bone marrow transplant	Lowest risk of infections among the bone marrow transplants	Use of CD34-enriched autografts Use of previous potent immunosuppression for treatment of refractory malignancy
Solid organ transplant	Lung transplant has the highest risk	Immunosuppression to treat allograft rejection
Neutropenia	Highest risk among patients treated with chemotherapy for acute leukemia or aplastic anemia	Intensity (absolute neutrophil count <200 cells/ μ L) and duration of neutropenia (>10 d)
Receipt of immunosuppressive therapy	Therapy for autoimmune diseases	Receipt of high-dose steroids (dose equivalent to prednisone more than 20 mg for >3 wks), antilymphocyte immunoglobulin, anti-TNF α agents, and other immunosuppressive drugs
AIDS	Advanced HIV infection with CD4 ⁺ <100 cells/ μ L	

CMV, cytomegalovirus; GVHD, graft versus host disease; TNF, tumor necrosis factor.

Diagnosis

- Diagnosis of invasive aspergillosis is problematic.
 - *Aspergillus* spores are ubiquitous, common colonizers of the bronchopulmonary tree.
 - Definitive diagnosis, therefore, requires histologic evidence of tissue invasion by hyphal elements, as well as culture of the organism.
 - Sensitivity of tissue biopsy in diagnosing invasive aspergillosis is low (e.g., 30% for lung biopsies).
 - Recovery of *Aspergillus* from the blood is extremely rare, with a recovery rate approximating 5% in cases of *Aspergillus*.
 - In immunocompromised hosts
 - Positive culture from a respiratory sample (sputum or BAL) is highly associated with invasive pulmonary disease.
 - Sensitivity of culture of sputum or BAL is only 50%.
- **Radiography:** In neutropenic patients and bone marrow transplant recipients, high-resolution CT scan of the chest has become an important adjunct to the diagnosis of IPA.
 - One or more nodules surrounded by halo signs (ground glass opacity or haziness) are early findings of angioinvasive mold infections.
 - Cavitation is a late finding.
 - These lesions are highly suggestive of IPA in high-risk patients.
 - Other infections (other fungi, *Nocardia*, and so forth) can also present with halo signs.
 - Classic CT scan findings lead to earlier diagnosis of IPA, more timely administration of antifungal therapy, and improved outcome.

- **Serologic Detection:** A double-sandwich enzyme-linked immunosorbent assay (ELISA) for the detection of galactomannan (GM) in serum has been used as a marker for aspergillosis.
 - GM is a cell wall polysaccharide of most *Aspergillus* and *Penicillium* species that is released in serum during growth in tissue.
 - Sensitivity of the test in different reports has ranged from 30% to 100%, with the wide range explained in part by various definitions of positive tests (e.g., different cutoff values and number of values above a cutoff) and different patient populations.
 - In adult neutropenic patients, a single serum GM level of ≥ 0.8 ng/mL is equivalent to two consecutive serum GM levels of ≥ 0.5 ng/mL.
 - Sensitivity using these cutoffs (0.8 vs. 0.5 ng/mL) 96.5% and 93.3%
 - Specificity 96.5% and 98.6%
 - Positive predictive values (PPV) 97.3%, and 98.6%, respectively
 - Negative predictive value (NPV) 93.3% and 98.4%, respectively
 - Major limitation of this assay is false-positive results
 - Drugs such as piperacillin-tazobactam or cyclophosphamide and certain foods can result in falsely high serum GMs
 - In 27 studies encompassing about 4,000 patients
 - Overall sensitivity of the serum ELISA was 61% to 71%
 - Specificity of 89% to 93%
 - PPV of 26% to 53%

TABLE 79.8

RECOMMENDED ANTIFUNGAL AGENTS AGAINST ASPERGILLOSIS

Antifungal agents	Primary therapy	Alternative therapy
Monotherapy		
Voriconazole	More effective and yields better outcome than conventional AmB. There have not been head-to-head comparisons between voriconazole and lipid formulations of AmB.	
Posaconazole	Has not been evaluated as initial monotherapy for invasive aspergillosis.	Yields favorable response (42%) when used as salvage therapy
Caspofungin	Has not been evaluated as initial monotherapy for invasive aspergillosis.	Yields favorable response (45%) when used as salvage therapy. To date only caspofungin has been evaluated for invasive aspergillosis among echinocandins
Lipid formulations of AmB	Have not been evaluated in controlled trials.	Anecdotal reports demonstrating efficacy as salvage therapy
Combination Therapy		
Liposomal formulations of AmB and caspofungin	Have not been evaluated in controlled trials.	Yield favorable outcome in 40%–60% of patients
Voriconazole and caspofungin	Has not been evaluated in controlled trials.	Superior to voriconazole alone in salvage therapy of invasive aspergillosis

- NPV of 95% to 98%
- Test performed best among bone marrow transplant recipients and patients with hematologic malignancies
- Serial testing strategies in these populations are widely accepted.
- Experience among solid organ transplantation is much more limited.
 - In lung and liver transplant recipients
 - Sensitivities of the assay were 30% and 56%, respectively
 - Specificities of 93% to 95% and 87% to 94%, respectively
 - Not clear at present whether serial GM testing of serum plays a useful role in surveillance for IPA among solid organ transplant recipients
 - Moderate sensitivity and relatively low positive predictive value of the serum GM in diagnosing IPA might be improved by applying the assay to BAL samples
 - Among bone marrow transplant recipients and patients with hematologic malignancies, detection of GM within BAL samples reported to add to sensitivity of both BAL culture and serum GM detection.
 - Specificity of BAL GM detection has generally been good
 - High rates of false-positive results were reported.
 - BAL testing is likely to be influenced by the collection techniques of individual bronchoscopists.

Management

- Voriconazole the first-line therapy against invasive aspergillosis.
 - Proven superior to conventional amphotericin B
 - There have not been head-to-head comparisons of voriconazole versus lipid formulations of amphotericin B.
 - Therapy is generally prolonged for at least 6 weeks or until the primary infection is resolved.

- Role of other systemic antifungal agents is summarized in Table 79.8.
- Debridement of the involved sinuses or primary cutaneous aspergillosis should be performed in conjunction with systemic antifungal therapy.
- Combined antifungal therapy and surgical resection of single lesions from the lungs or central nervous system (CNS) might clear the infection faster than antifungal therapy alone, improve outcome, and prevent reactivation during consecutive chemotherapy courses.
- Procedures are generally well tolerated and associated with low rates of complications and mortality.
- Patients who recover from an episode of invasive aspergillosis are at risk for recurrence of disease during subsequent chemotherapy or transplantation.
 - Should be treated with a systemic antifungal agent for at least 6 weeks or until the primary infection resolves, whichever is longer, before further immunosuppressive therapy is considered
 - Secondary prophylaxis is advised during any subsequent periods of immunosuppression.

VIRAL INFECTIONS

- Recent years have seen the emergence of unexpected viral diseases with high case fatality rates, including:
 - Hantavirus pulmonary syndrome
 - West Nile virus encephalitis
 - Severe adult respiratory syndrome
 - Avian influenza
- Several reasons for critical care physicians to be familiar with a range of viral infections and to consider viral causes in their differential diagnosis
- There is a small window of time to effectively intervene with antiviral agents in many of these diseases.

- Timely identification of persons with potentially infectious viral diseases has significant public health implications and may reduce the risk of transmission to other persons.
- In the era of long-distance travel, clinicians must recognize previously unfamiliar diseases.
- Viruses such as those causing hemorrhagic fevers are possible agents of bioterrorism.
- In general, viral infections can be diagnosed by several means:
 - Serologic tests: The antibody response to viral antigens can be detected in the serum of patients with viral infections
 - IgM response usually indicates recent exposure to a virus.
 - Presence of IgG reflects past exposure
 - Culture: Several types of cells are available for growing viruses, and no single cell line is appropriate for all of them.
 - Pathology: Histologic examination of biopsy and autopsy tissues may demonstrate changes that are typical of certain viruses (e.g., DNA viruses usually produce inclusions in the cytoplasm).
 - Detection of viral antigens: Viral antigens can be detected in tissues by direct or indirect immunofluorescence using appropriate antibodies.
 - Amplification of viral nucleic acids: Small copy numbers of viral DNA and RNA can be detected by polymerase chain reaction (PCR) and reverse transcription-PCR (RT-PCR), respectively. Real-time amplification methods permit simultaneous detection and quantification of viral nucleic acids.
- Table 79.9 lists leading viruses that might be encountered in the ICU.

Viral Infections on Admission to the Intensive Care Unit

Viral Pneumonitis

- Severe community acquired pneumonia is caused by bacteria in approximately 60% of cases.
- In a French ICU, bronchoscopy of 41 patients with severe pneumonia revealed that 30% of all BALs and 63% of bacteria-negative BALs were positive for a respiratory virus.
- Influenza A and B are the most common causes of viral pneumonia in immunocompetent adults.
- CMV and other herpes viruses are more important in immunocompromised patients.
- Frequently difficult to differentiate bacterial from viral pneumonia
 - Viral pneumonia often less severe
 - Patients may complain of a dry hacking cough.
 - Cultures often necessary to make definitive diagnosis
 - Radiographic findings of viral pneumonia generally nonspecific
 - Ranging from minimal changes on chest radiograph to hyperinflation or bilateral reticular opacities that are diffuse in distribution
 - Uncommonly, viral pneumonias can be associated with thickened interlobular septae that result in Kerley B lines.
 - Viral pneumonias are rarely associated with pleural effusions, unless complicated by secondary bacterial pneumonia.
 - CT scan of the chest may show poorly defined air space nodules, patchy areas of peribronchial ground glass opacity, and consolidation.

Influenza Virus

- Epidemics of influenza typically occur during the winter.
- Approximately 66% of patients hospitalized with influenza are older than 64 years of age.
- Morbidity and mortality are highest among:
 - The elderly
 - Children younger than 2 years of age
 - Persons of any age who have comorbid illnesses such as cardiac, pulmonary, or renal diseases, diabetes mellitus, and/or immunosuppression
- **Microbiology:** Human infections are caused by influenza A, B, or C viruses.
 - Wild birds are the natural host for influenza A.
 - Virus infects humans, birds, pigs, and other animals.
 - Influenza B and C viruses are usually found only in humans.
 - Influenza A and B can cause severe disease and occur in epidemics.
 - Influenza A can also be responsible for pandemics.
 - Influenza C causes only mild illness in humans.
 - Does not result in epidemics or pandemics
 - Influenza A viruses are divided into subtypes on the basis of the two main surface glycoproteins, hemagglutinin (HA) and neuraminidase (NA).
 - 16 known HA and 9 known NA subtypes of influenza A
 - New influenza virus variants result from frequent antigenic change, termed *antigenic drift*.
 - Resulting from point mutations that occur during viral replication
 - Influenza B viruses undergo antigenic drift less rapidly than influenza A viruses.
 - In 2006–2007, H5N1 virus (avian influenza) was the circulating virus in Asia and Europe.
 - Caused severe respiratory diseases, life-threatening complications, and death
 - Immunity to the surface antigens, particularly HA, reduces the likelihood of infection and severity of disease
 - Antibody against one influenza virus type or subtype confers limited or no protection against another type or subtype of influenza.
 - Furthermore, antibody to one antigenic variant of influenza virus might not completely protect against a new antigenic variant of the same type or subtype.
 - Antigenic drift is the basis for seasonal epidemics and the reason for the incorporation of one or more new strains in each year's influenza vaccine.
 - More dramatic antigenic changes, or shifts:
 - Occur less frequently
 - Can result in the emergence of a novel influenza virus with potential to cause a pandemic
- **Clinical Manifestations:** The classic influenza symptoms in healthy adults include:
 - Abrupt fever
 - Myalgia
 - Headaches
 - Upper respiratory symptoms
 - In the elderly or immunocompromised hosts, these classic symptoms might be absent, and patients might present only with fever and altered mental status.
 - Influenza-associated lower respiratory tract infections can be classified into four general forms:

TABLE 79.9

VIRAL PATHOGENS MOST LIKELY TO BE ENCOUNTERED IN THE ICU

DNA Viruses		
Family	Viruses	Acute critical illness
Adenoviridae	Adenovirus	Myocarditis
Hepadnaviridae	Hepatitis B	Fulminant liver failure, myocarditis
	Hepatitis delta virus	Fulminant liver failure
Herpesviridae	Herpes simplex	Myocarditis
	Varicella zoster	Pneumonitis
	Cytomegalovirus	Opportunistic infection in immunosuppressed hosts
	EBV	Fulminant liver failure
	HHV8 (Kaposi sarcoma virus)	Pulmonary or GI bleeding in HIV
Papovaviridae	JC, BK, other polyomavirus	Renal failure, encephalitis
Parvoviridae	Parvovirus B19	Myocarditis
Poxviridae	Vaccinia	Postvaccinia vaccine complication
RNA Viruses		
Family	Viruses	Acute critical illness
Arenaviridae	Lymphocytic choriomeningitis virus	Encephalitis
	South American hemorrhagic fever	Hemorrhagic fever
Bunyaviridae	California encephalitis	Encephalitis
	Hantavirus pulmonary syndrome	Pneumonitis
	Bunyavirid hemorrhagic fever	Hemorrhagic fever
Coronaviridae	Coronavirus (including SARS associated)	Pneumonitis
Filoviridae	Marburg	Hemorrhagic fever
	Ebola	Hemorrhagic fever
Flaviviruses	Yellow fever	Encephalitis
	Dengue, dengue hemorrhagic fever	Hemorrhagic fever
	Japanese encephalitis	Encephalitis
	West Nile encephalitis	Encephalitis
	St. Louis encephalitis	Encephalitis
	Tick-borne encephalitis	Encephalitis
	Hepatitis C	Myocarditis
	Influenza virus	Pneumonitis, myocarditis
Orthomyxoviridae	Avian influenza	Pneumonitis
	Parainfluenza	Pneumonitis
Paramyxoviridae	Mumps	Myocarditis
	Respiratory syncytial virus	Pneumonitis in children, IC
	Human meta-pneumovirus	
	Measles virus (rubeola)	Encephalitis, myocarditis
	Enterovirus	Myocarditis
	Hepatitis A	Fulminant hepatic failure
Picornaviridae	Poliovirus	Myocarditis
	Coxsackievirus, echovirus, and newer enteroviruses	Myocarditis
	Rhinovirus	
	Human T-cell lymphotropic virus I and II	Acute adult T cell leukemia
Retroviridae	Human immunodeficiency virus	Refer to Chapter 81
	Vesicular stomatitis virus and related virus	Encephalitis
Rhabdoviridae	Rhabdovirus	
Togaviridae	Rubella virus (German measles)	Myocarditis

EBV, Epstein-Barr virus; HHV8, human herpes virus 8; GI, gastrointestinal; SARS, severe acute respiratory syndrome; IC, intensive care.

- Influenza without radiographic evidence of pneumonia—up to 30% of hospitalized patients with influenza have no evidence of pulmonary infiltrates
- Viral pneumonia followed by bacterial pneumonia—true incidence is unknown
 - Most common bacteria:
 - *Staphylococcus aureus*
 - *Streptococcus pneumoniae*
 - *Haemophilus influenzae*

- Rapidly progressive diffuse viral pneumonia—may be decreasing due to increased rate of influenza vaccination in the elderly
- Concomitant viral and bacterial pneumonia—*S. aureus*, *S. pneumoniae*, and *Haemophilus influenzae*
 - Generally more ill than other groups
 - Higher rate of ICU admission
 - Greater morbidity
 - Poor outcomes result from:

- Worsening of underlying heart or lung conditions
- Secondary bacterial pneumonia
- Toxic shock syndrome
- Endotoxemia
- Myopericarditis
- Cytokine-induced shock syndrome
- Encephalitis
- Transverse myelitis
- **Diagnosis:** Several tests can be performed to diagnose influenza. Nasopharyngeal swabs, nasal washes, and aspirates obtained within the first 4 days of illness are preferred respiratory samples.
 - **Rapid influenza tests:** provide results within 30 minutes, and some distinguish between influenza A and B
 - Overall sensitivity is 70% to 75%
 - Specificity of 90% to 95%
 - Useful in the diagnosis of individual patients and in detecting outbreaks
 - **Direct immunofluorescent antibody (DFA) staining:** Requires 2 to 4 hours for results
 - Distinguishes influenza A and B
 - Often performed in a panel that also detects parainfluenza and respiratory syncytial viruses
 - **RT-PCR:** Detects and distinguishes both influenza A and B in 1 to 2 days
 - **Viral culture:** Takes up to 10 days
 - Essential for determining influenza A subtypes and influenza A or B strains
 - Information needed for following year's vaccine
 - **Serology:** Used mainly for research or public health investigations
 - Results not helpful for clinical decision making
- **Treatment:** Two classes of antiviral drugs are available for the prevention and treatment of influenza (Table 79.10):
 - **Amantadine and rimantadine:**
 - Target the M2 protein of influenza A
 - Not effective against other influenza viruses
 - Both are generally well tolerated
 - CNS side effects are more common in the elderly.
 - Dosing modification is based on renal function.
 - **Zanamivir and oseltamivir:**
 - Neuraminidase inhibitors active for prevention and therapy against both influenza A and influenza B
 - Work best if initiated within 48 hours of clinical symptoms
 - Only oseltamivir has been shown to reduce lower respiratory tract complications requiring antibiotics
 - Patients with asthma or COPD are advised to have a fast-acting inhaled bronchodilator available when inhaling zanamivir.
 - Zanamivir should be stopped if patients develop difficulty breathing.
- **Prevention:** Yearly vaccination is the best means to prevent influenza.
 - Particularly important in people who are at high-risk of having serious complications:
 - Those 65 years of age or older
 - Those with:
 - Cardiac or pulmonary diseases
 - Diabetes or other metabolic diseases
 - Renal dysfunction
 - Hemoglobinopathies
 - Immunosuppression

- People (physicians, nurses) caring for those at high risk for serious complications
- During influenza outbreaks within institution/community:
 - Public health practice is to:
 - Combine influenza vaccine and antiviral medications.
 - Vaccine is given to the exposed patients and staff.
 - Antiviral agent is also given for about 2 weeks until the vaccine takes effect.

Respiratory Syncytial Virus (RSV)

- RSV causes acute respiratory illness in persons of all ages
 - Annual frequency of RSV infection in the elderly and high-risk adults is about 5.5%.
 - Among patients admitted to a hospital for community-acquired pneumonia
 - RSV is second to influenza among viral causes.
 - RSV and influenza A result in comparable lengths of stay, admissions to ICUs, and mortality (8% and 7%, respectively).
- **Transmission:** RSV is transmitted:
 - Person-to-person through close contact
 - By inhalation of large droplets following sneezing or coughing
 - By contact with infected fomites
 - In the United States, RSV outbreaks occur in the winter.
 - In tropical regions, outbreaks occur usually in the rainy season.
- **Clinical Manifestations:** The clinical presentation varies depending on the patient's age and health status.
 - Older children and young adults typically present with upper respiratory symptoms or tracheobronchitis.
 - Elderly and immunocompromised may develop pneumonia.
 - Wheezing occurs in 35% of elderly patients with RSV infection.
 - Presentations can be difficult to differentiate from other causes of viral illnesses, including influenza.
 - In general, URI symptoms tend to last longer than those caused by other respiratory viruses.
 - Associated with a bronchitic cough and wheezing
 - Findings on chest radiograph range from focal interstitial or lobar consolidations to diffuse alveolar interstitial infiltrates
 - Infections are particularly severe in compromised hosts.
 - Mortality of 30% to 100% in bone marrow transplant recipients
- **Diagnosis:** The diagnosis is made by viral detection (by culture or immunofluorescence) or by detection of viral antigens, RNA, or serology.
 - Cultures are performed on respiratory secretions and require 4 to 14 days for results.
 - Rapid assays using *antigen capture technology*:
 - Can be performed in <30 minutes
 - Sensitivity and specificity approach 90%
 - Multiplex PCR ELISA is being developed to allow simultaneous diagnosis of multiple respiratory pathogens.
 - In general, diagnosis is more difficult to establish in adults than in children due to low titers of viral shedding.
- **Treatment:** Therapy is mainly supportive.
 - Bronchodilators may help to relieve bronchospasm in some patients.
 - Early use of inhaled ribavirin has been shown to reduce morbidity and mortality in adult bone marrow transplant patients who develop RSV infections.

TABLE 79.10

ANTIVIRAL AGENTS (EXCLUDING ANTI-HIV DRUGS)

Drugs	Description	Viral agents	Infection and sites	Dose in patients with normal renal function	Toxicities	Viral resistance	Mechanism of resistance
Acyclovir	Acyclic guanosine nucleoside analogue	HSV1, HSV2, and VZV	Mucocutaneous HSV infection HSV or VZV encephalitis or VZV pneumonitis	400 mg tid PO or 5 mg/kg q8h IV (also available as topical agent) 10 mg/kg q8h IV	Headache, nausea Renal, neurologic toxicities	> 1% in immunocompetent hosts 6%–8% in immunocompromised hosts 11%–17% in patients with AIDS and transplant recipients	Most common: no or low production of viral thymidine-kinase (TK) → cross-resistant to penciclovir and ganciclovir Altered TK substrate specificity Altered viral DNA polymerase Same as acyclovir
Valacyclovir	L-valine ester prodrug of acyclovir	HSV1, HSV2, and VZV	Mucocutaneous HSV	1 g bid PO 1 g tid PO	Similar to acyclovir		
Famciclovir	Ester prodrug of penciclovir	HSV1, HSV2, and VZV	Cutaneous HZV Mucocutaneous HSV	125–500 mg bid PO 500–750 mg bid to tid PO	Headache, nausea, and diarrhea		Inactive against TK-deficient strains of HSV and VZV
Ganciclovir	Acyclic guanosine nucleoside analogue	HSV1, HSV2, VZV, CMV, EBV	Cutaneous VZV CMV retinitis, pneumonitis, or other organ disease	5 mg/kg q12h IV	Hematologic	About 8% of isolates in AIDS patients are resistant to ganciclovir after a course of therapy; resistance also documented among transplant recipients Same as ganciclovir	Mutation of UL97 gene or of viral DNA polymerase Some ganciclovir-resistant strains with DNA polymerase mutations are cross-resistant to foscarnet and cidofovir Same as ganciclovir
Valganciclovir	Ester prodrug of ganciclovir	CMV	CMV retinitis	900 mg bid po	Hematologic		
Foscarnet	Pyrophosphate analogue	HSV1, HSV2, VZV, CMV, HIV	CMV HSV VZV	60 mg/kg q8h IV or 90 mg/kg IV q12h IV 40 mg/kg q8h or 60 mg/kg q12h IV 60–90 mg/kg q12h IV	Renal (azotemia, acute tubular necrosis) Metabolic and electrolyte imbalance Neurotoxicity (tremor, headache)	<5% of patients on foscarnet therapy	Point mutations in DNA polymerase of HSV and CMV, and reverse transcriptase of HIV. In general, no cross-resistance with ganciclovir or cidofovir, although some ganciclovir-resistant strains with DNA polymerase mutations are cross-resistant to foscarnet and cidofovir

(continued)

Drugs	Description	Viral agents	Infection and sites	Dose in patients with normal renal function	Toxicities	Viral resistance	Mechanism of resistance
Cidofovir	Nucleotide analogue	HSV1, HSV2, VZV, HHV-6, HHV-8, CMV, EBV, DNA viruses (papilloma, pox viruses)	CMV retinitis	5 mg/kg once a week IV	Renal (proximal tubular dysfunction), Ocular (anterior uveitis or ocular hypotony)	Uncommon	Ganciclovir-resistant CMV (due to DNA polymerase mutations plus UL97 mutations) and some foscarnet-resistant CMV strains are cross-resistant to cidofovir
Amantadine Rimantadine	Tricyclic amine	Influenza A	Influenza A within 48 h of symptoms	100 mg bid po	Gastrointestinal complaints and neurologic toxicities (rimantadine has lower neuro effects)	Up to 30% of patients treated shed resistant viruses by the 5th day	Cross-resistance between amantadine and rimantadine Resistant viruses remain susceptible to neuraminidase inhibitors
Zanamivir	Neuraminidase inhibitor	Influenza A, B	Influenza within 48 h of symptoms	10 mg bid via inhalation	Bronchospasm		
Oseltamivir	Neuraminidase inhibitor	Influenza A, B	Influenza within 48 h of symptoms	75 mg bid po	Neuropsych, nausea		
Ribavirin	Nucleoside analogue	RSV	RSV in infants	6 g/300 mL over 12–18 h/d via aerosol	Teratogenic, embryotoxic	No viral resistance has been detected (except for Sindbis virus)	
		Hepatitis C	Hepatitis C	500–600 bid po (together with IFN)	Anemia Reversible hyperbilirubinemia		
		Lassa fever or Hantavirus		IV, may be obtained from CDC			
Interferon alpha		Hepatitis C virus	Hepatitis C (with ribavirin)	Peg IFN alpha-2a 180 mg/wk SC (in combination with ribavirin)	Depression Flulike symptoms Bone marrow toxicity		
		Hepatitis B virus	Hepatitis B	Peg IFN alpha-2a 180 mg/wk SC			
Lamivudine	Nucleoside analogue	Hepatitis B HIV	Hepatitis B	100 mg daily po	Benign	16%–31% resistance after 6 mo to 1 y. Rate is higher in transplant recipients	Mutations in HBV DNA polymerase
Entecavir	Nucleoside analogue	Hepatitis B	Hepatitis B	0.5–1 mg PO daily	Headache, Abdominal pain Pharyngitis	Rare in nucleoside-naïve patients	
Adefovir	Nucleotide analogue	Hepatitis B	Hepatitis B	10 mg PO daily		9%, 18%, and 28% resistance after 3, 4, and 5 y, respectively	Mutations in HBV reverse transcriptase domain

- More aggressive therapy with combined ribavirin, IV immunoglobulin with high titers of neutralizing RSV antibody, and/or steroids can be considered in immunosuppressed patients with severe RSV pneumonia.

Varicella-Zoster Virus (VZV)

- VZV causes chickenpox or shingles.
- Primary infection usually occurs in childhood.
- Generally a benign self-limited illness in immunocompetent hosts
- Pneumonia is uncommon complication of varicella in healthy children.
 - The most frequent complication in healthy adults
 - Reported incidence rate is about 2.3 in 400 cases in the United States.
 - Overall mortality between 10% and 30%.
 - With respiratory failure due to VZV pneumonia requiring mechanical ventilation
 - Mortality rates approach 50% despite institution of aggressive therapy and supportive measures.
 - Risk factors for VZV pneumonia:
 - Cigarette smoking
 - Pregnancy
 - Immunosuppression
 - Male gender
- **Clinical Manifestations:** VZV pneumonia develops insidiously 1 to 6 days after onset of:
 - Vesicular rash
 - With symptoms of cough, shortness of breath, fever, and occasionally pleuritic chest pain or hemoptysis
 - Examination of the chest may reveal rhonchi or wheezes.
 - Chest radiograph typically reveals diffuse or patchy nodular infiltrates with a prominent peribronchial distribution.
 - Reticular markings, pleural effusions, and hilar adenopathy may be seen as well.
- **Treatment:** Prompt treatment with IV acyclovir
 - Dose of 10 mg/kg every 8 hours associated with clinical improvement and resolution of pneumonia
 - Addition of steroids for treatment of life-threatening varicella pneumonia is controversial
 - In one series, patients who received steroids as adjunctive therapy had shorter hospitalizations and ICU stays and no mortality.
 - Rapid institution of extracorporeal life support has been reported to improve outcome in patients with severe life-threatening varicella pneumonia.

Hantavirus Pulmonary Syndrome (HPS)

- Among agents causing HPS, the *Sin Nombre* (Spanish for “nameless” or “without a name”) virus that caused the 1993 Four Corners outbreak in the southwestern United States was the most severe.
- Many hantaviruses are shed in the urine, feces, or saliva of infected rodents.
 - Transmission to humans occurs via aerosols
 - Deer mouse *Peromyscus maniculatus* the predominant reservoir
 - CDC reported an increase in human cases of HPS during January through March of 2006 in Arizona, Texas, North Dakota, New Mexico, and Washington
- **Clinical Manifestations:** Incubation period is 1 to 3 weeks.
 - After which patients experience:

- Fever
- Muscle pain
- Fatigue
- Some also experience headache, dizziness, vomiting, or diarrhea
- Four to 10 days later patients develop:
 - Cough
 - Respiratory distress
- No defined sets of symptoms and signs that reliably distinguish HPS from other forms of noncardiogenic pulmonary edema or ARDS
- Features associated with HPS are:
 - Thrombocytopenia
 - Hemoconcentration
 - Leukocytosis with increased band forms on differential
 - Hypoalbuminemia
 - Lactic acidosis
- Classic diagnostic triad includes thrombocytopenia, neutrophilia, and an immunoblast count of >10% of the total lymphocytes.
 - Shock and lactic acidosis associated with poor prognosis
 - Case fatality ratio is 30% to 40%.
- **Diagnosis:** Consider HPS in the differential diagnosis of previously healthy patients from endemic areas who present with fever >101°F and develop bilateral diffuse interstitial edema of the lungs within 72 hours of hospitalization.
 - Edema can resemble ARDS on chest radiograph.
 - Serologic tests are the main method of diagnosing HPS.
 - High levels of IgM antibodies present by the time symptoms are evident.
 - In the United States, states that offer hantavirus diagnostic testing use IgG and mu capture IgM ELISA assays developed and distributed by the Centers for Disease Control and Prevention.
- **Treatment:** No specific antiviral therapy for HPS, and treatment is mainly supportive, with early initiation of mechanical ventilation to treat respiratory failure.
 - Use of extracorporeal membrane oxygenation (ECMO) should be considered in patients with a cardiac index of <2.5 L/minute/m² despite inotropes.
 - Placebo-controlled double-blind trial of IV ribavirin for the treatment of hantavirus cardiopulmonary syndrome in North America was terminated early due to the drug's probable ineffectiveness.

Severe Acute Respiratory Syndrome (SARS)

- SARS a serious pulmonary illness caused by a coronavirus that jumped species from semidomesticated animals to humans and spread from China to Hong Kong in late 2002.
- Infection spread by close person-to-person contact via respiratory droplets
- Incubation period is 2 to 10 days.
- Patients first experience:
 - High fever associated with chills, headache, and myalgia
 - Diarrhea is seen in approximately 10% to 20%.
 - Two to 7 days later a dry nonproductive cough develops.
 - Hypoxia that progresses to ARDS and multiple organ dysfunction may be seen.
 - Ten percent to 20% require mechanical ventilation.
- RT-PCR, serology, and cultures of blood, stool, and nasal secretions possible diagnostic tools.
 - Routine clinical use difficult

TABLE 79.11

COMMON CAUSES OF VIRAL MENINGITIS AND ENCEPHALITIS

Types of infection	Viral pathogen	Comments
<i>Viral meningitis</i>	Enterovirus	Most common cause of viral meningitis More than 50 serotypes of enteroviruses Can cause meningitis or meningoencephalitis Associated with genital herpes infection
	Herpes simplex type 2	Generally develops at the time of HIV seroconversion
	HIV	Sporadic cause of meningitis
	Lymphocytic choriomeningitis (LCM)	Can cause meningitis or meningoencephalitis Rare cause of viral meningitis Can cause severe meningoencephalitis in children
<i>Encephalitis</i>	Adenovirus	
	Japanese encephalitis	Most common cause worldwide
	Herpes simplex type 1	Most common cause of sporadic viral encephalitis Associated with focal symptoms
	Arboviruses	Transmitted by mosquitoes or ticks. Causes disease in immunocompromised patients only
	CMV, VZV	

HIV, human immunodeficiency virus; CMV, cytomegalovirus; VZV, varicella-zoster virus.

- No specific treatment against SARS-associated coronavirus
- Supportive care remains principal therapeutic alternative
- Ribavirin and corticosteroids have been used.
 - Efficacy has not been established.
- Mortality approximates 11%.
- Infection control practices are extremely important in halting progression of an outbreak.

Other Viruses

- Although uncommon in adults
- Adenovirus pneumonia outbreaks have been described among military recruits and among adults in chronic care facilities.
- Diagnosis is established by culture of a nasopharyngeal aspirate or swab, throat swab, or sputum.
- Other viruses associated with acute pneumonias in adults include:
 - Measles
 - Parainfluenza
 - Parvovirus

Viral Meningitis and Encephalitis

- Refer to infections of the leptomeninges and brain parenchyma, respectively.
- Important differentiating feature between viral meningitis and encephalitis is presence or absence of altered sensorium
 - With viral meningitis, one sees lethargy and severe headache, but cerebral function remains normal.
 - In encephalitis, cerebral functions are abnormal, including altered mental status, altered behavior and personality changes, speech or movement disorder, and focal neurologic deficits.
- Reported incidences:
 - Viral meningitis 11 per 100,000 person years
 - Encephalitis 7 per 100,000 person-years
- Patients may have both a parenchymal and meningeal process called *meningoencephalitis*

Viral (Aseptic) Meningitis

- Common causes of viral meningitis are summarized in Table 79.11.
- Other viruses are even rarer causes, such as:
 - Epstein-Barr virus (EBV)
 - Cytomegalovirus (CMV)
 - Human herpes virus 6 (HHV-6)
 - Herpes zoster (reactivation of VZV infection) of aseptic meningitis
- Arboviruses such as St. Louis encephalitis and California encephalitis (SLE and CE, respectively)
 - More commonly cause encephalitis or meningoencephalitis
 - But can also cause aseptic meningitis
- Clinical presentations of viral meningitis are nonspecific:
 - Fever
 - Headache
 - Photophobia
 - Nuchal rigidity
- Helpful clues to the diagnosis include:
 - Travel to arbovirus endemic areas
 - Exposure history (rodents, ticks)
 - Sexual activity (HSV-2)
 - Contact with other people with similar symptoms (enteroviruses)
- Clinicians should look for:
 - Pharyngitis and pleurodynia (enteroviruses)
 - Rash (zosteriform rash of VZV, vesicular rash of HSV, maculopapular rash measles or enteroviruses)
 - Adenopathy (primary HIV or EBV)
- Cerebrospinal fluid (CSF) findings include:
 - White blood cells (WBC) <500 cells/ μ L
 - Of which >50% are lymphocytes
 - Protein <80 mg/dL
 - Normal glucose
 - Negative Gram stain
- CSF should be sent for:
 - Bacterial and viral cultures
 - HSV PCR

- HIV viral load
- Other tests that can be sent if indicated include:
 - Enterovirus PCR
 - Acute/convalescent serologic testing for specific viruses
- If patient is neither immunocompromised nor toxic appearing
 - One can observe without giving antibiotic therapy.
 - Treatment for enteroviral meningitis is mostly supportive (pain management and hydration).
 - Pleconaril
 - Inhibits viral attachment to host cells and viral uncoating
 - Has shown disappointing results in the treatment of enteroviral meningitis
 - If the patient is immunosuppressed, elderly, or toxic appearing, or has received antibiotics before presentation
 - May consider empiric antibiotics for 48 hours while waiting for culture results

Viral Encephalitis

- In the United States, most common cause of sporadic encephalitis is HSV-1
- Arboviruses account for approximately 5% of viral encephalitis.
 - SLE virus the most common.
 - Clues to arboviral infection include:
 - Season (arboviruses cause disease when mosquitoes are active, whereas HSV-1 can occur at any time)
 - Location (woody or marshy areas would suggest viruses such as the cause of Colorado tick fever or nonviral illness such as Lyme disease or Rocky Mountain spotted fever)
 - Geographic region (SLE occurs in the midwest and southern United States, whereas West Nile virus [WNV] occurs in multiple continents)
 - History of animal exposure (rabies)
 - Clues on physical exam include:
 - Parotitis (mumps)
 - Flaccid paralysis (WNV)
 - Tremors of the eyelids, tongue, lips, and extremities (SLE)
 - Findings of hydrophobia, aerophobia, and hyperactivity (rabies)
- CSF findings can be similar to those of viral meningitis.
 - Depending on clinical suspicion, the CSF can also be sent for:
 - PCR for enteroviruses, HSV, or CMV
 - Acute and convalescent sera against specific viral pathogens such as arboviruses, and lymphocytic choriomeningitis virus (LCMV) might also be useful in determining a cause
 - CT scan with IV contrast or MRI should be obtained:
 - To exclude an intracranial process (cerebritis, abscess, subdural empyema, mass occupying lesions)
 - To detect findings suggestive of a viral cause
 - Temporal and basal frontal lobe involvement suggests HSV encephalitis.
 - Basal ganglia and thalamic involvement suggest Eastern equine encephalitis.
 - Until HSV encephalitis is ruled out
 - Acyclovir at 10 mg/kg IV every 8 hours should be considered in patients with suspected viral encephalitis
- HSV encephalitis: A fulminant hemorrhagic and necrotizing meningoencephalitis that involves primarily the temporal and basal frontal cortices and the limbic system
- HSV-1 accounts for most fatal cases of sporadic encephalitis in adults.
 - HSV-1 encephalitis can arise either from:
 - Primary infections, or
 - Reactivation of a latent infection
 - No difference in outcome from patients suffering encephalitis from a primary or reactivation HSV infection
- Herpes simplex virus type 2 (HSV-2) accounts for herpes encephalitis in 80% to 90% of neonates and children.
- *Clinical Manifestations:* Most common early symptoms are fever and headache.
 - Additional symptoms include:
 - Meningeal irritation
 - Nausea
 - Vomiting
 - Altered consciousness
 - Generalized seizures
 - Other changes are referable to involved brain areas, including:
 - Anosmia
 - Memory loss
 - Abnormal behavior
 - Speech defects
 - Olfactory and gustatory hallucinations
 - Focal seizures
 - Can be rapid progression of the disease in some patients with the development of focal paralysis, hemiparesis, and coma
- *Diagnosis:* Diagnosis of HSV encephalitis can be strongly suggested if:
 - Typical clinical presentations associated with specific findings on EEG and MRI
 - Typical EEG findings are:
 - Focal temporal abnormalities
 - Found in about 80% of patients
 - Periodic lateralized epileptiform discharges also suggest HSV encephalitis
 - Although not as specific
 - In HSV encephalitis, a normal EEG essentially excludes the diagnosis.
 - Typical MRI appearance is:
 - Medial temporal abnormalities that do not respect hippocampal borders
 - CSF findings are similar to other cases of viral meningoencephalitis.
 - Isolation of HSV from CSF is rare
 - Occurring in <5% of cases
 - Definitive diagnosis is made by detection of HSV DNA in CSF by PCR.
 - Which is very sensitive and specific
 - Availability of PCR has largely obviated the need for brain biopsy, the previous gold standard diagnostic test
- *Treatment:* Morbidity and mortality are reduced by early antiviral therapy.
 - IV acyclovir, 10 mg/kg every 8 hours
 - Continued for 14 to 21 days
 - A 5% relapse rate after the discontinuation of antiviral therapy

- **Rabies:** Caused by neurotropic RNA viruses
 - In addition to classic rabies virus, at least 10 other rabies-related viruses can cause clinically indistinguishable fatal encephalitis.
 - Has a worldwide distribution
 - Found throughout the United States except Hawaii
 - In developing countries, dogs are major reservoir.
 - Wild animals remain most important reservoir in the United States
 - Most reported cases occur in carnivores
 - Raccoons in the northeast
 - Skunks in the south and southwest
 - Foxes in the southwest and Alaska
 - And insectivorous bats
 - In the United States, an average of three fatal human cases per year since 1980
 - Acquisition of rabies usually occurs after:
 - Bite from an infected animal
 - Scratching and licking by a rabid animal
 - Cases have also been reported after solid organ, cornea, or vascular tissue transplantation from unsuspected rabies-infected individuals
 - *Clinical Manifestations:* Human rabies assumes two forms: furious (encephalitic) and paralytic (dumb).
 - Furious form—observed in 80% of patients—manifests as:
 - Hyperactivity
 - Hydrophobia
 - Pharyngeal spasms
 - Aerophobia
 - Paralytic form can mimic Guillain-Barré syndrome with quadriparesis, sphincter involvement, and late cerebral involvement
 - Some bat-associated rabies may present atypically with:
 - Neuropathic pain
 - Sensory or motor deficits
 - Choreiform movements of the bitten limb
 - Focal brainstem signs
 - Myoclonus
 - Seizures
 - Regardless of presentation, the disease is almost always fatal.
 - *Diagnosis:* Confirmed in several ways:
 - Detection of viral RNA in saliva by RT-PCR
 - Biopsy of the nape of the neck for detection of RNA or viral antigen within hair follicles by RT-PCR or immunofluorescence staining, respectively
 - Antibodies in serum and CSF
 - Presence of pathognomonic Negri bodies (eosinophilic neuronal cytoplasmic inclusions) in brain biopsy
 - *Treatment:* There is no proven effective treatment for rabies after the onset of illness.
 - Only six survivors have been reported.
 - Five of whom received postexposure vaccination
 - The sixth patient survived after induction of coma and treatment with ribavirin and amantadine.
 - Clinicians who wish to consider this protocol should contact Dr. Rodney Willoughby at Children's Hospital of Wisconsin (414-266-2000).
 - Rabies vaccination after onset of illness is not recommended and may be detrimental.
 - After definitive diagnosis, the primary focus is comfort care.
- Management of patients with rabies poses no greater risk to health care providers than caring for patients with more common infections.
 - Adherence to standard precautions should be maintained:
 - Gloves
 - Gowns
 - Masks
 - Eye protection
 - Face shield (particularly during intubation or suctioning)
 - Because of the lack of effective treatment:
 - Postexposure prophylaxis should be initiated as soon as possible after exposure to rabid or unknown animals.
 - Includes the administration of:
 - Human rabies immunoglobulin (HRIG: HyperRab Tm S/D or Imogam Rabies-HT)
 - Rabies vaccination (purified chick embryo cell vaccine (PCECV; 1-800-244-7668; www.rabavert.com)
- **West Nile virus:** WNV a single-stranded RNA virus that can infect humans, mosquitoes, and animals such as birds and horses.
 - In temperate climates, WNV is transmitted primarily in the summer or early fall.
 - Transmission can occur year round in warmer climates.
 - Most human WNV infections result from mosquito bites.
 - Infection can also be transmitted via:
 - Transfusion of WNV-infected blood products
 - Transplacental fetal infection
 - Transplantation of infected organs
 - *Clinical Manifestations:* Patients infected with WNV can be asymptomatic (80%), develop West Nile fever (WNF, 20%) or West Nile neuroinvasive disease (WNND, <1%).
 - WNND includes:
 - Meningitis, encephalitis, and acute flaccid paralysis
 - WNV encephalitis is more common in the elderly or immunocompromised patients.
 - Incubation period ranges from 3 to 14 days.
 - Symptoms generally last 3 to 6 days.
 - Patients with WNF or WNND present with an abrupt onset of:
 - Fever
 - Headache
 - Fatigue
 - Anorexia
 - Gastrointestinal complaints
 - Myalgia
 - Lymphadenopathy
 - Generalized nonpruritic maculopapular rash
 - Patients with WNND also present with:
 - Altered mental status (46% to 74%)
 - Tremor (12% to 80%)
 - Extrapyrimal features such as rigidity or bradykinesia (67%)
 - Cerebellar abnormalities (11% to 57%)
 - Myoclonus—present in 33% of cases—a clue to WN infection
 - Rare in other causes of viral encephalitis
 - Seizures are unusual (1% to 16%)
 - *Diagnosis:* Diagnosis of WNV infection is based on a high index of suspicion and obtaining specific laboratory tests.

- IgM antibody capture ELISA (MAC-ELISA) can detect WNV in nearly all CSF and serum specimens from WNV-infected patients.
- IgM antibody does not cross blood–brain barrier.
 - IgM antibody in the CSF strongly suggests acute CNS infection.
 - WNV testing of patients with encephalitis, meningitis, or other serious CNS infections can be obtained through local or state health departments.
- **Treatment:** Treatment is supportive, with hospitalization, IV fluids, respiratory support, and prevention of secondary infections for patients with severe disease.
- Ribavirin and interferon alpha 2b have some activity against WNV *in vitro*.
 - No controlled studies have been completed.
 - Role of corticosteroids has not been assessed.

Viral Infections Acquired during Intensive Care Unit Stay

- Herpes family viruses recognized as pathogens in immunosuppressed transplant patients and HIV/AIDS patients.
- Increasingly reported as pathogens in nonimmunosuppressed critically ill
- At least 14% of chronic critically ill surgical patients had occult CMV or HSV infection/reactivation.

CMV Infection

- Infects about 60% to 70% of people during their lifetimes
 - Like other members of the herpes family, becomes latent or persistent after primary infection
 - Infection can reactivate at a later time
 - Especially in the settings of immunodeficiency or significant stress from operations or injuries
- **Transmission:** CMV can be found in body secretions:
 - Urine
 - Saliva
 - Sputum
 - Breast milk
 - Semen
 - Cervical fluid
 - In circulating mononuclear and polymorphonuclear cells, vascular endothelium, and renal epithelium
 - CMV spreads from person to person by contact with body fluids.
 - Transmission is particularly high among toddlers in day care.
 - Day care employees are also at significant risk for CMV exposure and/or infection.
 - So are health care personnel with direct patient contact
 - Congenital transmission from a mother with acute infection during pregnancy is a significant cause of neurologic abnormalities and deafness in newborns.
 - Can also be transmitted by:
 - Breastfeeding
 - Blood transfusion
 - Receipt of an organ transplant
 - Major risk factors for CMV disease in solid organ transplant recipients are CMV mismatch. . .
 - Transplantation of a CMV-positive organ into a CMV-seronegative recipient
 - . . . and the degree of immunosuppression
- **Clinical manifestations:** Most immunocompetent children and adults who are infected with CMV do not develop symptoms.
 - Some may experience an illness resembling infectious mononucleosis with fever, swollen glands, and mild hepatitis.
 - Rare complications of primary CMV infection include:
 - Hepatitis
 - Interstitial pneumonia
 - Guillain-Barré syndrome
 - Meningoencephalitis
 - Pericarditis
 - Myocarditis
 - Thrombocytopenia
 - Hemolytic anemia
 - In immunocompromised patients, primary CMV infection is life threatening. Most common manifestations:
 - Myelosuppression
 - Encephalitis
 - Hepatitis
 - Pneumonitis
 - Retinitis
 - GI infection
 - Reactivation of latent CMV causes disease in immunocompromised hosts, although typically milder than primary infection.
 - In general, the severity of CMV disease is related to the degree of immunosuppression.
 - CMV appears to target allografts in particular.
 - Hepatitis common in liver transplant recipients
 - Pancreatitis in pancreatic transplant
 - Pneumonitis in lung and heart-lung transplant
 - CMV pneumonia highest among bone marrow transplant recipients
 - In solid organ transplant recipients, CMV infections predispose to other opportunistic infections, especially fungal or *Pneumocystis* infections
 - CMV infection can also affect graft survival.
 - Causing early allograft rejection in renal transplant recipients
 - Chronic allograft rejection in cardiac transplant recipients (allograft atherosclerosis)
 - Vanishing bile duct syndrome in liver transplant recipients
- **Diagnosis:** CMV can be shed in biologic fluids from patients with no evidence of disease.
 - Gold standard for diagnosis remains finding intranuclear inclusion bodies in histologically examined tissue.
 - Infection may be confirmed by *in situ* hybridization or direct or indirect staining of intranuclear inclusions using specific antibodies linked to an indicator system.
 - Histopathology is limited by poor sensitivity.
 - Tests that can detect and quantify CMV or its products in blood, leukocytes, or tissues are reviewed in Table 79.12
 - CMV excretion in saliva and urine is common in immunocompromised patients.
 - Generally of little consequence
 - Viremia in organ transplant patients identifies those at greatest risk for CMV disease.

TABLE 79.12
DIAGNOSTIC TESTS FOR CMV INFECTION

Test	Concept	Advantages/disadvantages	Interpretation of positive tests in the immunocompromised host	Interpretation of tests in the immunocompetent host
SEROLOGY CMV-specific IgG	Detect IgG seroconversion.	Disadvantage: Need acute and convalescent sera (or known baseline negative IgG).	Documented seroconversion implies primary CMV infection.	Documented seroconversion implies primary CMV infection.
CMV-specific IgM	Acute phase of primary CMV infection should have positive CMV-specific IgM and negative IgG antibodies.	Advantage: Depending on assays used, sensitivity and specificity can be as high as 100% and 98%, respectively. Disadvantage: Interference due to presence of rheumatoid factor and antinuclear antibody.	Since IgM can also be elevated in reactivation, positive IgM alone does not indicate primary CMV infection. In this setting, should interpret in conjunction with CMV-specific IgG. In the immunocompromised host, IgM might persist for a long time after primary infection.	Problems with false-positive and persistent IgM due to reactivation are less than with the immunocompromised hosts.
Detection of virus	Recovery of CMV from the biologic sites signifies either primary infection, reactivation, or asymptomatic shedding without infection.			
Shell-vial assay	Detection and quantitation of viremia.	Disadvantage: 1. Tissue culture is time-consuming. Shell-vial assay can provide results within 24 h. 2. Low sensitivity. 3. Loss of CMV viability in stored clinical samples.	High risk of developing CMV disease. Marker for initiation of antiviral therapy and monitoring the efficacy of therapy.	Specific for primary CMV infection. Sensitivity of 26.3%, highest within 1 mo of primary infection. Test positivity can last up to 4–6 mo. Low false-positive rate.
Antigenemia	Detection and quantitation of leukocytes that are positive for CMV phosphoprotein pp65.	Advantages: 1. Rapid test with turnover time of a few hours. 2. In transplant recipients, antigenemia becomes positive before viremia detection, but later than DNA-emia at the onset of CMV infection. Disadvantages: 1. Subjective slide reading. 2. Levels of antigenemia might lag behind clinical response to antiviral therapy.	Associated with CMV disease.	Specific for primary CMV infection. Sensitivity of 57.1%, highest within 1 mo of primary infection. Test positivity can last 4–6 mo. Negligible false-positive rate.
CMV DNA in blood (DNA-emia)	Detection and quantitation of CMV DNA in whole blood and leukocytes: PCR and hybridization techniques.	Advantages: 1. Useful for diagnosis of systemic or local CMV infections (CNS, eye, central nervous system, amniotic fluid). 2. Useful for evaluation of efficacy of antiviral therapy	1. Systemic and local site CMV infections.	Marker for primary CMV infection. Leukocyte DNA-emia has sensitivity of 100%, highest within 1 month of primary infection. Test positivity can last 4–6 mo.
Immediate-early and late CMV mRNA (RNA-emia)	Detection of immediate-early and late CMV mRNA transcripts in blood	Advantage: slightly more sensitive than DNA-emia in diagnosing early phase of primary CMV infection. Disadvantage: Slightly less sensitive than DNA-emia in the late phase of primary CMV infection.	1. RNA-emia in blood is a marker of CMV replication 2. Late viral transcripts are markers for active CMV replication and dissemination.	Immediate-early mRNA in the blood is a marker for primary infection.

- Bone marrow transplant recipients, the sensitivity of viremia as a marker for CMV pneumonia is 60% to 70%
 - Lack of viremia also has a high negative predictive value
- Detection of CMV or its products in the blood of transplant recipients is a basis for starting antiviral therapy.
- Value of positive CMV tests in the nontransplant ICU patient less clear.
- Viremia does not necessarily signify CMV disease in ICU patients.
- Data needed to elucidate impact of CMV infection/reactivation in critically ill patients and to clarify the effects of CMV treatment on morbidity and mortality
- **Management:** Ganciclovir, foscarnet, and cidofovir are antiviral agents active against CMV (Table 79.10).
 - Efficacy of anti-CMV therapy evaluated primarily in immunocompromised hosts
 - CMV disease in transplant recipients is typically treated with a 3-week course of ganciclovir.
 - Foscarnet is an alternative for patients who cannot tolerate, or fail to respond to, ganciclovir.
 - Foscarnet is associated with high rates of nephrotoxicity.
 - CMV retinitis requires a longer course of systemic therapy.
 - Intravitreal administration of ganciclovir or fomivirsen, an antisense inhibitor of CMV, frequently used in addition to systemic therapy
 - Long-term maintenance therapy is required for AIDS patients who do not undergo immune reconstitution; this strategy is generally not required for transplant recipients.
 - Recurrence of CMV disease seen in up to 25% of transplant recipients.
 - Appears to respond to ganciclovir as well as the initial episode

HSV Infection

- HSV-1 and HSV-2 are closely related, but the epidemiology of infections by the viruses is distinct.
 - HSV-1 is transmitted mainly by contact with infected saliva.
 - HSV-2 is transmitted by contact with the genital tract.
 - HSV-1 is acquired more commonly and at an earlier age than HSV-2.
 - By age 50 years, over 90% of people have antibodies against HSV-1.
 - HSV-1 is also more common among ICU patients.
- **Clinical manifestations:** HSV encephalitis and meningitis are discussed above.
 - HSV-1 can infect virtually any mucocutaneous or visceral site.
 - Primary infections associated with:
 - Systemic signs and symptoms
 - Mucosal and extramucosal involvement
 - Longer duration of symptoms
 - Viral shedding
 - Higher complication rates
- Gingivostomatitis and pharyngitis are the most common clinical syndromes of HSV-1 infection.
 - Lesions are ulcerative with or without exudates and can be difficult to differentiate from bacterial pharyngitis.
 - HSV-1 has predilection for regenerating epithelium.
 - Healing partial-thickness skin burns
 - Skin donor sites
 - Skin diseases (e.g., eczema, pemphigus, Darier disease)
 - Areas of cutaneous trauma are common sites of infection
 - HSV-1 keratitis is the most frequent cause of corneal blindness.
 - Can also cause chorioretinitis—a sign of disseminated infection—and acute necrotizing retinitis, affecting both immunocompetent and immunocompromised hosts
- In immunocompromised hosts and patients with atopic eczema or burns
 - Severe orofacial HSV lesions can rapidly spread and disseminate infection.
 - Bone marrow and solid organ transplant recipients are at highest risk for HSV reactivation during the pre-engraftment period or within the first month posttransplant.
 - Complications include pneumonitis, tracheobronchitis, esophagitis, hepatitis, and disseminated viral infection.
- HSV-1 shedding is observed in immunocompetent but critically ill patients.
 - Significance unclear
 - HSV-1 may predispose to subsequent bacterial or fungal infection.
- **Diagnosis:** The diagnosis of HSV-1 infection can be made using a direct immunofluorescence test or by culture of tissue or aspirated fluid.
 - Serology is helpful in diagnosing primary HSV infection.
 - Improved testing methods have led to increased detection of HSV-1 in ICU patients.
 - As with CMV, it is often unclear whether HIV-1 is an active pathogen or merely a marker of immune dysfunction.
- **Management:** For mucocutaneous and visceral infections
 - Acyclovir or related agents (famciclovir and valacyclovir) the standard therapy
 - For disseminated disease or encephalitis due to HSV-1
 - IV acyclovir is recommended
 - For HSV keratitis
 - Debridement along with topical therapy with idoxuridine or vidarabine is the treatment of choice.
 - Other ophthalmologic disease such as chorioretinitis or retinal necrosis requires systemic antiviral therapy.

CHAPTER 80 ■ INFECTIONS IN THE IMMUNOCOMPROMISED HOST

- Consider when evaluating immunocompromised patient presenting with suspected infection
- Due to impaired inflammatory response, signs and symptoms of infection may be absent.
 - Organ transplant recipient with perforated viscus presents with fever but no clinical evidence of peritonitis.
 - Neutropenic patient with pneumonia has cough but no infiltrate on chest radiograph (CXR).
- Thorough repeated history and physical examination basis for investigations and management
 - Subtle signs often basis for fruitful investigation
- Assessment of immune deficits based on underlying condition and immunosuppressive therapies, and other therapeutic interventions suggest probable pathogens.
- Aggressive initial approach to diagnosis is generally warranted.
 - Cultures of blood, urine, and sputum; CXR; and so forth should be performed.
 - Invasive procedures such as biopsy and bronchoscopy should be considered early.
 - Delay in arriving at a diagnosis results in delays of appropriate therapy or exposure to toxicities of unneeded therapies.
 - Will compromise treatment outcomes
- When tissue or body fluids are collected, specimens are evaluated for both infectious and noninfectious syndromes.
 - Such as malignancy, drug toxicity, rejection, and graft-versus-host disease (GVHD)
- Initial empiric antimicrobial therapy warranted due to severity of presentation and/or potential for rapid clinical deterioration.
 - Microbiologic specimens obtained prior to antimicrobial therapy facilitate diagnosis and directed therapy to limit toxicities and improve patient outcome.

THE IMMUNOCOMPROMISED HOST WITH SUSPECTED INFECTION

- Infection risk in immunocompromised host determined by interaction of two factors:
 - Epidemiologic exposures including timing, intensity, and virulence of organisms to which individual is exposed
 - Patient's "net state of immunosuppression"
 - Measure of host factors potentially contributing to infection risk (Table 80.1)
 - Including anatomic defects and exogenous immunosuppression
 - Specific immunosuppressive therapies and deficits predispose to specific types of infection (Table 80.2).

- Consideration of these factors allows development of differential diagnosis.
- Aggressive approach to making microbiologic diagnosis undertaken
- Delays in appropriate therapy may compromise outcome.
 - Initiate empiric therapy while awaiting results of investigations.
 - Infections often due to organisms with antimicrobial resistance patterns that make selection of empiric therapy more difficult
 - Perform appropriate histologic and microbiologic investigations of fluids and tissues
 - Diagnosis may require special stains:
 - Modified acid-fast stain for *Nocardia*

TABLE 80.1

FACTORS CONTRIBUTING TO THE NET STATE OF IMMUNOSUPPRESSION

IMMUNOSUPPRESSIVE THERAPY

- Type
- Temporal sequence
- Intensity
- Cumulative dose

PRIOR THERAPIES

- Chemotherapy or antimicrobials

MUCOCUTANEOUS BARRIER INTEGRITY

- Surgery
- Catheters
- Lines
- Drains
- Fluid collections

NEUTROPENIA/LYMPHOPENIA

- Often drug induced

UNDERLYING IMMUNE DEFICIENCY

- Hypogammaglobulinemia (e.g., from proteinuria)
- Complement deficiencies
- Autoimmune diseases (e.g., systemic lupus erythematosus)
- Other disease states:
 - HIV
 - Lymphoma/leukemia

METABOLIC CONDITIONS

- Uremia
- Malnutrition
- Diabetes mellitus
- Cirrhosis

IMMUNOMODULATORY VIRAL INFECTIONS

- Cytomegalovirus
- Hepatitis B and C
- Respiratory viruses

TABLE 80.2

INFECTIONS ASSOCIATED WITH SPECIFIC IMMUNE DEFECTS

Defect	Common causes	Associated infections
Granulocytopenia	Leukemia, cytotoxic chemotherapy, AIDS, drug toxicity, Felty syndrome	Enteric gram negatives, <i>Pseudomonas</i> , <i>Staphylococcus aureus</i> , <i>Staphylococcus epidermidis</i> , streptococci, <i>Aspergillus</i> , <i>Candida</i> , and other fungi
Neutrophil chemotaxis	Diabetes, alcoholism, uremia, Hodgkin disease, trauma (burns), Lazy leukocyte syndrome, connective tissue disease	<i>S. aureus</i> , <i>Candida</i> , streptococci
Neutrophil killing	Chronic granulomatous disease, myeloperoxidase deficiency	<i>S. aureus</i> , <i>Escherichia coli</i> , <i>Candida</i> , <i>Aspergillus</i> , <i>Torulopsis</i>
T-cell defects	AIDS, congenital lymphoma, sarcoidosis, viral infection, connective tissue disease, organ transplants, steroids	Intracellular bacteria (<i>Legionella</i> , <i>Listeria</i> , <i>Mycobacteria</i>), herpes simplex virus, varicella-zoster virus, cytomegalovirus, Epstein-Barr virus, parasites (<i>Strongyloides</i> , <i>Toxoplasma</i>), fungi (<i>Candida</i> , <i>Cryptococcus</i>)
B-cell defects	Congenital/acquired agammaglobulinemia, burns, enteropathies, splenic dysfunction, myeloma, acute lymphocytic leukemia	<i>Pneumocystis carinii</i> (<i>jiroveci</i>) <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Salmonella</i> and <i>Campylobacter</i> spp., <i>Giardia lamblia</i>
Splenectomy	Surgery, sickle cell, cirrhosis	<i>S. pneumoniae</i> , <i>H. influenzae</i> , <i>Salmonella</i> spp., <i>Capnocytophaga</i>
Complement	Congenital/acquired defects	<i>S. aureus</i> , <i>Neisseria</i> spp., <i>H. influenzae</i> , <i>S. pneumoniae</i>
Anatomic	Vascular/Foley catheters, incisions, anastomotic leaks, mucosal ulceration, vascular insufficiency	Colonizing organisms, resistant nosocomial organisms

- Silver stain for *Pneumocystis carinii* (*jiroveci*)
- Or culture media for *Mycobacteria* species
- Since noninfectious etiologies such as organ rejection, drug toxicity, and GVHD are often in differential diagnosis, histology is integral to making definitive diagnosis.

THE NEUTROPENIC PATIENT

- Neutropenic patients from cytotoxic chemotherapy for hematologic or solid tumors commonly encountered immunocompromised hosts
- With absolute neutrophil count <500 cells/ μ L, risk of infection increases.
 - Reduction in absolute neutrophil count impairs innate host immune response of phagocytosis.
 - Predisposing neutropenic patient to array of bacterial and fungal infections
 - Usually from endogenous colonization

Presentation, Common Pathogens, and Infectious Disease Syndromes

- Fever is defined as:
 - Single oral temperature $\geq 38.3^{\circ}\text{C}$ (101°F) or
 - A temperature $\geq 38^{\circ}\text{C}$ (100.4°F) for ≥ 1 hour
 - It is often the only predictor of infection.
 - About 50% of neutropenic patients with fever have documented infection.
 - About 20% of those with neutrophil counts <100 cells/ μ L have bacteremia.
- Gastrointestinal tract including oropharynx and periodontium
 - Where chemotherapeutic agents induce mucosal damage
 - The most common source of infection in febrile neutropenic patients
 - Often difficult to document:
 - Pulmonary infections and bacteremia—especially related to central venous lines (CVLs)—more commonly documented
- Historically, gram-negative (GN) organisms are seen in most bloodstream infections:
 - *Escherichia coli*
 - *Klebsiella* species
 - *Pseudomonas aeruginosa*
- Gram-positive (GP) organisms now isolated in almost 66% of bloodstream infections:
 - *Streptococcus* species and coagulase-negative *Staphylococcus*
- Shift from GN to GP bacteremia related to placement of CVLs
 - Also reduction in risk of GN infections with fluoroquinolone prophylaxis
- Skin, especially CVL sites, and lower respiratory and urinary tracts other common infection sites
- Risk of opportunistic fungal infection increases with the duration and severity of neutropenia.
 - Up to 33% of febrile neutropenic patients failing to respond to 1-week course of empiric antibacterial therapy have systemic fungal infections.
 - Most commonly (>80%) due to *Candida* or *Aspergillus* species

- Epidemiology of invasive fungal infections evolved with growing “at-risk” population and increased use of azole prophylaxis.
- Over 50% of bloodstream isolates seen are due to non-*albicans Candida*.
 - With increasing intrinsic (*Candida krusei*) or acquired (*Candida glabrata*) fluconazole resistance
- Neutropenic patients become infected with highly resistant non-*Aspergillus* molds in addition to *Aspergillus*.

Approach to Diagnosis

- Signs and symptoms of inflammation may be minimal or absent in neutropenic host.
- Cutaneous infection often occurs at former sites of intravenous (IV) catheters or drains.
 - May be tender or edematous, without the usual signs of cellulitis
- Urinary tract infection may present without pyuria, often with viral pathogens.
- CXR often normal despite rapidly progressive pneumonia.
 - Up to 50% of neutropenic patients with a normal CXR and fever lasting 2 days, despite empiric antibiotic therapy, will have findings on chest CT suggestive of pneumonia.
- Daily search for subtle signs and symptoms of infection should be performed:
 - Periodontium
 - Oropharynx
 - Perianal
 - Skin
 - Vascular access sites
- Basic investigations include:
 - CBC with differential
 - Serum creatinine, liver enzymes, and liver function tests
 - Cultures of blood, urine, and sputum
 - CXR
 - If CXR is normal but the patient has pulmonary symptoms or no identified source of infection, a CT scan should be performed.
- Collection of additional specimens guided by clinical presentation and preliminary investigations
 - Oral ulcerations should be swabbed for viral (herpes simplex virus [HSV]) studies.
 - Skin lesions should be biopsied for culture and histology.
 - Unexplained pulmonary infiltrates should be assessed with bronchoscopy and bronchoalveolar lavage (BAL), and/or transbronchial biopsy, or open lung biopsy.
- In those recovering from neutropenia with persistent fever:
 - Liver function tests and chest and abdominal imaging performed to look for:
 - Hepatosplenic candidiasis
 - Typhlitis
 - Invasive mold infection
 - Many infections asymptomatic during neutropenic event
 - Becoming apparent with recovery
- After obtaining microbiologic studies, empiric antimicrobial therapy indicated in neutropenic patients with or without fever.
- Selection of initial empiric antibiotic regimen takes into consideration:
 - General trend of increasing GP infections
 - Local hospital epidemiology
 - Susceptibility patterns of isolates from neutropenic patients
 - Clinical presentation, epidemiologic exposures, and antimicrobial use history
- Options include monotherapy with:
 - Third- or fourth-generation cephalosporin (e.g., cef-tazidime or cefepime)
 - Carbapenem such as imipenem or meropenem
 - Piperacillin-tazobactam
 - Dual therapy may be used without a glycopeptides.
 - Antipseudomonal β -lactam plus aminoglycoside or fluoroquinolone
 - For inpatients with recent surgery or vascular access catheters, a glycopeptides, vancomycin, can be combined with one- or two-drug therapy.
 - Empiric addition of vancomycin therapy in febrile neutropenia is not shown to alter outcomes in patients without pulmonary infiltrates, septic shock, CVL or skin and soft tissue infections, or documented GP infections resistant to primary empiric therapy
 - Vancomycin use is associated with the emergence of vancomycin-resistant *Enterococcus*.
- Controversy exists regarding optimal timing of adding antifungal therapy.
- Patients in the ICU >5 to 7 days, hypotensive or otherwise critically ill, anti-*Candida* therapy added after cultures obtained (Table 80.3)
- Those failing to defervesce on empiric antibiotic therapy after 5 to 7 days
 - In whom no source of infection identified
 - High risk of systemic fungal infection, and empiric therapy should be added
 - Amphotericin B the historical gold standard for empiric therapy
 - Lipid products of amphotericin B (e.g., liposomal amphotericin B [AmBisome, Astellas, Deerfield, IL] and amphotericin B lipid complex [Abelcet, Elan, Dublin, Ireland]) have similar efficacy with less toxicity
 - Voriconazole, caspofungin, other echinocandins (e.g., anidulafungin and micafungin), and posaconazole are effective in persistently febrile patients with neutropenia.
 - Renal and hepatic function, potential drug interactions, cost, and suspected source of fungal infection are all considerations in choosing initial empiric antifungal agent.

THE CORTICOSTEROID-TREATED PATIENT

- Identification of best candidates for empiric therapy and avoiding excessive use of prophylactic antimicrobial agents and toxicities associated with many therapies are central goals

Management

- Treatment with corticosteroids results in:
 - Reduced proliferation of B and T lymphocytes
 - Inhibition of neutrophil adhesion to endothelial cells
 - Inhibition of macrophage differentiation

TABLE 80.3**RISK FACTORS FOR CANDIDEMIA IN THE ICU SETTING^a**

- Prolonged length of stay (≥ 10 d)
- Immunosuppression
- High acuity of illness
- Cancer and chemotherapy
- Acute renal failure
- Severe acute pancreatitis
- Hemodialysis
- Surgery (gastrointestinal)
- Broad-spectrum antibiotics
- Transplantation
- Central venous catheter (≥ 3 d)
- Prematurity/low Apgar/congenital malformations
- Parenteral nutrition
- *Candida* colonization at multiple sites (longer than about 8 d)
- Burns
- Mechanical ventilation
- Diabetes

d, days.

^aReviewed in Rex JH, Sobel JD. Prophylactic antifungal therapy in the intensive care unit. *Clin Infect Dis*. 2001;32(8):1191; and Ostrosky-Zeichner L, Pappas PG. Invasive candidiasis in the intensive care unit. *Crit Care Med*. 2006;34(3):857.

- Reduced recruitment of mononuclear cells, including monocytes, into sites of immune inflammation
- Suppress cellular (Th1) immunity and promote humoral (Th2) immunity
- Risk of infection in corticosteroid-treated patients related to dose and duration of therapy
 - Treated with more than 10 to 20 mg/day of prednisone for more than a month at risk for infectious complications
 - Corticosteroids have a broad effect on immune system, but primary immune deficit is cell-mediated immunity.
 - Placing host at risk for fungal, viral, protozoal, and intracellular bacterial infections.
 - Common pathogens to be considered include:
 - *P. carinii* (*jiroveci*)
 - *Listeria monocytogenes*
 - *Legionella*
 - *Nocardia* species

***Pneumocystis carinii* (*jiroveci*)**

- Has a worldwide distribution and is an important cause of pneumonia in immunocompromised patients
 - Most notably those with HIV infection
 - Also those immunosuppressed due to malnutrition, organ transplantation, and prolonged corticosteroid use
 - Usually at a dose > 15 to 20 mg/day
 - Those requiring prolonged steroid therapy are appropriate candidates for prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX).

Presentation

- Onset of symptoms is often associated with recent dose reduction or discontinuation of steroids and/or with intensification of overall immunosuppressive regimen.

- Generally presents as subacute illness with history of weeks of progressive dyspnea and nonproductive cough in HIV-infected individuals
 - But non-HIV immunocompromised patients with *Pneumocystis carinii* pneumonia (PCP) have a more acute presentation.
- PCP patients are generally hypoxemic with few physical or radiographic findings
 - Nonproductive cough, dyspnea, and low-grade fever frequently present.
 - Physical examination findings nonspecific, inspiratory crackles on auscultation, with or without other signs of respiratory distress
 - May progress to respiratory failure requiring intubation and mechanical ventilation.

Diagnosis

- Classic CXR appearance of PCP: bilateral interstitial infiltrates with perihilar predominance
 - Can be highly variable, including patchy airspace disease and small pulmonary nodules
- Elevated lactate dehydrogenase level is a nonspecific finding associated with PCP.
- Definitive diagnosis relies on identification of organism by staining from pulmonary secretions or tissue.
 - Diagnosis may be made by staining secretions obtained through sputum induction with hypertonic saline.
 - 97% negative predictive value
 - If diagnosis remains uncertain, bronchoscopy with transbronchial tissue biopsy is the gold standard for diagnosis of PCP.
 - Yielding better results than BAL
 - Examination done quickly by staining with Gomori methenamine silver or calcofluor white
 - Diagnosis improved with immunofluorescent staining with monoclonal antibodies

Treatment

- Treatment for PCP is outlined in Table 80.4.

Listeria monocytogenes

- A GP bacillus capable of intracellular survival after phagocytosis by macrophages
 - Capable of infecting normal hosts
 - Invasive disease seen predominantly in those with cell-mediated immune deficits due to such factors as extremes of age (neonates and the elderly), pregnancy, malignancy, organ transplantation, or other immunosuppressive therapy

Presentation

- Infection presents as meningitis or primary bacteremia in 80% to 90% of cases.
 - Gastrointestinal symptoms present in a minority of cases.
- Onset of symptoms may be acute or subacute.
 - Fever nearly universal
 - Central nervous system (CNS) involvement may present as meningitis with headache and neck stiffness, focal parenchymal involvement with cerebritis and/or abscess, or meningoencephalitis with impaired level of consciousness.

TABLE 80.4
TREATMENT MODALITIES FOR THE COMMONEST INFECTIONS

Infectious agent	Primary therapy	Secondary therapy	Other considerations
<i>Pneumocystis jiroveci</i> (PCP)	Trimethoprim-sulfamethoxazole (TMP-SMX), dosed as 15–20 mg/kg/d of TMP component, divided every 6–8 h × 21 days	<ul style="list-style-type: none"> • Atovaquone 750–1,500 mg orally bid • Pentamidine 4 mg/kg/d, to max of 300 mg • Dapsone 100 mg orally plus TMP as above • Clindamycin 600 mg IV every 6 h plus primaquine 15–30 mg/d (as base) 	Adjunctive use of corticosteroids common but not evidence based in non-HIV patients
<i>Listeria monocytogenes</i>	<p>Empiric or confirmed: Ampicillin 2 g IV every 4 h × 21 d or more</p> <p>For synergy: Ampicillin plus TMP-SMX 20 mg/kg/d divided every 6 h</p>	Ampicillin plus gentamicin 2 mg/kg IV load, then 1.7 mg/kg IV every 8 h	
<i>Legionella pneumophila</i> and other species	Levofloxacin 250–750 mg IV every 24 h × 7–14 d	Azithromycin 500 mg daily for 7–14 d	
<i>Nocardia asteroides</i> complex	TMP-SMX, dosed as 15 mg/kg/d of TMP component, divided every 6–12 h, PO or IV	<ul style="list-style-type: none"> • Imipenem 500 mg IV every 6 h plus amikacin 7.5 mg/kg IV every 12 h, both × 3–4 wk, then switch to PO regimen • Linezolid 300–600 mg orally bid × 3–24 mo 	<ul style="list-style-type: none"> • Surgical resection of necrotic material often necessary • Therapy duration is 6–12 mo; for central nervous system infection 9–12 mo

Diagnosis

- Generally made through culture of blood or cerebrospinal fluid (CSF)
- Approximately 75% of cases of CNS listeriosis are associated with bacteremia.
 - Positive blood culture for *Listeria* should prompt a CSF examination.
 - CSF parameters are variable.
 - Common presentation is pleocytosis with neutrophil predominance, elevated protein, and normal glucose
 - Gram stain is frequently negative.

Treatment

- See Table 80.4.
- In patients at risk for *Listeria* presenting with meningitis of uncertain etiology
 - Empiric therapy should include ampicillin, 2 g IV every 4 hours initially.
 - If confirmed, ampicillin is the drug of choice.
 - *In vitro* data suggest bactericidal synergy of combination of ampicillin and gentamicin.
 - Also demonstrated between ampicillin and TMP-SMX
 - This combination is superior to ampicillin and gentamicin in treatment of *Listeria* meningoenitis.
 - May be indicated in those with severe disease
 - Minimum duration of therapy recommended is 3 weeks.
 - May be extended based on clinical response and radiographic resolution of CNS parenchymal disease if present

Legionella

- Small GN bacilli widely distributed in aqueous environment
 - Both community and hospital outbreaks have occurred in association with contaminated water sources such as air conditioners, cooling towers, and whirlpools
 - Capable of causing disease in normal hosts
 - Patients with impaired cell-mediated immunity are at highest risk.

Presentation

- Most commonly presents as pneumonia
 - Extrapulmonary disease and a self-limited febrile illness, *Pontiac fever*, may occur.
 - Physical and laboratory findings and radiographic appearance are not specific.
 - Fever with pulse-temperature dissociation, diarrhea, hyponatremia, and elevated liver enzymes may occur, but are not distinctive enough.
 - In patients at risk, must be considered in differential diagnosis of pneumonia
 - Empiric therapy administered when appropriate

Diagnosis

- A fastidious organism
 - Culture of respiratory secretions for diagnosis is insensitive and time-consuming.
 - Immunofluorescent microscopy improves sensitivity of culture techniques.

- More rapid diagnosis with urinary antigen test and nucleic acid detection
- Urinary antigen tests sensitive for *Legionella pneumophila* serogroup 1
 - Perform less well in other serogroups of *L. pneumophila*, or other *Legionella* species
- Combination culture, urinary antigen detection, and serology may optimize diagnosis.

Treatment

- See Table 80.4.
- Macrolides and fluoroquinolones have *in vitro* activity against *Legionella* sp.
 - Quinolones may be superior to macrolides.
 - Fewer complications and shorter hospital stays in those receiving quinolones
 - No comparison of newer macrolides (e.g., azithromycin) to new quinolones

Nocardia

- Part of aerobic actinomycetes genus, ubiquitous environmental saprophytes
- There are several species
 - *Nocardia asteroides* complex—*Nocardia asteroides sensu strictu*, *Nocardia farcinica*, and *Nocardia nova*—most common cause of disease
 - Immunosuppression the major risk factor for nocardial infections
 - Solid organ transplant recipients, advanced HIV patients (CD4⁺ counts <100 cells/ μ L), patients with lymphoproliferative malignancy, patients on chronic corticosteroid therapy

Presentation

- Predominantly causes pneumonia
 - Initial presentation includes respiratory symptoms generally in association with fever
 - CXR demonstrates nodular lesions, may progress to cavitation
 - Diffuse infiltrates or consolidation may also occur
- Has high propensity to disseminate to CNS
 - Immunocompromised patients with nocardiosis may present with CNS symptoms.
 - With or without concomitant pulmonary symptoms
- Usual route of infection is inhalational.
 - Direct cutaneous inoculation with resultant skin disease, subcutaneous nodules, seen

Diagnosis

- Definitive diagnosis with special stain and culture from suspected site of infection
 - Modified acid-fast stain (Kinyoun) demonstrates branching and beading GP bacilli.
 - Grows on nonselective media; lab should be notified if diagnosis suspected.
 - Selective media can be used to avoid overgrowth by other organisms.
 - When diagnosis of pulmonary nocardiosis made, neuroimaging to exclude CNS dissemination is performed.

Treatment

- See Table 80.4.
- Antimicrobial therapy the foundation of treatment, although adjunctive surgical resection of necrotic tissue necessary on occasion
- Duration of therapy individualized based on clinical response.
 - Pulmonary and cutaneous disease is treated for at least 6 to 12 months.
 - CNS disease is treated for at least 9 to 12 months.
 - Immunosuppression is reduced as much as possible to aid in treatment.

PATIENTS TREATED WITH IMMUNOMODULATORY AGENTS

- A number of monoclonal antibody therapies have revolutionized treatment of rheumatologic as well as other systemic inflammatory and autoimmune conditions (Table 80.5).
- Immune modulation results in selected immune deficits, and infectious complications have been recognized with several of these agents.

Tumor Necrosis Factor- α Antagonists

- Three tumor necrosis factor (TNF)- α antagonists are currently marketed in the United States:
 - Infliximab (Remicade, Centocor Inc., Horsham, PA)
 - Etanercept (Enbrel, Amgen and Wyeth Pharmaceuticals, Thousand Oaks, CA)
 - Adalimumab (Humira, Abbott Laboratories, Abbott Park, IL)
- Effective for rheumatoid arthritis, active Crohn disease, and ankylosing spondylitis

TABLE 80.5

SELECTED THERAPEUTIC ANTIBODIES

Antibody	Trade name	Target	Indication
Antithymocyte globulin	Thymoglobulin (others)	T cells (polyclonal rabbit IgG)	Transplant induction, rejection
Muromonab OKT3	Orthoclone OKT3	CD3 ⁺	Transplant induction, rejection
Alemtuzumab	Campath-1H	CD52 ⁺	B-cell chronic lymphoid leukemia
Daclizumab	Zenapax	Interleukin (IL)-2 receptor α chain (CD25 ⁺)	Transplant induction
Basiliximab	Simulect	IL-2 receptor α chain (CD25 ⁺)	Transplant induction
Efalizumab	Raptiva	CD11a ⁺	Psoriasis
Natalizumab	Tysabri	α_4 -integrin	Multiple sclerosis, Crohn disease

- Blockade of TNF- α results in improvement in systemic inflammatory conditions.
 - However, TNF- α , and interferon- γ and other cytokines are an important component in maintaining cellular immunity.
- Tuberculosis (TB) associated with TNF- α antagonists
 - Probably resultant from cell-mediated immune deficits
 - Majority of cases occurred with infliximab
 - Cases also described with etanercept and adalimumab
 - Occurred in those with risk factors for latent TB infection
 - TB skin testing is recommended prior to initiation of a TNF- α antagonist.
 - Regardless of TB skin testing results, TB in differential diagnosis in patient presenting on TNF- α antagonist with compatible symptoms
- Other infections including histoplasmosis, listeriosis, aspergillosis, coccidiomycosis, and candidiasis associated with use of TNF- α antagonists

Rituximab

- Rituxan (Genentech Inc., San Francisco, CA; and Biogen Idec, Boston, MA) a chimeric murine/human monoclonal antibody
 - Binds CD20⁺ marker, expressed on B lymphocytes
 - Results in rapid depletion of circulating CD20⁺ B cells
 - Approved for treatment of CD20⁺ B-cell lymphoma
 - In combination with methotrexate for rheumatoid arthritis
 - Used for treatment of posttransplant lymphoproliferative disease, idiopathic thrombocytopenia (ITP), autoimmune hemolytic anemia, systemic lupus erythematosus, multiple sclerosis, GVHD, treatment of antibody-mediated graft rejection
- Following rituximab therapy, antibody production is maintained by plasma cells.
 - CD20⁻
 - Peripheral B-cell recovery takes 3 to 12 months.
 - Despite B-cell deficiency and use of rituximab for treatment of malignant and autoimmune conditions
 - No evidence of an increased risk of infection in patients treated

Natalizumab

- Tysabri (Biogen Idec, Boston, MA, and Elan Pharmaceuticals, Dublin, Ireland) a recombinant humanized monoclonal antibody that binds to α_4 -integrin
 - Inhibiting α_4 -integrin-mediated leukocyte adhesion
 - Prevents transmigration of leukocytes across the endothelium into inflamed tissue
- Monotherapy for treatment of patients with relapsing multiple sclerosis and in those with inadequate response to, or who are unable to tolerate, alternate therapies
 - Increases remission rate and improves quality of life in patients with active Crohn disease
- Progressive multifocal leukoencephalopathy
 - Demyelinating disease of CNS caused by human polyomavirus John Cunningham virus
 - Reported in three patients who received natalizumab
 - U.S. FDA-approved application for resumed marketing in June of 2006

- Given mechanism of action, it is possible that further opportunistic infections may be associated with the use of this agent.

THE SOLID ORGAN TRANSPLANT RECIPIENT

Timeline of Posttransplant Infections

- Three overlapping periods of risk for infection after transplantation, each most often associated with unique groups of pathogens:
 - Perioperative period to approximately 4 weeks after transplantation, reflecting surgical and technical complications
 - Period 1 to 6 months after transplantation, depending on the rapidity of tapering immunosuppression and the use of antilymphocyte “induction” therapy, reflecting intensive immunosuppression with viral activation and opportunistic infections
 - Period beyond 6 to 12 months after transplantation, reflecting community-acquired exposures and some unusual pathogens based on the level of maintenance immunosuppression
- First month after transplantation
 - Infections related to surgery, similar to those in complex general surgical population
 - Include pneumonia and surgical site, urinary tract, and CVL-associated infections caused by typical bacterial and fungal pathogens such as *Candida*
 - Exposure to nosocomial pathogens and colonization alter use of empiric antimicrobial therapy, including those for:
 - Methicillin-resistant *S. aureus* (MRSA)
 - Vancomycin-resistant *Enterococcus*
 - Fluconazole-resistant *Candida* species
 - *Clostridium difficile*
 - *P. aeruginosa*
 - Opportunistic infections rarely occur the first month post-transplant unless there has been pretransplant immunosuppression.
 - Absent prophylaxis 24% to 34% of recipients will have HSV disease
 - Most occurring as orolabial or genital disease due to reactivation of latent infection in the recipient during first posttransplant month
 - Rarely, infections are transmitted from bacteremic or fungemic donor with potentially serious complications.
 - Including seeding of vascular suture line
 - Use of prophylactic antibiotics in recipient, directed by donor culture results, allows organs from donors with bacteremia and/or meningitis to be safely used without compromising transplant outcomes.
- First through sixth month posttransplant are the highest-risk period for opportunistic infections.
 - Effects of immunosuppression greatest during this period
 - Infections may include:
 - Viral (cytomegalovirus [CMV], varicella-zoster virus [VZV], Epstein-Barr virus [EBV], and hepatitis B)
 - Bacterial (*Nocardia*, *Listeria*, and TB)
 - Fungal (*Aspergillus* and *Cryptococcus*)

- Parasitic (*Pneumocystis*, *Toxoplasma* and *Strongyloides*) infections
- Beyond 6 months, most recipients are on reduced levels of maintenance immunosuppression with good graft function and are at low risk for opportunistic infections.
- Most infectious complications here due to conventional community-acquired pathogens occurring in the general population.
- These include:
 - Viral respiratory infections
 - Pneumococcal pneumonia
 - Gastroenteritis
- Intense exposure to opportunistic pathogen may result in disease
 - Transplant recipients should be counseled regarding strategies to avoid high-risk exposures
 - If augmentation of immunosuppression needed for management of acute chronic rejection, and for those with chronic or recurrent CMV infection, increased risk for other opportunistic infections, particularly:
 - *P. carinii* (*jirovecii*)
 - Invasive fungal infection
 - EBV-associated, posttransplant lymphoproliferative disease

Disease-specific Prevention and Management

Cytomegalovirus

- Remains significant cause of morbidity in organ transplant recipients
- Strategies for prevention have decreased the morbidity and mortality.
- Risk of CMV disease depends on a number of factors, including:
 - Donor and recipient serostatus
 - Immunosuppression
 - Particularly the use of antilymphocyte antibody preparations for induction or treatment of rejection
- The American Society of Transplantation Guidelines on CMV prevention and management are used to guide institutional approaches to CMV prevention in conjunction with local CMV epidemiology, available laboratory support, and infrastructure.
- If both donor and recipient are CMV negative:
 - Antiherpes virus prophylaxis (for HSV and VZV) are generally used for the first 3 to 12 months posttransplantation.
 - 5% to 10% of such patients may develop community-acquired CMV at some point after transplant
- CMV-seronegative recipients who receive seropositive organ are at greatest risk of primary CMV infection.
 - Receive prophylaxis with valganciclovir (900 mg/day) for 100 days
- CMV-seropositive recipients receive either prophylaxis with valganciclovir or preemptive therapy based on results of sensitive monitoring assay (e.g., CMV antigenemia or polymerase chain reaction [PCR]) used.
- Given the high risk of CMV infection and disease in seropositive lung and heart–lung recipients, prophylaxis is generally preferred.
- All patients are at risk for CMV receiving lymphocyte-depleting agents for induction or treatment of rejection should receive antiviral prophylaxis.

- CMV disease refers to the presence of symptoms attributable to CMV in face of viral replication:

- “CMV syndrome”
 - Defined by constellation of fever $>38^{\circ}\text{C}$, neutropenia or thrombocytopenia, and detection of CMV in blood by antigenemia, PCR, or shell vial culture
- Tissue-invasive disease
 - Requires biopsy for confirmation, except in case of retinitis
 - Defined by presence of signs or symptoms of organ dysfunction in association with histologic evidence of CMV in affected tissue
- Established CMV syndrome or tissue-invasive disease treated with:
 - IV ganciclovir, 5 mg/kg every 12 hours
 - No data to support oral ganciclovir/valganciclovir use in treatment of CMV disease
 - Therapy continued a minimum of 14 days until symptoms resolved and viremia cleared (until CMV PCR/antigenemia undetectable)
 - Ganciclovir-resistant CMV an emerging problem; risk factors include:
 - Donor–recipient mismatch, donor is seropositive and recipient seronegative
 - Prolonged use of ganciclovir
 - Suboptimal ganciclovir levels
 - Intense immunosuppression
 - High CMV viral load
 - Ganciclovir-resistant CMV suspected in setting of:
 - Stable, or rising, viral load in patients treated with ganciclovir
 - No decrease in antigenemia after 7 days of therapy
 - Lack of clinical improvement after 14 days of full-dose IV ganciclovir
 - CMV infection developing shortly after prolonged course of low-dose ganciclovir
 - If resistance suspected, ID/microbiology consulted for consideration of molecular resistance testing and alternative (e.g., foscarnet, cidofovir) or adjunctive (CMV-Ig) therapies

Epstein-Barr Virus and Posttransplant Lymphoproliferative Disease

- Primary EBV infection after transplantation is the most important risk factor for posttransplant lymphoproliferative disease (PTLD).
- Complications with mortality ranging as high as 40% to 60%.
- Risk exacerbated by occurrence of CMV disease and treatment with polyclonal or monoclonal antilymphocyte antibody.
- Some benefit of antiviral prophylaxis.
- Quantitative EBV viral load monitoring shown to decrease the risk of PTLD.
- For patients at high risk of PTLD (EBV donor seropositive/recipient seronegative)
 - Preventative strategies with antiviral prophylaxis
 - EBV viral load monitoring may be considered
 - If EBV viremia is detected, immunosuppression reduction is considered.
- PTLD represents highly diverse spectrum of disease with variable clinical presentation:
 - Benign B-cell proliferation (mononucleosis)

- To true monoclonal malignancy
 - May be nodal or extranodal and localized or disseminated, and commonly involves allograft
 - Diagnosis of PTLD requires histologic confirmation and staging of disease.
- Options for treatment of PTLD depend on histology and stage of disease.
 - In all cases, attempts are made to reduce or withdraw immunosuppression.
 - Additional considerations for treatment depend on clinical presentation and previously mentioned criteria
 - In addition to immunosuppression reduction or withdrawal, potential options include:
 - Antiviral agents
 - IVIG
 - Surgical resection
 - Local radiation
 - Use of rituximab, anti-CD20 monoclonal antibody, a second-line option if reduction in immunosuppression alone fails given its low toxicity and response rates, which range from 61% to 76%.
 - Cytotoxic chemotherapy is generally considered third-line option due to high incidence of toxicity in this population.

Pneumocystis carinii (jiroveci)

- Absent prophylaxis, *P. pneumoniae* occurs in 5% to 15% of solid organ transplant recipients.
 - TMP-SMX prophylaxis, one single-strength tablet daily, eliminates risk.
 - Indicated in all nonallergic transplant recipients for minimum of 6 months following transplantation
 - Also acts as prophylaxis for a number of other infections:
 - *Nocardia*
 - *Listeria*
 - Community-acquired pneumonia
 - In sulfa-allergic patients, dapsone 100 mg daily, aerosolized pentamidine 300 mg monthly, or atovaquone 1,500 mg daily are alternatives.

Toxoplasmosis

- Of particular concern among cardiac transplant recipients given the site of latency is cardiac muscle
 - Seronegative recipients of a seropositive heart are at risk and require prophylaxis.
 - TMP-SMX is used effectively for prophylaxis as one double-strength tablet daily.
 - Lifelong prophylaxis is recommended.

Diagnosis and Treatment of Infectious Syndromes

- Initial approach to transplant patient with suspected infection includes:
 - Thorough history and physical examination to assess overall state of immune function and exposure history and localize potential site of infection
 - Basic testing includes CBC, creatinine, liver enzyme and function studies, blood cultures, and CXR.
 - Additional specimens for microbiologic testing are obtained as directed by history and physical examination (e.g., urine cultures, stool for bacterial culture, *Clostridium difficile* toxin, ova and parasites, blood for CMV antigenemia, or PCR).

TABLE 80.6

DIFFERENTIAL DIAGNOSIS OF FEVER AND PULMONARY INFILTRATE IN ORGAN TRANSPLANT RECIPIENTS

Chest radiograph finding	Acute onset	Subacute/chronic onset
Consolidation	Bacteria Pulmonary embolism Hemorrhage Pulmonary edema	Fungal <i>Nocardia</i> Tuberculosis Viral (adenovirus)
Reticulonodular	Pulmonary edema Viral <i>P. carinii</i> (<i>jiroveci</i>)	<i>Pneumocystis carinii</i> (<i>jiroveci</i>) Drug reaction (including sirolimus)
Nodular	Bacterial	Viral Fungal <i>Nocardia</i> Tuberculosis Tumor (including PTLD)
PTLD, posttransplant lymphoproliferative disease.		

Fever and Pulmonary Infiltrate

- Transplant patients presenting with fever and pulmonary infiltrate, differential diagnosis broad
 - Includes infectious and noninfectious etiologies
 - Infection is ultimately identified in 75% to 90% of cases.
 - Dual or sequential infections are common.
- Pneumonia may rapidly progress in immunocompromised hosts with high mortality
 - Initial empiric therapy is directed at likely pathogens following collection of blood and sputum cultures, viral respiratory studies, a complete blood count, and serum creatinine.
 - Consultation with pulmonary and infectious diseases specialists is recommended.
 - Identification of pathogen is key to directing appropriate therapy
 - Consider early invasive diagnostic tests (bronchoscopy, lung biopsy).
 - CXR, clinical presentation, rate of progression, exposure history, and assessment of net state of immunosuppression help narrow differential diagnosis (Table 80.6).
 - Chest CT will delineate extent of pulmonary disease and guide invasive diagnostic tests.

CNS Infections

- Presentation of CNS infection in transplant patients may differ from general population due to immunosuppression.
 - Fever may or may not be present, and presentation can be subtle.
 - Headache or minor changes in mental status
 - Differential diagnosis in transplant patients presenting with neurologic symptoms with or without fever (Table 80.7)

TABLE 80.7**COMMON CNS INFECTIONS IN TRANSPLANT RECIPIENTS****Community-Acquired Pathogens**

- Pneumococcus
- Meningococcus
- *Listeria monocytogenes*
- Herpes simplex virus
- *Cryptococcus neoformans*
- Lyme disease

Metastatic Infection

- Bacteremia (endocarditis)
- *Mycobacterium tuberculosis*
- *Aspergillus*
- *Nocardia* species
- *Strongyloides stercoralis* (gram-negative meningitis)
- Mucoraceae (sinuses)
- Dematiaceae—cerebral phaeohyphomycosis (skin)
- *Histoplasma* and *Pseudoallescheria/Scedosporium*, *Fusarium*

Other CNS Processes

- Cytomegalovirus (nodular angiitis)
- Varicella – zoster virus
- Human herpesvirus 6
- *Toxoplasma gondii*
- JC virus (progressive multifocal leukoencephalopathy)
- West Nile virus, lymphocytic choriomeningitis virus
- Lymphoma (PTLD)
- *Naegleria/Acanthamoeba*

- Consultation with ID/microbiology is recommended to assist in diagnosis and to ensure appropriate samples collected for diagnostic testing
- CSF analysis after neuroimaging with CT and/or MRI should be obtained in such individuals

HEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENT

- Despite advances, severe infectious complications are common.
 - Up to 40% of hematopoietic stem cell transplant (HSCT) recipients requiring ICU admission
 - 60% of these require mechanical ventilation.
 - Associated with high mortality rate
 - Outcomes of HSCT recipients admitted to the ICU are improving with advances in infection prevention, diagnosis and management, and ICU care.
- In attempt to eliminate malignant cells and decrease risk of GVHD, positively selected CD34⁺ progenitor cells may be used for transplantation.
 - Results in significant T-lymphocyte and monocyte depletion of graft
 - Increased risk of opportunistic infection
- Resultant from pretransplant conditioning chemotherapy, with or without total body irradiation, humoral- and cell-mediated immunity are diminished.
 - Natural host barrier defenses are impaired by mucositis and use of CVLs.

- Risk of infectious complications in HSCT recipient divided into three phases:
 - Period from conditioning therapy to engraftment when patients are neutropenic—the pre-engraftment phase—carries high risk of bacterial and fungal infections.
 - Second phase, from engraftment to day 100—or during period of treatment for acute GVHD—viral and filamentous fungal infections predominate.
 - Beyond day 100—late phase or with chronic GVHD—incidence of infections is reduced.
 - Determined by level of immunosuppression needed for chronic GVHD

Phase 1: Pre-engraftment Infections

- Early pre-engraftment, neutropenic phase lasts 10 to 15 days in most current nonmyeloablative HSCT patients, and longer with ablative regimens
- Predominant infections seen to time of engraftment similar to those in association with neutropenia
 - Shift from predominantly GN to GP—coagulase-negative *Staphylococci*, *Streptococci*, *Enterococci*—bacterial infections with use of fluoroquinolone prophylaxis
 - Azole prophylaxis has reduced incidence of candidemia.
 - But continues to be early cause of bloodstream infection with increase in risk of azole-resistant *Candida*
 - HSV may reactivate during this phase.
 - Prevented with prophylactic acyclovir in seropositive HSCT recipients

Phase 2: Engraftment to Day 100 (Acute GVHD)

- Characterized by deficits in cellular immunity
 - Most important infectious complications are viral, particularly CMV, and invasive mold infections.
 - Most common manifestations of CMV disease in HSCT recipients are pneumonia and gastrointestinal disease
 - Highest risk of disease occurs in seropositive recipients of seronegative transplants
 - CD34⁺ selected PBSC transplantation associated with increased risk of CMV infection due to T-lymphocyte depletion
 - Use of ganciclovir prophylaxis or preemptive therapy resulted in decreased risk of CMV infection during this period.
 - Most infections now occurring after ganciclovir are discontinued.
- Interstitial pneumonitis, an important clinical syndrome, presents during the postengraftment phase.
 - Etiologies include CMV, respiratory viruses, *Pneumocystis*, or idiopathic pneumonia syndrome.
 - Diagnosis of CMV pneumonitis requires histology for definitive diagnosis.
 - Often impractical, and presumptive diagnosis made on basis of presence of interstitial pneumonia, detection of CMV antigen/nucleic acid in peripheral blood and/or respiratory secretions, combined with negative investigations for other etiologies of pneumonitis

- Despite treatment with IV ganciclovir and CMV hyperimmunoglobulin or IVIG, mortality from CMV pneumonitis remains $\geq 50\%$.
- *P. carinii* (*jiroveci*) essentially eliminated as cause of pneumonitis with TMP-SMX prophylaxis.
- Respiratory viral infections such as RSV, parainfluenza virus, and human metapneumovirus are increasingly recognized as etiology of pneumonia in HSCT.
- Noninfectious etiologies of pneumonia also exist, including idiopathic pneumonia syndrome and diffuse alveolar hemorrhage, which must also be considered in differential diagnosis of HSCT recipients with pneumonitis.
- Majority of invasive mold infections occur during the postengraftment phase and are associated with treatment of acute GVHD.
 - *Aspergillus* is the predominant pathogen.
 - Non-*Aspergillus* molds, including Zygomycetes, are emerging pathogens.
 - Present as pulmonary nodules, but invasive sinus disease and disseminated disease including CNS involvement also common
 - Given high mortality associated with invasive mold infections, empiric antifungal therapy is initiated while definitive diagnosis is aggressively pursued.
 - Empiric liposomal amphotericin is preferred to voriconazole in HSCT patients with fever or pulmonary infiltrates.
 - It has the broadest spectrum of activity.
 - Treatment of choice for documented invasive aspergillosis is voriconazole.
 - Has survival benefit over amphotericin B deoxycholate therapy and is associated with less toxicity, particularly nephrotoxicity
 - Despite appropriate therapy, mortality of invasive mold infections remains high.
 - In those with disseminated or CNS disease, mortality reaches 80% to 100%.
 - Newer antifungal agents, such as posaconazole, and combination therapies are not fully studied for therapy.

Phase 3: Late Infections beyond 100 Days

- Beyond 100 days posttransplant, a gradual recovery of humoral and cellular immune function occurs.
- Infection risk is driven by extra immunosuppression induced by chronic GVHD and treatment.
 - Up to 40% of HSCT recipients develop varicella-zoster virus infection.
 - Generally as result of reactivation of latent infection
 - Most cases occurring during first year
 - Disseminated disease associated with high mortality rate
 - Should be treated with IV acyclovir, 10 mg/kg every 8 hours
 - Late CMV disease occurs and is associated with history of early CMV disease and GVHD.
 - Late CMV disease is treated same as that occurring early.
 - Outcome of late disease is poor, particularly for CMV pneumonia.
 - Late invasive mold infections occur, particularly in GVHD and preceding viral (CMV) infection.
 - Management of late mold infections mimics that of early infections.
 - Attempt to decrease immunosuppression to assist in treatment of infection.
- About 33% of patients with chronic GVHD may develop recurrent infection with encapsulated bacteria (sinopulmonary, bacteremia).
 - Predominant pathogen is *Streptococcus pneumoniae*.
 - *Haemophilus influenzae* and *S. aureus* are also common.
 - Risk is related to deficit in opsonizing antibody.
 - HSCT recipients respond poorly to pneumococcal vaccine within the first 1 to 2 years posttransplant.
 - Antibiotic prophylaxis with penicillin or TMP-SMX is recommended in those with chronic GVHD.
 - In patients with chronic GVHD admitted with sepsis, broad-spectrum empiric antibiotic therapy is recommended pending microbiologic identification.

CHAPTER 81 ■ HUMAN IMMUNODEFICIENCY VIRUS IN THE ICU

EPIDEMIOLOGY OF HIV-INFECTED PATIENTS IN THE ICU

ICU Admission Rates and Outcomes

- The first cases of HIV/AIDS were reported in 1981.
- Many developments in HIV treatment and associated diseases
 - Most notably introduction of HAART in 1996

- ICU admission rates/-related mortality for HIV-infected patients have shifted multiply during AIDS epidemic.
- Analysis of ICU admissions during early 1980s reported mortality rates of nearly 70% for HIV-infected patients, with most patients admitted for *Pneumocystis carinii* pneumonia (PCP).
- Despite increasing hospital admissions of HIV-infected patients after 1984, rates of ICU admission declined.

TABLE 81.1

MORTALITY ASSOCIATED WITH ICU ADMISSION AMONG HIV-INFECTED PATIENTS IN THE HAART ERA

Setting	ICU patients (N)	Time period	HIV unknown at admission	HAART at admission	HIV or AIDS-related illness	Overall ICU mortality	Independent predictors of ICU or in-hospital mortality ^a
University hospital, Jacksonville, FL, USA	141	1995–1999	—	—	—	30% ^b	Transfer from another hospital ward, APACHE II score
University hospital, Paris, France	230	1997–1999	40%	28%	37%	20%	SAPS II score, mechanical ventilation, Omega score
University hospital, Paris, France	236	1998–2000	28%	50%	50%	25%	PCP with pneumothorax; mechanical ventilation; Kaposi sarcoma; inotropic support; CD4 ⁺ count <50 cells; SAPS II score
Urban hospital, New York, NY, USA	259	1997–1999	—	48%	60%	30%	Mechanical ventilation; admission with HIV-related illness
Urban hospital, New York, NY, USA	53	2001	—	52%	33%	29% ^b	No multivariate analysis provided; low albumin associated with increased mortality on univariate analysis
Urban hospital, San Francisco, CA, USA	295	1996–1999	7%	25%	37%	29% ^b	Mechanical ventilation; PCP; APACHE II scores >13; albumin <2.6 g/dL; AIDS-associated diagnosis
Hospital Virgen de la Victoria, Malaga, Spain	49	1997–2003	31%	31%	61%	57%	Not reported

ICU, intensive care unit; HIV, human immunodeficiency virus; HAART, highly active antiretroviral therapy; AIDS, acquired immunodeficiency syndrome; APACHE, Acute Physiology and Chronic Health Evaluation; SAPS, Simplified Acute Physiology Score; PCP, *Pneumocystis pneumonia*.

^aIn order of descending magnitude of association.

^bData given as in-hospital rather than ICU mortality.

- Likely result of both physicians' and patients' views of ICU care as futile
- In the late 1980s, mortality rates decreased coincident with introduction of adjunctive corticosteroids to treat PCP.
- In the early 1990s, ICU mortality increased in setting of increased rates of ICU use, possibly because of renewed optimism in outcomes.
- Data from immediate pre-HAART period of 1992 through 1995 showed overall improvement in mortality rate to 37% compared to early days of AIDS epidemic.
- In studies from San Francisco General Hospital, ICU mortality decreased significantly from 37% in 1992 through 1995 to 29% in 1996 through 1999.
- Likewise, studies comparing the mortality rate between 1991 and 1992 and 2001 from Beth Israel Medical Center in New York showed a decrease in mortality from 51% to 29%.
 - Analyses of ICU admissions in a Paris hospital found ICU mortality was unchanged comparing before and during the HAART era.
- Overall average reported in-hospital mortality for HIV-infected patients admitted to the ICU ranged between 25%

and 40%, with median ICU length of stay of 5 to 11 days (Table 81.1).

- Despite decreasing hospitalization rates for HIV-infected patients, ICU admission rates have not changed substantially in the HAART era.
- Approximately 5% to 12% of hospital admissions for HIV-infected patients involve ICU care.
 - A large proportion of HIV-infected patients continue to be admitted to the ICU without prior known HIV infection (range 28% to 40%)
 - Approximately 50% of patients are not on HAART at the time of admission.
 - Overall survival has improved in HIV-infected patients on HAART.
 - Number of persons living with HIV has increased.

Indications for ICU Admission

- Spectrum of diseases requiring ICU admission is changing in setting of HAART.

- Early in the epidemic, most patients were admitted with AIDS-associated condition, usually PCP.
- Now HIV patients are admitted with a non-AIDS-associated condition.
 - Non-HIV-related disease increased substantially from 12% of all admissions in 1991 through 1992 to 67% in 2001.
- Acute respiratory failure (ARF) is the most common indication for ICU care.
 - Accounts for approximately 25% to 50% of ICU admissions in HIV-infected patients
 - *Pneumocystis jirovecii* is the responsible pathogen in 25% to 50% of patients in earlier investigations.
 - Remains significant cause of respiratory failure in recent studies, accounting for 14% to nearly 50% of cases
 - Bacterial pneumonia is a frequent ARF cause and is as common as or more common than PCP.
- Sepsis is an increasingly frequent indication for ICU admission.
 - Increasing from 3% to 23% of admissions for HIV-infected patients recently
- Other commonly reported causes of ICU admission include:
 - Central nervous system dysfunction (11% to 27%)
 - Gastrointestinal bleeding (6% to 15%)
 - Cardiovascular disease (8% to 13%)
 - Other reasons for ICU admission unrelated to immunodeficiency include:
 - Trauma, routine postoperative care, noninfectious pulmonary diseases such as asthma and pulmonary embolism, renal failure, metabolic disturbances, and drug overdose
 - Given frequent coinfection with hepatitis C among patients with HIV, liver disease may be increasing as a cause of death.
 - Solid organ transplantation (liver, kidney) is currently being studied in HIV-infected patients.

Predictors of Mortality during ICU Admission

- Mortality in the ICU is related to reason for ICU admission.
 - Highest ICU mortality rates for HIV-infected patients are associated with sepsis and respiratory failure.
 - Mortality rates of 50% to 68% reported for sepsis
 - Respiratory failure due to PCP mortality remains nearly 50%.
 - Increased if complicated by PCP-associated pneumothorax
 - AIDS patients admitted to the ICU for other HIV-related reasons reported lower mortality.
 - Reported mortality for central nervous system dysfunction is 20% to 48%.
 - For gastrointestinal disease, 30% to 35%
 - Patients admitted with non-HIV-related conditions may have better outcomes.
 - Patients admitted with non-AIDS-associated diagnosis are significantly more likely to survive than patients admitted with an AIDS-associated condition (odds ratio [OR] 2.9, 95% confidence interval [CI] 1.5–5.8, $p = 0.002$).
 - Mortality during hospitalization is related to severity of acute illness (see Table 81.1).

- Predictors of increased hospital mortality include:
 - Need for mechanical ventilation
 - Disease severity (as assessed by scoring systems such as the Simplified Acute Physiology Score I [SAPS I], and the Acute Physiology and Chronic Health Evaluation II [APACHE II] score)
 - Decreased serum albumin level or history of weight loss
 - CD4⁺ T-cell count and the plasma HIV RNA level are generally not independent predictors of short-term mortality during ICU stay.
 - Long-term mortality after ICU admission is related to underlying severity of HIV disease.
 - Long-term survival following ICU discharge improved in HAART era.

PULMONARY MANIFESTATIONS OF HIV

Spectrum of Respiratory Diseases and Approach to Diagnosis

- ARF is still most common cause of ICU admission for HIV-infected patients.
 - Can occur from a multitude of causes including:
 - Infections
 - Neoplasms
 - Drug overdose
 - Neurologic conditions that may be both HIV- and non-HIV-related
 - Appropriate workup includes chest radiograph and occasionally computed tomography of the chest. Blood and sputum cultures should be obtained.
 - Bronchoscopy with BAL strongly considered for definitive diagnosis.
 - Biopsy of other sites such as lymph nodes or bone marrow can be useful.
 - Diagnoses such as pulmonary embolism, asthma, chronic obstructive pulmonary disease, and cardiogenic pulmonary edema also present with respiratory failure, and appropriate testing should be performed.

Pneumocystis carinii Pneumonia

- PCP is historically the most common cause of respiratory failure in AIDS patients.
 - **Treatment and Corticosteroids:** Duration of PCP treatment is 21 days.
 - First-line therapy for moderate to severe PCP is intravenous (IV) trimethoprim-sulfamethoxazole (Table 81.2).
 - Adjunctive corticosteroids are shown to decrease mortality in patients with moderate to severe PCP.
 - Administration of corticosteroids is associated with a risk ratio of 0.56 for mortality and 0.38 for requiring mechanical ventilation.
 - Patients with a room air arterial oxygen pressure < 70 mm Hg or with an alveolar-arterial gradient > 35 mm Hg should receive corticosteroids.

TABLE 81.2

SUMMARY OF TREATMENT REGIMENS FOR PCP IN THE ICU IN DECREASING ORDER OF PREFERENCE

Agent	Dose	Side effects
Trimethoprim-sulfamethoxazole	15–20 mg/kg/d trimethoprim with 75–100 mg/kg/d sulfamethoxazole IV, divided every 6–8 h	Bone marrow suppression, hyponatremia, hyperkalemia, nausea, nephrotoxicity, rash, transaminitis
Pentamidine isethionate	3–4 mg/kg/d IV	Bone marrow suppression, hypoglycemia or hyperglycemia, hypotension, nausea, pancreatitis, nephrotoxicity
Clindamycin-primaquine	900 mg IV every 8 h (clindamycin) 30 mg PO daily (primaquine)	Diarrhea, hemolytic anemia, leukopenia, methemoglobinemia, nausea, rash
Adjunctive therapy: Prednisone if PaO ₂ <70 mm Hg or A-a gradient >35 mm Hg	40 mg PO every 12 h for 5 d, 40 mg PO daily for 5 d, 20 mg PO daily for 11 d	Psychosis, hyperglycemia

PCP, *Pneumocystis* pneumonia; ICU, intensive care unit; IV, intravenously; PO, by mouth; PaO₂, arterial oxygen tension; A-a, alveolar-arterial; d, day; h, hour.

- Therapy should be started within 24 to 72 hours of initiation of PCP treatment, regardless of whether diagnosis is confirmed or only suspected.
- Corticosteroids reduce inflammatory response seen during first few days of treatment.
- Recommended regimen is 40 mg of oral prednisone given twice daily for 5 days, then 40 mg once daily for 5 days, and 20 mg daily for 11 days.
- If unable to tolerate oral medications, IV methylprednisolone or dexamethasone can be substituted.
- **Ventilatory Support:** Physiology of PCP is very similar to that of acute respiratory distress syndrome (ARDS).
 - Principles of ventilatory management the same
 - Barotrauma is of particular concern in ventilated patients with PCP.
 - Development of pneumothorax heralds a poor prognosis.
 - Should probably be ventilated with tidal volumes of 6 mL/kg and levels of positive end-expiratory pressure as needed to maintain oxygenation according to the ARDSnet guidelines.
 - Noninvasive positive pressure ventilation with continuous positive airway pressure or bilevel positive airway pressure may be useful.
 - Noninvasive positive pressure ventilation may decrease rate of intubation, lower the number of pneumothoraces, and improve survival.

Bacterial Pneumonia

- Absolute numbers of cases of bacterial pneumonia (BP) have declined since the introduction of HAART.
- Clinical risk factors for BP include:
 - IV drug use
 - Cigarette smoking
 - Older age
 - Lower CD4⁺ cell count
- One study found that 83% of HIV-infected patients admitted to the ICU with BP survived.

- CD4⁺ cell count <100 cells/μL shock, and radiographic progression associated with mortality from BP in HIV-infected patients

- **Clinical Presentation:** Clinical presentation of BP in the HIV-infected patient is similar to that in the non-HIV-infected population.

- Typically present with an acute onset of fever, cough, shortness of breath, and purulent sputum
- Chest radiographs frequently reveal lobar infiltrates that may progress to an ARDS-like picture in severe cases.
- Most common causes of BP in HIV include *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Pseudomonas aeruginosa*, and *Staphylococcus aureus*.
- Atypical pneumonia with *Mycoplasma pneumoniae* reported in 20% to 30% of HIV-infected patients with community-acquired pneumonia (CAP).
 - Less commonly a cause of ICU admission
- HIV-infected patients more likely to be bacteremic, particularly those with *Streptococcus pneumoniae* infection.

Other Respiratory Diseases

- Other respiratory diseases that occur in HIV-infected ICU patients include:
 - *Mycobacteria tuberculosis* pneumonia
 - Fungal pneumonias such as *Cryptococcus neoformans*, *Histoplasma capsulatum*, *Coccidioides immitis*, and *Aspergillus fumigatus*
 - Cytomegalovirus (CMV) pneumonia
 - *Toxoplasma gondii* pneumonitis
 - Malignancies such as Kaposi sarcoma and non-Hodgkin lymphoma also lead to respiratory failure but are less common than infections.

IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME

- Immune reconstitution inflammatory syndrome (IRIS) is a life-threatening syndrome occurring in HIV-infected patients started on HAART.

- In days to months following initiation of HAART, patients experience paradoxical worsening or new onset of infectious signs or symptoms.
- Results from an improvement in immune system with increased inflammatory response against infectious agents that can occur before CD4⁺ cell count has risen
- IRIS most often seen in infection with *Mycobacterium tuberculosis*, CMV, *Pneumocystis*, *Mycobacterium avium* complex, and endemic fungi
- Manifestations of IRIS resulting in the need for ICU care include pneumonitis, meningitis, hepatitis, and pericarditis.
- Respiratory failure secondary to IRIS most common in tuberculosis and PCP.
 - Paradoxical worsening in these cases presents with fever, hypoxemia, and new or increased radiographic infiltrates.
 - Care is supportive, and corticosteroids are generally advocated, particularly in PCP.
- Antiretroviral regimens should be continued whenever possible.
- Syndrome is difficult to distinguish from acute opportunistic infections or other causes of respiratory deterioration.
 - Imperative that other causes of respiratory failure are sought before assigning a diagnosis of IRIS

FEVER OF UNKNOWN ORIGIN

- Fever is common in all ICU patients.
- Differential for fever is broad in the HIV-infected patient and includes:
 - Infections
 - Neoplasms
 - Medications
 - Collagen vascular diseases
- Etiology of fevers of unknown origin in those with HIV infection found to be infectious
 - Mycobacterial diseases are most commonly diagnosed.
 - PCP and bacterial infections are also seen.
 - The most common neoplastic cause of prolonged fever is lymphoma.
- Common infectious causes of fever in the ICU include:
 - Hospital-acquired pneumonia
 - Catheter-related infections
 - Sinusitis
 - Pseudomembranous colitis
- Noninfectious causes include:
 - Drug reactions (which are particularly common in those with HIV)
 - Pancreatitis
 - Venous thromboembolism
 - Acalculous cholecystitis
 - Adrenal insufficiency
 - Thyroid storm
- Diagnostic workup should include standard evaluation for infections such as blood, sputum, and urine cultures.
 - Bronchoscopy with BAL performed in patients who demonstrate a new infiltrate on chest radiograph or have a worsening respiratory status
 - Testing performed for mycobacterial and fungal pathogens
 - Other testing performed as would be done in the non-HIV-infected population

ANTIRETROVIRAL THERAPY IN THE ICU

Treatment Strategies

- Use of antiretroviral therapy in critically ill patients presents distinct issues related to drug delivery, dosing, drug interactions, and antiretroviral-associated toxicities.
- No randomized clinical trials and no consensus guidelines to assist in decisions regarding HAART use in the ICU
- Patients receiving HAART prior to ICU admission with evidence of virologic suppression (plasma HIV RNA below the limit of detection) should continue HAART.
 - Prompt placement of a feeding tube is critical in these patients.
- Lapses in therapy create potential for subtherapeutic antiretroviral drug levels and the emergence of HIV drug resistance.

Drug Delivery, Dosing, and Interactions

- All currently approved antiretroviral medications are dispensed orally.
 - Either as tablets or capsules
- With sole exception of enfuvirtide, a fusion inhibitor that is delivered subcutaneously (Table 81.3)
- Critical illness may complicate absorption of antiretroviral medications.
 - Decreased gastric motility, continuous feeding, nasogastric suctioning, and gastric alkalization recommended for stress ulcer prophylaxis may contribute to variations in absorption of enterally administered drugs.
 - H₂-blockers and proton pump inhibitors for stress ulcer prophylaxis are contraindicated with certain antiretroviral medications, necessitating the use of alternative prophylaxis agents or antiretroviral medications (Table 81.4).
- Presence of renal insufficiency or hepatic impairment will affect antiretroviral dosing.
 - Renal insufficiency will reduce the clearance of all nucleoside reverse transcriptase inhibitors (NRTIs) except abacavir and will require dose adjustment of these NRTIs (see Table 81.3).
 - Patients with renal insufficiency cannot use most fixed-dose NRTI combinations.
 - Each antiretroviral medication must be used individually and dosed accordingly.
 - Liver impairment will reduce the hepatic metabolism of many protease inhibitors and nonnucleoside reverse transcriptase inhibitors and will require dose adjustment of these medications (see Table 81.3).
 - Finally, as the patient's renal and hepatic functions change, the dose of these medications must be readjusted accordingly.
- Antiretroviral medications, especially nonnucleoside reverse transcriptase inhibitors and ritonavir-boosted protease inhibitor regimens, have several important drug interactions with other medications (see Table 81.4).

TABLE 81.3

ANTIRETROVIRAL MEDICATION FORMULATIONS AND DOSING

Medication	Available formulation(s)		Daily dose	Dosing in renal insufficiency		Dosing in hepatic impairment
	Tablet/capsule	Other		No dosage adjustment	Dose/d	
Nucleoside/Nucleotide Reverse Transcriptase Inhibitors Abacavir, ABC (Ziagen)	300-mg tablets	20 mg/mL oral solution	300 mg BID or 600 mg QD	No dosage adjustment		No dosage recommendation
	125-, 200-, 250-, 400-mg enteric coated (EC) capsules		More than 60 kg 400 mg QD	(EC capsules)	Dose/d	No dosage recommendation
			<i>With tenofovir</i> 250 mg QD	CrCl (mL/min)	> 60 kg	<60 kg
			<60 kg 250 mg QD	30–59 10–29 <10*	200 mg 125 mg 125 mg	
				75 mg		
Emtricitabine, FTC (Emtriva)	200-mg hard gelatin capsule	10 mg/mL oral solution	<i>With tenofovir</i> 200 mg QD	*Includes patients receiving CAPD and HD; administer dose after dialysis.		No dosage recommendation
			200 mg QD or 240 mg (240 mL) oral solution QD	CrCl (mL/min)	Capsule dose	
				30–49 15–29 <15*	200 mg q48h 200 mg q72h 200 mg q96h	
				CrCl (mL/min)	Oral solution dose	
				30–49 15–29 <15*	120 mg q24h 80 mg q24h 60 mg q24h	
Lamivudine, 3TC (Epivir)	150-, 300-mg tablets	10 mg/mL oral solution	150 mg BID or 300 mg QD	*Includes patients receiving HD; administer dose after dialysis.		No dosage recommendation
				CrCl (mL/min)	Dose	
				30–49 15–29	150 mg QD 150 mg once, then 100 mg QD	
				5–14 <5*	150 mg once, then 50 mg QD 50 mg once, then 25 mg QD	
				*Includes patients receiving HD; administer dose after dialysis.

				CrCl <50 mL/min Not recommended		

Nonnucleoside Reverse Transcriptase Inhibitors				
Delavirdine, DLV (Rescriptor) ^b	100-, 200-mg tablets	400 mg TID	No dosage adjustment	No dosage recommendation; use with caution
Efavirenz, EFV (Sustiva) ^d	50-, 100-, 200-mg capsules, 600-mg tablets	600 mg QD on an empty stomach	No dosage adjustment	No dosage recommendation; use with caution
Nevirapine, NVP (Viramune)	200-mg tablets	50 mg/5 mL oral suspension	No dosage adjustment	No data available; avoid use in patients with moderate to severe impairment
Atazanavir, ATV (Reyataz) ^c	100-, 150-, 200-mg capsules	400 mg QD <u>With tenofovir or efavirenz</u> RTV 100 mg QD must be added to ATV 300 mg QD	No dosage adjustment	C-P Score Dose 7-9 300 mg QD >9 Not recommended
Darunavir, DRV Prezista ^{c,d,f}	300-mg tablet	<u>With ritonavir</u> 600 mg BID (RTV 100 mg BID)	No dosage adjustment	No dosage recommendation; use with caution
Fosamprenavir, f-AP (Lexiva)	700-mg tablet	ARV naïve 1,400 mg BID <u>With ritonavir</u> 1,400 mg QD (RTV 200 mg QD) or 700 mg BID (RTV 100 mg BID) <u>With efavirenz</u> (RTV 100 mg BID must be added to f-APV 700 mg BID or RTV 300 mg QD added to f-APV 1,400 mg QD)	No dosage adjustment	C-P Score Dose 5-8 700 mg BID >9 Not recommended RTV boosting should not be used
Indinavir, IDV (Crixivan) ^{b,d}	200-, 333-, 400-mg capsules	800 mg q8h ^a <u>With ritonavir</u> 800 mg q12h (RTV 100 or 200 mg q12h)	No dosage adjustment	Mild to moderate insufficiency due to cirrhosis: 600 mg q8h
Lopinavir/ritonavir, LPV/r (Kaletra)	200/50-mg capsule	400/100 mg/5 mL oral solution Oral solution contains 42% alcohol	No dosage adjustment	No dosage recommendation; use with caution

(continued)

TABLE 81.3

CONTINUED

Medication	Available formulation(s)		Daily dose	Dosing in renal insufficiency	Dosing in hepatic impairment
	Tablet/capsule	Other			
Nelfinavir, NFV (Viracept) ^{b,c}	250-, 625-mg tablets	50 mg/g oral powder	1,250 mg BID or 750 mg TID	No dosage adjustment	No dosage recommendation; use with caution
Ritonavir, RTV (Norvir) ^{b,e}	100-mg capsules	600 mg/7.5 mL oral solution	600 mg q12h (when used as sole protease inhibitor) 100–400 mg daily in 1 to 2 divided doses (when used as pharmacokinetic booster)	No dosage adjustment	No dosage adjustment in mild impairment; no data for moderate to severe impairment, use with caution
Saquinavir hard gel capsule, SQV HGC (Invirase) ^{b,d}	200-mg capsules		<u>With ritonavir</u> 1,000 mg BID (RTV 100 mg BID)	No dosage adjustment	No dosage recommendation; use with caution
Tipranavir, TPV (Aptivus) ^{c,d,f}	250-mg capsules		<u>With ritonavir</u> 500 mg BID (RTV 200 mg BID)	No dosage adjustment	No dosage recommendation; use with caution; contraindicated in C-P Class B and C
Enfuvirtide, T20 (Fuzeon) ^{b,f}		108 mg/1.1 mL sterile H ₂ O (90 mg/1 mL)	90 mg SQ BID	No dosage adjustment	No dosage recommendation

BID, twice a day; QD, once daily; CAPD, continuous ambulatory peritoneal dialysis; HD, hemodialysis; ESRD, end-stage renal disease; TID, three times a day; C-P, Child-Pugh; SQ, subcutaneously.

^aHold enteral nutrition 2 h before and 1 h after administration.

^bGenerally not recommended as initial therapy if alternatives are available due to inferior virologic activity, inconvenient dosing, high pill burden, and/or increased toxicity and adverse events.

^cAdministration with food increases bioavailability. Take with food. For atazanavir, avoid taking with antacids.

^dGenerally not recommended unless accompanied by ritonavir as a pharmacokinetic booster.

^eGenerally not recommended as the sole protease inhibitor but used in combination with other protease inhibitors as a pharmacokinetic booster.

^fNo clinical trial data in antiretroviral therapy-naïve patients.

Adapted from Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents. These guidelines are updated frequently, and the most recent information is available on the AIDSinfo Web site: <http://AIDSinfo.nih.gov>. Accessed October 10, 2006.

TABLE 81.4**COMMON ICU MEDICATIONS AND POTENTIALLY SERIOUS LIFE-THREATENING INTERACTIONS WITH ANTIRETROVIRALS**

Drug	Antiretroviral	Interaction
NEUROLOGIC AGENTS		
Anticonvulsants	Darunavir	May decrease ARV levels
Phenytoin, phenobarbital, carbamazepine	Delavirdine	May decrease anticonvulsant levels
	Efavirenz	
SEDATIVES/ANALGESICS		
Midazolam/triazolam ^a	Most PIs, NNRTIs	Increased sedative effects
Methadone	Most PIs, NNRTIs, NRTIs	Narcotic withdrawal
Meperidine	Ritonavir	Increased normeperidine levels
ANTIMICROBIALS		
Metronidazole	Amprenavir	Disulfiram-like reaction
	Ritonavir	
	Tipranavir	
Rifampin	Most PIs	Decreased ARV levels
	Delavirdine	Increased hepatotoxicity
	Efavirenz	
	Nevirapine	
Voriconazole	Efavirenz	Decreased voriconazole levels
	Ritonavir	Increased ARV levels
RESPIRATORY AGENTS		
Fluticasone	Most PIs	Increased plasma fluticasone levels and adrenal suppression
CARDIAC AGENTS		
Amiodarone	Most PIs	Increased cardiac effects
	Amprenavir	Increased cardiac effects
Diltiazem	Atazanavir	
	Indinavir	
Nifedipine	Amprenavir	Increased cardiac effects
	Darunavir	
	Delavirdine	
	Lopinavir/ritonavir	
Simvastatin/lovastatin	PIs	Increased statin levels
	Delavirdine	
	Efavirenz	
Sildenafil	Most PIs	Increased sildenafil effects
GASTROINTESTINAL AGENTS		
Proton pump inhibitors/H ₂ blockers	Atazanavir	Decreased ARV levels
	Delavirdine	

ICU, intensive care unit; ARV, antiretroviral; PI, protease inhibitor; NNRTI, nonnucleoside reverse transcriptase inhibitor; NRTI, nucleoside reverse transcriptase inhibitor.

^aMidazolam can be used with caution as a single dose and given in a monitored situation for procedural sedation.

Drug Toxicity

- Newer antiretroviral medications possess better safety profiles compared to their predecessors.
- Several antiretroviral medications are associated with potentially life-threatening and serious adverse effects (Table 81.5).
 - Abacavir associated with a hypersensitivity syndrome rarely can lead to death if patient is rechallenged
 - Rash associated with nevirapine can be severe, presenting with systemic symptoms and, in rare cases, progressing to Stevens-Johnson syndrome and toxic epidermal necrosis.
 - Efavirenz is associated with mental status alterations that may be attributed erroneously to analgesics, sedatives, or the sleep-disrupted schedule in the ICU.

TABLE 81.5

POTENTIALLY LIFE-THREATENING AND SERIOUS ADVERSE EFFECTS OF ANTIRETROVIRAL AGENTS

Life-threatening and adverse effect	Principal antiretroviral agent	Estimated frequency, onset	Prevention/monitoring and management
<i>Dermatologic</i> -Hypersensitivity reaction (HSR)—fever, diffuse rash; may progress to hypotension, respiratory distress, and vascular collapse	Abacavir (ABC)	Approximately 5%–8% Onset, 9 d (median); approximately 90% within first 6 wk	<ul style="list-style-type: none"> Discontinue ABC and other ARVs. Most signs and symptoms resolve 48 h after discontinuation Rule out other causes of symptoms Discontinue other potential agent(s) Do not rechallenge patients with ABC after suspected HSR
<i>Dermatologic</i> -Stevens-Johnson syndrome/toxic epidermal necrolysis (TEN)	Chiefly NNRTIs: Nevirapine (NVP) more than efavirenz (EFV), delavirdine (DLV)	NVP: 0.3%–1%, EFV and DLV: 0.1%; case reports for other ARVs Onset within first few days to weeks	<ul style="list-style-type: none"> NVP: 2-week lead in period with 200 mg QD dosing, then increase to 200 mg BID. Avoid use of corticosteroids during lead-in period—may increase incidence of rash Discontinue NNRTI and other ARVs Rule out other causes of symptoms Discontinue other potential agent(s) Do not rechallenge patients with NNRTI
<i>Neurologic</i> -Central nervous system (CNS) effects including drowsiness, somnolence, insomnia, hallucination, psychosis, suicidal ideation, exacerbation of psychiatric illness	Efavirenz (EFV)	More than 50% may have some symptoms Onset within first few days; most symptoms subside or diminish after 2–4 wk	<ul style="list-style-type: none"> Administer at bedtime or 2–3 h before bedtime for nonintubated, nonsedated patients Take on an empty stomach to reduce drug concentration and CNS effects Consider discontinuing EFV if symptoms persist and cause significant impairment or exacerbation of psychiatric illness
<i>Gastrointestinal</i> -Hepatotoxicity	All ARVs, especially nevirapine (NVP)	Frequency varies with ARV Onset (NRTIs), months to years; PIs generally weeks to months; NVP, 2/3 within first 12 wk	<ul style="list-style-type: none"> Monitor liver enzymes Rule out other causes of hepatotoxicity For symptomatic patients, discontinue all ARVs Discontinue other potential agent(s)
<i>Gastrointestinal</i> -Pancreatitis	Didanosine (ddI), also stavudine (d4T) plus ddI	ddI: 1%–7%, d4T plus ddI: increased frequency Onset usually weeks to months	<ul style="list-style-type: none"> ddI should not be used in patients with a history of pancreatitis Avoid concomitant use of ddI with d4T Monitoring of serum amylase/lipase in asymptomatic patients is generally not recommended Discontinue offending agent
<i>Hematologic</i> -Bone marrow suppression	Zidovudine (AZT, ZDV)	Anemia: 1.1%–4%; neutropenia: 1.8%–8% Onset, weeks to months	<ul style="list-style-type: none"> Avoid use in patients at risk Avoid other bone marrow suppressants if possible Monitor CBC with differential Switch to another NRTI if there is an alternative Discontinue concomitant bone marrow suppressants if there are alternatives Identify and treat other causes for anemia and neutropenia Blood transfusion if indicated Consider erythropoietin therapy for anemia Consider filgrastim for neutropenia

(continued)

TABLE 81.5

CONTINUED

Life-threatening and adverse effect	Principal antiretroviral agent	Estimated frequency, onset	Prevention/monitoring and management
Lactic acidosis, hepatic steatosis ± pancreatitis (severe mitochondrial toxicities)	NRTIs, especially stavudine (d4T), didanosine (ddI), and zidovudine (AZT, ZDV)	Rare, but mortality up to 50% in some case series Onset, months	<ul style="list-style-type: none"> Discontinue ARV if this syndrome is highly suspected Routine monitoring of lactic acid is generally not recommended Some patients may require IV bicarbonate infusion, hemodialysis, or hemofiltration Thiamine, riboflavin, and/or L-carnitine resulted in rapid resolution of hyperlactatemia in some case reports
Lactic acidosis, rapidly progressive ascending neuromuscular weakness	Stavudine (d4T), most frequent	Rare Onset, months; then dramatic motor weakness may occur within days to weeks	<ul style="list-style-type: none"> Discontinue ARV. Symptoms may be irreversible Do not rechallenge patients with suspected ARV Plasmapheresis, high dose corticosteroids, intravenous immunoglobulin, carnitine, acetylcarnitine attempted with varying success
Renal-Nephrolithiasis/ urolithiasis/crystalluria	Indinavir (IDV) most frequent	Approximately 12% Onset is any time after beginning of therapy, especially at times of decreased fluid intake	<ul style="list-style-type: none"> Maintain hydration, increase hydration at first sign of darkened urine Monitor serum creatinine, urinalysis Consider switching to alternative agent or therapeutic drug monitoring Stent placement may be required
Renal-Nephrotoxicity	Indinavir (IDV), potentially tenofovir (TDF)	Frequency unknown Onset-(IDV): months; (TDF): weeks to months	<ul style="list-style-type: none"> Avoid use of other nephrotoxic medications IDV: Maintain hydration, increase hydration at first sign of darkened urine Monitor serum creatinine, urinalysis, serum potassium and phosphorus Stop offending agent (generally reversible)

ARV, antiretroviral; NNRTI, nonnucleoside reverse transcriptase inhibitor; QD, daily; BID, twice a day; NRTI, nucleoside reverse transcriptase inhibitor; PI, protease inhibitor; CBC, complete blood count.

This table only lists potential life-threatening and serious adverse effects with an onset starting from initial dose up to months after initiation of therapy. However, there are several important adverse effects including cardiovascular effects, hyperlipidemia, insulin resistance or diabetes mellitus, and osteonecrosis that may result from antiretroviral therapy.

Adapted from Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents. These guidelines are updated frequently, and the most recent information is available on the AIDSinfo Web site: <http://AIDSinfo.nih.gov>. Accessed October 10, 2006.

HIV TESTING IN THE ICU

- In the current era, up to 40% of patients are unaware of HIV infection at time of ICU admission.
 - Current guidelines recommend HIV testing whenever HIV infection is suspected.
 - However, prompt recognition of previously undiagnosed HIV infection and HIV testing and disclosure requirements present challenges to critical care physicians.
 - In general, HIV testing requires consent from the patient.
 - If the patient is incapacitated, some states permit a surrogate to consent.
- HIV testing cannot be performed if a patient or their surrogate refuses.
- In cases where HIV testing cannot be performed, well-intentioned physicians may wish to order plasma HIV RNA assays or CD4⁺ cell counts to infer HIV status.
 - This practice is ill advised and may be in violation of legal statutes in some states.
 - Normal CD4⁺ cell count argues strongly against the presence of an HIV-associated opportunistic infection such as PCP; low CD4⁺ counts characteristic of advanced HIV disease are often seen in critically ill patients without HIV.

CHAPTER 82 ■ UNUSUAL INFECTIONS

- This chapter describes the epidemiology, clinical presentation, diagnosis, therapy, and prevention of relatively unusual infections.
- The incidence of these is low in the United States, they have potential to cause rapidly progressive disease, and, in some cases, they present unique problems in management and infection control in critical care.
- Prompt diagnosis and rapid treatment are critical.
- Many organisms causing these infectious diseases have gained new relevance as potential biologic warfare agents.
 - Epidemiology, clinical presentation, and management of infections resulting from intentional release may differ significantly from disease resulting from traditional modes of spread.
 - An intentional bioterrorist attack will result in large social disruptions affecting housing, public hygiene, and mass migration.
 - This may allow epidemic transmission of some agents.
- Globalization with increased travel of humans, and transport of animals and plant materials all increase likelihood that unusual infections will become more prevalent in the United States.

TULAREMIA

- A multisystem zoonotic infection caused by gram-negative coccobacillus, *Francisella tularensis*
 - Tularemia has been recognized since the 1800s.
 - Primarily transmitted through contact with infected animals, contaminated food and water, or arthropod bites
 - Tularemia is listed as a category A bioterrorism agent and defined as follows:
 - Can be easily disseminated or transmitted from person to person
 - Results in high mortality rates and has the potential for major public health impact
 - Might cause public panic and social disruption
 - Requires special action for public health preparedness

Epidemiology

- Incidence in the United States has declined since 1950s and is currently <200 per year
 - In the United States, most cases occur in the western and southwestern states in small sporadic clusters.
 - Primarily occurs during summer months, likely due to increased exposure to biting arthropods
 - Cases during the fall and winter linked to hunting and handling infected animals.
 - A 3-to-1 preponderance of male-to-female cases.

- Inhalational exposures occurred in Martha's Vineyard in Massachusetts.
 - Were associated with mowing grass and cutting brush
- In the United States, ticks and biting flies are the most important arthropod vectors.
 - Major animal reservoirs are lagomorphs (rabbits and hares) and rodents including prairie dogs, squirrels, and rats.
 - Mosquitoes were implicated as primary vector in Scandinavia in one large outbreak.
 - Direct contact with infected animals is another significant mode of transmission.
 - Hunting, trapping, butchering animal carcasses, and handling meat are all risk factors.
 - Contamination of food and water by rodents and other carriers is also linked to human infection.
 - Organism survives well in cold, moist conditions and can withstand freezing.
 - Cats and other carnivores transiently carry organisms in mouths or claws.
 - Can thereby transmit infection to humans
 - Pets increase likelihood of tick-borne transmission to humans.
- Inhalational exposure may occur in laboratory or as consequence of deliberate release of weaponized *Francisella* cultures.
- Human-to-human transmission of tularemia is not known to occur.

Clinical Presentation

- Classically described as presenting one of six syndromes:
 - Ulceroglandular
 - Oculoglandular
 - Glandular
 - Pharyngeal
 - Typhoidal
 - Pneumonic
 - Individual patients may have symptoms of several of these types simultaneously.
- After initial entry into host, through cutaneous inoculation, ingestion, or inhalation
 - Organisms multiply at site of infection.
 - Vigorous inflammatory response ensues, leading to subsequent necrosis
 - Organism multiplies within macrophages and travels to regional lymph nodes, kidney, liver, lung, and spleen.
 - Meninges and pericardium are occasionally involved secondarily in untreated tularemia.
 - Inhalation/cutaneous inoculation of 10 to 50 organisms is sufficient for infection.
 - Symptoms begin 3 to 5 days after infection.
 - Although longer incubation periods are possible

- Differences in clinical presentation are partly attributable to type and route of infection.
- Tick-borne infection is more likely to result in skin lesions on head and neck, trunk, and perineum.
- Animal-associated infections more commonly result in upper extremity lesions.
- Ingestion of contaminated water or food is more likely to cause pharyngeal infection.
- Inoculation into mucous membranes of eye results in oculoglandular syndrome.
 - Ocular lesion with local lymphadenopathy
- Inhalation of organism leads to pneumonic form of tularemia.
 - Other forms of tularemia can also cause pulmonary involvement through hematogenous dissemination.
- Typhoidal form of tularemia occurs in <30% of cases, in which there are no characteristic localized mucocutaneous or glandular signs or symptoms.
- Onset of systemic symptoms in tularemia is abrupt and includes:
 - Fever, headache, myalgia, coryza, cough, malaise, and chest pain or tightness
 - Mucocutaneous infection, presenting complaint is usually painful lymphadenopathy
 - May precede or follow skin lesion
 - Purely glandular form, there is no apparent skin lesion
 - Skin lesions usually begin as erythematous painful papules.
 - Progress to necrotic ulcers that are slow to heal
 - Enlarged lymph nodes slow to resolve and may suppurate.
 - Ocular infection, a painful conjunctivitis occurs
 - Pharyngeal tularemia presents as exudative pharyngitis with adenopathy unresponsive to standard therapy.
 - Tularemic pneumonia is characterized by fever, cough, and pleuritic pain.
 - Sputum production and hemoptysis are unusual.
 - Relative bradycardia, with normal pulse despite elevated temperature, is common (40%) in tularemia and may be a useful diagnostic finding.
 - Chest radiograph (CXR) findings include hilar adenopathy, patchy or less commonly lobar infiltrates, and pleural effusions.
- There has not been a documented biologic attack with weaponized tularemia organisms.
 - An aerosolized release of organisms would likely cause pneumonic disease.
 - Would also likely result in ocular and cutaneous forms
 - Tularemia in urban settings and among healthy individuals should prompt suspicion of a biologic attack.
 - Onset of symptoms is expected to be rapid.
 - Closely resemble acute onset of influenza
 - Differential diagnosis of pneumonia due to an aerosolized biologic weapon attack would include anthrax, plague, and Q fever.
 - Important distinguishing characteristics between these causes would include:
 - More rapid and fulminant course in both anthrax and plague
 - Pneumonic anthrax would not cause bronchopneumonia but would result in mediastinal widening.
 - Pneumonic plague results in frankly purulent sputum with hemoptysis and rapid progression.

- Laboratory testing is important in distinguishing between these various causes
- Initial empiric treatment will require diagnosis based primarily on clinical and epidemiologic data.

Diagnosis

- Cultures require incubation on special supportive media.
 - Cultures of pharyngeal washings, sputum, and fasting gastric aspirates most likely to yield positive results.
 - Blood samples are usually negative.
- Direct fluorescent staining of specimens performed by specialized laboratories for a relatively rapid diagnosis.
 - Serology is positive approximately 10 days after infection.
 - Serology is useful for confirmation of suspected cases.
 - It is important to promptly contact the hospital epidemiologist or infection control department.

Treatment

- Treatment regimens for most of the select agents are devised for either a contained or a mass casualty setting (Table 82.1).

PLAGUE

- Caused by the gram-negative bacillus *Yersinia pestis*
 - One of oldest and most feared illnesses known to man
 - Developed by various groups and nations as a biologic weapon since the 1950s
 - Listed as an important potential agent of bioterrorism.

Epidemiology

- Primarily a rural disease that occurs in all continents except Australia.
- Most common in rural settings in developing nations
 - Most cases occur between spring and autumn in the western United States where disease is enzootic in wild rodents.
 - Humans are infected via bites from infected rodent fleas or by handling infected animals, either domestic pets or wild animals.
 - Worldwide, the most important reservoir is the domestic rat.
 - But, as in the United States, sylvatic foci (in wild animals) also exist.
 - Human-to-human transmission can occur in pneumonic plague.
 - Requires close contact
 - In the United States, the last known case acquired in this manner was reported in 1925.

Clinical Manifestations

- Three main types of plague are:
 - Bubonic
 - Septicemic
 - Pneumonic

TABLE 82.1
TREATMENT RECOMMENDATIONS FOR TULAREMIA

Contained casualty setting	
Adults	<p><i>Preferred choices:</i> Streptomycin, 1 g IM BID Gentamicin, 5 mg/kg IM or IV once daily</p> <p><i>Alternative choices:</i> Doxycycline, 100 mg IV BID Chloramphenicol, 15 mg/kg IV QID Ciprofloxacin, 400 mg IV BID</p>
Children	<p><i>Preferred choices:</i> Streptomycin, 15 mg/kg IM BID (not to exceed 2 g/d) Gentamicin, 2.5 mg/kg IM or IV TID</p> <p><i>Alternative choices:</i> Doxycycline If weight 45 kg or more, 100 mg IV BID If weight <45 kg, 2.2 mg/kg IV BID Chloramphenicol, 15 mg/kg IV QID Ciprofloxacin, 15 mg/kg IV BID</p>
Pregnant women	Same as adults above except chloramphenicol is not recommended.
Mass casualty setting	
Adults, including pregnant women	<p><i>Preferred choices:</i> Doxycycline, 100 mg PO BID Ciprofloxacin, 500 mg PO BID</p>
Children	<p><i>Preferred choices:</i> Doxycycline If ≥45 kg, 100 mg PO BID If <45 kg, 2.2 mg/kg PO BID Ciprofloxacin, 15 mg/kg PO BID^a</p>

BID, twice daily; IM, intramuscularly; IV, intravenously; PO, orally; TID, three times daily; QID, four times daily.

For full details and most current treatment recommendations, the reader is referred to the CDC Web site: Centers for Disease Control and Prevention. Consensus statement: tularemia as a biological weapon: medical and public health management. <http://www.bt.cdc.gov/agent/tularemia/tularemia-biological-weapon-abstract.asp#4>. Accessed February 6, 2007.

^aCiprofloxacin dosage should not exceed 1 g/d in children.

- No current experience with pneumonic plague acquired from biologic attack
 - But clinical presentation expected to differ from natural infection

Bubonic Plague

- The most common type of plague
 - Occurring in 76% of cases reported in the United States between 1990 and 2005
 - Large numbers of bacteria inoculated at site of flea bite and multiply locally.
 - Followed by rapid replication in nearby lymph nodes
 - Incubation period is between 2 and 7 days.
 - Abrupt onset of fever, chills, and headache
 - Characteristic bubo typically develops as an extremely tender smooth, firm oval mass.
 - Overlying skin is warm and erythematous, but suppuration is rare.
 - Primary lesion is often inapparent but can develop into an ulcer.

- Most common site of buboes is in femoral lymph nodes.
 - Also seen in inguinal, cervical, and axillary locations depending on location of inoculation
- Bacteremia occurs in about 25% of cases.
- In untreated cases, mortality is approximately 50%.
 - Deterioration is usually rapid, with progression of typical signs of shock and death occurring as early as 2 to 3 days.

Septicemic Plague

- Defined as plague absent an apparent bubo
- Diagnosis of septicemic plague is often delayed and prognosis is poorer than other forms of plague.
- In the United States, from 1990 to 2005, 18% of reported plague cases were septicemic.
 - 38% of the cases in 2006 were of this variety.
- Useful clue to diagnosis of septicemic plague is that gastrointestinal symptoms (nausea and vomiting, diarrhea, and abdominal pain) were prominent in several recent cases.
- Disseminated intravascular coagulation (DIC) may develop with cutaneous and visceral hemorrhage.
 - Rapidly progressive gangrene may also develop.
- Septicemic plague and pneumonic plague are fatal if untreated.
 - Even with treatment, mortality rates of 33% in septicemic plague were reported from New Mexico in the 1980s.

Pneumonic Plague

- May develop secondary to either bubonic or septicemic plague
 - Incidence of secondary pulmonary involvement approximates 12%.
 - In the United States, recent cases of primary pneumonic plague occurred from laboratory accidents or cat exposure.
- Similar to other acute pneumonia with abrupt onset of fever and dyspnea
 - Bloody, watery or purulent sputum is produced.
 - Is HIGHLY infectious
 - Transmission *via* respiratory droplets
 - Simple respiratory isolation with droplet precautions is sufficient.
 - Chest radiograph usually reveals bronchopneumonia and multilobar consolidation, or cavitation may be seen
- Clues to plague arising as result of biologic attack include:
 - Cases outside areas of known enzootic infection
 - Occurrences in area without associated rodent die-offs
 - Numerous cases of pneumonia in otherwise healthy patients
 - Routine laboratory tests are not markedly different from those in fulminant pneumonia and sepsis.
 - White blood cell count is often markedly elevated.
 - Fibrin degradation products are detectable in cases where DIC present.

Diagnosis

- Specialized laboratory tests to definitively/rapidly identify *Y. pestis* are not widely available.
- When suspected, coordination with state public health officials and the Centers for Disease Control and Prevention (CDC) allows more specialized tests and susceptibility testing to be performed.

- Blood, sputum, lymph node aspirates, and lesion swabs examined by Gram or Wright-Giemsa stain for presence of bipolar-staining gram-negative bacilli
 - Have appearance of safety pins
 - Laboratory alerted to possibility of plague so appropriate biosafety procedures followed

Treatment

- Recommendations for therapy of plague provided were derived from recommendations of Working Group on Civilian Biodefense and CDC.
- Treatment recommendations are complicated by lack of clinical efficacy trials, lack of experience with widespread pneumonic plague, and potentially unpredictable clinical responses in infections due to a biologic attack.
 - Historically, the proven, effective antibiotic therapy for plague has been streptomycin.
 - Because of limited availability of streptomycin, gentamicin is the recommended alternative.
 - Tetracycline and doxycycline are effective and recommended for the treatment of plague.
 - Recommended duration of therapy for plague (Table 82.2) is 10 days.
 - Oral therapy is substituted when condition improves.
 - Duration of postexposure prophylaxis to prevent plague infection is 7 days.

ANTHRAX

- Extremely rare disease in the United States until bioterrorism attacks of 2001
 - Caused by the gram-positive, spore-forming bacillus *Bacillus anthracis*
 - Anthrax was tested as a biologic weapon by the United States in the 1960s and other countries until the 1970s.
 - Technology to produce highly infectious anthrax spores and disseminate as aerosol exists and is known to have been developed for use as a biologic warfare agent.

Epidemiology

- Three major modes of infection with anthrax:
 - Inhalational
 - Cutaneous
 - Gastrointestinal
- *Cutaneous anthrax* is the most common type.
 - Extremely rare in the United States, with 224 cases reported from 1944 to 1994.
- Barring exposure to intentionally produced anthrax, *inhalational anthrax* is less common.
 - Occurs primarily in those with occupational or laboratory exposure
 - Prior to 2001, only 18 cases of inhalational anthrax were reported from 1900 to 1978.
- *Gastrointestinal anthrax* is most commonly reported.
 - Improperly cooked meat contaminated with large numbers of anthrax bacilli is consumed.

TABLE 82.2

RECOMMENDATIONS FOR TREATMENT OF PATIENTS WITH PNEUMONIC PLAGUE IN CONTAINED AND MASS CASUALTY SETTINGS AND FOR POSTEXPOSURE PROPHYLAXIS

CONTAINED CASUALTY SETTING

Adults

Preferred choices:

Streptomycin, 1 g IM BID
Gentamicin, 5 mg/kg IM or IV once daily or
2 mg/kg loading dose followed by
1.7 mg/kg IM or IV TID

Alternative choices:

Doxycycline, 100 mg IV BID or
200 mg IV once daily
Ciprofloxacin, 400 mg IV BID
Chloramphenicol, 25 mg/kg IV QID

Children

Preferred choices:

Streptomycin, 15 mg/kg IM BID
(maximum daily dose, 2 g)
Gentamicin, 2.5 mg/kg IM or IV TID[†]

Alternative choices:

Doxycycline
If ≥45 kg or more, give adult dosage
If <45 kg, give 2.2 mg/kg IV BID
(maximum, 200 mg/d)
Ciprofloxacin, 15 mg/kg IV BID
Chloramphenicol, 25 mg/kg IV QID
In children, ciprofloxacin dose should not exceed 1 g/d, and chloramphenicol should not exceed 4 g/d.
Children younger than 2 y should not receive chloramphenicol.

Pregnant Women

Same as adults above except chloramphenicol is not recommended.

MASS CASUALTY SETTING AND POSTEXPOSURE PROPHYLAXIS

Adults, including pregnant women

Preferred choices:

Doxycycline, 100 mg PO BID
Ciprofloxacin, 500 mg PO BID

Alternative choice:

Chloramphenicol, 25 mg/kg PO QID

Children

Preferred choices:

Doxycycline
If ≥45 kg, give adult dosage.
If <45 kg, give 2.2 mg/kg PO BID
Ciprofloxacin, 20 mg/kg PO BID

Alternative choice:

Chloramphenicol, 25 mg/kg PO QID
(maximum 200 mg/dL)

BID, twice daily; IM, intramuscularly; IV, intravenously; PO, orally; TID, three times daily; QID, four times daily.

Clinical Manifestations

- Presentation of anthrax due to a biologic attack is still incompletely characterized.
- Most information relevant to inhalational anthrax from anthrax manufactured as a biologic weapon is from the

2001 U.S. attacks and an unintentional release in Sverdlovsk, Russia, in 1979.

- There were 11 cases of inhalational anthrax resulting from exposures in 2001.
- Aspects of pathophysiology of inhalational anthrax are highly relevant to clinician.
 - Infection occurs after spores are inhaled and deposited in alveoli.
 - Spores are phagocytosed by macrophages and transported to regional lymph nodes to germinate and replicate vegetatively.
 - There may be a period of extended latency in lymph node because spores remain dormant.
 - Although usual, incubation period is 2 to 6 days.
 - Cases have occurred as late as 6 weeks after exposure to aerosolized anthrax.
 - When replication occurs, toxin production leads to edema, necrosis, and hemorrhage.
- Typical symptoms are:
 - Fever and chills
 - Chest discomfort and dyspnea
 - Severe fatigue
 - Vomiting
- Two stages may occur, with an initial period of improvement followed by rapid deterioration.
 - Initial finding on CXR is widened mediastinum due to mediastinal lymph node involvement.
 - Hemorrhagic mediastinal lymphadenitis ensues, often accompanied by bloody pleural effusions.
 - 8 of 11 patients in 2001 developed bloody pleural effusions.
 - 10 of 11 had radiologic evidence of mediastinal adenopathy.
 - Anthrax does not cause typical bronchopneumonia.
 - Pulmonary infiltrates or consolidation were observed in 8 of 11 cases.
 - In an autopsy series from the Sverdlovsk outbreak, primary focal hemorrhagic necrotizing pneumonia was described in 11 of 42 cases.
- Anthrax may present as meningitis, which was the initial presentation of index case in 2001.
 - As many as 50% of inhalational anthrax cases may develop meningitis.
 - Causes rapidly progressive hemorrhagic meningitis with characteristic large gram-positive bacilli in cerebrospinal fluid (CSF)
- Although portal of infection is lung, hemorrhagic submucosal lesions may develop in gastrointestinal tract along with mesenteric infection.
 - Such lesions were seen in 39 of 42 of autopsy cases reported in the Sverdlovsk outbreak and in one 2001 case.
 - Latter patient presented with primarily gastrointestinal symptoms.
- Diagnosis of inhalational anthrax is difficult, especially in early stages.
 - Tachycardia and severe diaphoresis may be present.
 - Rhinorrhea or sore throat are common in viral respiratory infections but were uncommon in inhalational anthrax.
 - High index of clinical suspicion should be maintained.
 - Blood cultures are invariably positive if obtained prior to antibiotics.
- Cutaneous anthrax is expected to occur as a result of a biologic anthrax attack.
 - Cutaneous cases occurred up to 12 days after exposure in the Sverdlovsk outbreak.
 - Initial lesion is papule or macule.
 - Leads to ulceration at site of inoculation within 2 days, followed by vesiculation
 - Lesion is painless, although it may be highly pruritic.
 - Vesicular fluid contains large amounts of bacteria.
 - Characteristic depressed black eschar that subsequently develops is painless.
 - Surrounding edema is often a prominent feature of cutaneous anthrax lesions.
 - In the 2001 case, cutaneous anthrax developed in a 7-month-old infant, and microangiopathic hemolytic anemia and renal insufficiency occurred.

Diagnosis

- Blood cultures obtained when anthrax suspected
 - Blood smears examined for presence of organisms
- CXR and chest CT scans are obtained to look for evidence of mediastinal widening, pleural effusions, and parenchymal abnormalities.
- Thoracentesis of pleural effusions should be performed.
- Lumbar puncture (LP) should be done as indicated.
- Clinical microbiology laboratory and state public health department should be notified.
 - Specimens can be sent to specialized laboratories (Laboratory Response Network) for specific testing such as immunohistochemical staining or polymerase chain reaction (PCR).
 - Cutaneous lesions, especially vesicle fluid, should be swabbed for stain and culture.
 - Punch biopsy of the periphery of lesions may also be performed and analyzed by immunohistochemistry or PCR if Gram stain is negative.
 - Nasal swabs are not sensitive indicators of exposure or infection and should not be used to diagnose or rule out infection in individual patients.
 - Sputum culture generally negative in inhalational anthrax.

Treatment

- Current recommendations for anthrax therapy provided here are derived from the Working Group on Civilian Biodefense and CDC guidelines (Table 82.3).
- Treatment summary guidelines are as follows:
 - For a mass exposure setting
 - Both treatment and prophylaxis, where parenteral or multidrug therapy problematic
 - Consist of oral ciprofloxacin, 500 mg every 12 hours or 10 to 15 mg/kg twice daily for children
 - Gastrointestinal and oropharyngeal anthrax: use regimens recommended for inhalational anthrax
 - Cutaneous anthrax: recommendations are ciprofloxacin or doxycycline alone at same doses as inhalational anthrax
 - Recommended duration of treatment is a minimum of 60 days after exposure because of the risk of latent spores that may cause reactivation

TABLE 82.3

INHALATIONAL ANTHRAX TREATMENT PROTOCOL IN THE CONTAINED CASUALTY SETTING

Adults (including pregnant women)	Ciprofloxacin, 400 mg every 12 h or Doxycycline ^a 100 mg every 12 h and one or two additional antimicrobials ^b	IV treatment initially. Switch to oral antimicrobial therapy when clinically appropriate. Continue for 60 days (IV and PO combined)
Children	Ciprofloxacin ^c , 10–15 mg/kg every 12 h Or Doxycycline ^a Older than 8 y and >45 kg: 100 mg every 12 h Younger than 8 y or ≤45 kg: 2.2 mg/kg every 12 h And One or two additional antimicrobials ^b	Same as adult

^aIf meningitis is suspected, doxycycline may be less optimal because of poor central nervous system penetration.

^bOther agents with *in vitro* activity include rifampin, vancomycin, penicillin, ampicillin, chloramphenicol, imipenem, clindamycin, and clarithromycin. Because of concerns of constitutive and inducible beta-lactamases in *Bacillus anthracis*, penicillin and ampicillin should not be used alone.

^cThe ciprofloxacin dosage in children should not exceed 1 g/d.

- Use of adjunctive steroids may be considered in anthrax meningitis.
- Initial therapy may be altered based on clinical course of patient.
 - One or two first-line antimicrobials—ciprofloxacin or doxycycline—may be adequate as patient improves.

VIRAL HEMORRHAGIC FEVER

- Major diseases considered here are Marburg, Ebola, and Lassa fevers
- Marburg and Ebola viruses are filoviruses.
- Lassa virus is an arenavirus with different clinical characteristics.
- All have the potential to create similar problems in hospital management because of the sometimes dramatic nature of illness and potential for human-to-human transmission.

Epidemiology

- Since 1976, approximately a dozen outbreaks of Ebola in Africa
 - Mortality ranging from 53% to 88%
 - In the United States, eight cases of documented human infection occurred from contact with imported monkeys from Philippines.
 - Infections with this Reston strain of Ebola virus are sub-clinical.
- Marburg virus is associated with six outbreaks since the disease was recognized in 1976 in German and Yugoslav laboratory workers infected by African green monkeys of Ugandan origin.
- Six other infection clusters in Africa, most recently in Angola and Democratic Republic of Congo
 - Involving more than 400 people
 - Mortality was 83% and 90%, respectively, in last two outbreaks.

- Infections transmitted by exposure to infected primate blood or cell culture.
- Secondary transmission occurs from exposure to blood and body fluids and by intimate contact.
- Ebola transmission ranged from 3% to 17% in household contacts.
- Droplet and small-particle aerosol transmission thought to have occurred in Reston outbreak, but not documented in human-to-human transmission.
- Nosocomial transmission associated with
 - Percutaneous exposure and mucous membrane
 - Cutaneous exposure to infected body fluids
 - Skin of patients also infected and serves as source of secondary transmission
- Lassa virus chronic infection of rodents and is endemic throughout West Africa
 - Human transmission is through infected rodents, primarily through contact with urine.
 - Person-to-person transmission primarily via contact with infected body fluids.
 - Aerosol transmission may also occur.
 - Incubation is between 3 and 16 days.
- Other arenaviruses present worldwide in rodent reservoirs and are potential source of new clinical syndromes.

Clinical Manifestations

- Clinical pictures of Ebola and Marburg infection similar
 - Incubation period ranges between 5 and 10 days.
 - Abrupt onset of fever, myalgias, and headache is typical.
 - Nausea/vomiting, abdominal pain, diarrhea, chest pain, and pharyngitis are common.
 - Photophobia, lymph node enlargement, jaundice, and pancreatitis are all manifestations of widespread organ involvement.
 - Central nervous system involvement manifests as obtundation or coma.
 - Bleeding diathesis is seen in at least 50% of patients.
 - Characteristic maculopapular rash described by day 5 of illness.

- By the second week, either a period of defervescence and improvement, or further deterioration with multiorgan system failure
 - DIC as well as hepatic and renal failure may ensue.
- Convalescence often protracted
- Mortality is estimated at:
 - 25% for Marburg
 - 50% for Ebola-Sudan
 - 90% for Ebola-Zaire
 - Ebola-Reston has not led to any known human deaths.
 - There is viremia with infection of all organs
 - Leading to necrosis in areas of viral replication
 - Pathogenesis thought also due to cytokine release
 - With increased vascular permeability and hemodynamic instability
- Lassa fever presents with relatively nonspecific signs and symptoms
 - Makes recognition of cases in initial stages difficult
 - Combination of fever, retrosternal pain, pharyngitis, and proteinuria indicative of Lassa fever
 - Diffuse capillary leak syndrome in second week of illness is a cardinal manifestation.
 - Mortality of hospitalized cases ranges from 15% to 25%.
 - Seventh cranial nerve deafness is a common sequela of Lassa infection.
 - Occurs in approximately one-third of cases.
 - Persistent vertigo is another reported side effect.
 - Pathogenic mechanism of Lassa fever is not well understood.
 - Variable necrosis in affected organs
 - Systemic manifestations of vascular dysfunction perhaps due to soluble macrophage-derived factors

Diagnosis

- History of travel to endemic areas and clinical syndrome compatible with viral hemorrhagic fever (VHF) are key elements.
- Cluster of cases with signs and symptoms of VHF may be the first clue of biologic attack.
- Specialized testing for Marburg and Ebola is available through reference laboratories.
 - Includes PCR and direct antigen visualization in clinical samples
- Local public health authorities and CDC involvement allows testing *via* mobile laboratory facilities.
 - BSL-4 level containment facilities are required for attempts to isolate virus and BSL-3 facilities for routine testing.
- Lassa virus is easily cultured, as levels of viremia are usually high.
- Reverse transcription-PCR (RT-PCR) may also be used to identify Lassa virus.

Treatment

- Treatment of Marburg and Ebola virus primarily supportive
 - No effective specific therapy
 - Interferon is felt to not be useful.
 - Unnecessary movement/manipulation of patient avoided
 - Contact and respiratory isolation of the patient necessary, including:
 - Use of goggles and face shields to prevent exposure to body fluids

- Thorough disinfection of all materials coming into contact with patient performed
 - Containers of biologic waste should be externally disinfected.
- In Lassa fever, where aspartate transaminase levels exceed 150 IU/L
- Early treatment with IV ribavirin reported to be beneficial in tapering doses over 12 days.

SMALLPOX

- Caused by infection with variola, a double-stranded DNA orthopoxvirus
 - One of the most feared and lethal diseases known
 - Was virtually eliminated as natural threat by vaccination
 - In 1980, the World Health Organization declared it to be eradicated worldwide.
 - Last known naturally occurring case was in 1977.
 - In the United States, the universal childhood vaccination ended in 1972.
 - Most people in the United States today susceptible to smallpox infection.
 - The 2001 Anthrax attacks raised the possibility of smallpox being used as biologic weapon.
 - Classified as a category A bioterrorism agent
 - High-priority organism that poses a risk to national security
 - Considered one of most dangerous agents because of high infectiousness, capability for rapid spread, lack of effective treatment, and capacity to induce mass social disruption and overburden the public health system

Epidemiology

- Spread by direct close contact *via* large droplet inhalation
 - No known animal reservoirs
 - Spread can also occur by contact with lesions or infected fomites
- Household spread is reported to range from 30% to 80%.
- Outbreaks were most common during winter and early spring.
- All ages susceptible
- Patients are most contagious when they have rash.
 - May be infectious during symptomatic prodrome prior to development of skin lesions
- Incubation is from 7 to 17 days, during which period the patient is not infectious.

Clinical Manifestations

- Prodromal phase: patient experiences high fever with back pain and prostration
 - Rash follows within a 1 or 2 days
 - With more lesions on face, oral mucosa, and extremities than on the trunk
 - Termed *centrifugal pattern*

- Lesions begin as macules, progress to vesicles, and become pustules over first week
- Fever is usually persistent throughout period of rash development.
- Lesions are deep seated, firm, and painful.
- Important for diagnosis: **All lesions at same stage of development at each phase.**
 - These characteristics of rash serve to differentiate it from rash of chickenpox.
 - Superficial, appears in crops, is centripetal in distribution, and is associated with relatively mild prodrome
- Extent of smallpox rash correlates with mortality, which ranges from 10% to 75%.
 - In fatal cases, death usually occurs by second week.
 - Lesions begin to crust over after 7 to 9 days.
 - Patient is noninfectious only after all scabs have fallen off.
 - Scarring and pitting result in characteristic pock-marked appearance of survivors.
 - Pathologic damage in smallpox is generally confined to skin and mucous membranes.
 - Although virus present throughout internal organs
 - Systemic manifestations and fatalities are attributed to toxinemia and antigenemia.
- Vaccine-modified smallpox presents as milder illness with fewer lesions, mortality <10%.
- Hemorrhagic form of smallpox may occur:
 - There is diffuse erythema
 - Followed by petechial hemorrhages
 - Reported to have mortality approaching 100%
- In malignant or “flat” smallpox, discrete lesions do not develop, but confluent rubbery lesions present.
- Form of smallpox known as variola minor, with much milder symptoms and mortality <10%, now known due to genetically distinct strain of virus.

Diagnosis

- Specimens of vesicular or pustular fluid obtained for culture and electron microscopic examination
 - Transported in double-sealed, leakproof containers designed for transport of body fluids
 - Specimens handled only in BSL-4 laboratories
 - Public health authorities notified to assist with specimen handling if case of smallpox suspected
 - Diagnosis of orthopoxvirus infection is made by electron microscopic examination.
 - Speciation performed by molecular techniques such as PCR and DNA sequencing

Treatment and Prevention

- The following principles should be followed:
 - Patient is isolated.
 - Contact and airborne precautions are instituted when case of smallpox suspected.
 - All personnel with face-to-face contact with patient are vaccinated.
 - As are all personnel with patient contact while the latter was febrile

- Local health authorities are contacted immediately.
- CDC will provide assistance with prioritizing contacts for vaccination and monitoring.
- Contraindications to vaccinations do not apply to high-risk exposures.
- Treatment is primarily supportive.
 - Maintaining hemodynamic stability and treating secondary infections

MONKEYPOX

- Clinically similar to smallpox
 - Sporadically reported in Africa since 1960
 - Pronounced lymphadenopathy is an additional sign that may help differentiate it from smallpox.
 - Monkeypox thought endemic in rodents and transmitted to humans *via* direct animal contact
 - Occasional human-to-human transmission
 - Vaccination against smallpox is thought to ameliorate symptoms and lessen likelihood of infection.
 - Cidofovir has activity against monkeypox *in vitro*
 - Used in severe infection
 - No clinical data regarding its effectiveness

MALARIA

- The fourth largest killer of children younger than 5 years of age
 - Causes over 350 million clinical episodes and one million deaths per year
 - *Plasmodium falciparum* is strain of parasite is most likely to cause high-level parasitemia and severe life-threatening malaria.

Epidemiology

- Endemic throughout much of world
 - Greatest number of cases in Africa and Asia
 - Officially eradicated in the United States since 1970
 - About 1,200 cases are reported annually, mostly in travelers from endemic areas.
 - Other cases are due to:
 - Local transmission from infected mosquitoes (so-called airport malaria)
 - Congenital malaria
 - Malaria acquired from blood transfusion
 - Local transmission of malaria in the United States has occurred at least 11 times since 1970, with 20 probable cases.
 - In recent outbreak in Florida, seven cases were verified as being caused by the same strain of *P. vivax*.
 - In endemic areas, adults are partially immune to malaria and, although infected, may be asymptomatic.
 - Children are particularly prone to infection and to developing severe disease.
 - Other high-risk groups include pregnant women, asplenic individuals, and other immunocompromised hosts.

Clinical Manifestations

- Typically has an incubation period of 1 to 3 weeks
- May be extended by partial immunity or chemoprophylaxis
 - Suggested that any traveler returning from endemic area be considered at risk for as long as 3 months
- Clinical presentation usually nonspecific:
 - Fever and headache universally present.
 - Myalgia, sweats, and weakness are common.
 - Paroxysmal and cyclical fever classically associated with malaria not consistently present
 - In case of falciparum malaria, fever is often continuous.
 - Other infections are common in malaria-endemic areas, but malaria is considered one of most likely diagnoses in a patient with a consistent clinical picture and travel history.
 - If is suspected, ID consultation indicated to help with management and assess likelihood of alternate diagnoses.
- Pathogenesis of malaria complex and related to both:
 - Direct effects of parasite on erythrocytes and vasculature
 - Indirect effects on cytokine production, tissue oxygen consumption, and other systemic effect
 - Several aspects of biology of *Plasmodium falciparum* relevant to development of severe malaria
 - *P. falciparum* sequesters itself in venous microcirculation of virtually all tissues, including brain
 - Hypoglycemia common during *P. falciparum* infection
 - Thought to be due to oxygen consumption by replicating parasites
 - As well as result of increased tissue metabolism
 - Severe anemia may occur due to lysis of infected erythrocytes and clearance of uninfected erythrocytes and decreased erythrocyte production.
 - Anemia in severe malaria is often normochromic and normocytic.
 - A combination of factors aggravate tissue hypoxia and lead to metabolic acidosis.
 - Capillary leak syndrome due to parasite sequestration and cytokine production leads to pulmonary edema.
 - Renal failure is multifactorial and more common in adults than children.
 - Hemoglobinuria may be severe enough to cause dark urine.
 - Termed, when present, *blackwater fever*

Diagnosis

- Gold standard for diagnosis remains microscopic identification of parasites on blood smear.
 - Examination of thick and thin blood smears performed immediately by trained personnel.
 - If initial examination is negative, repeat every 12 to 24 hours for total of 48 to 72 hours.
 - When parasites are detected, the percentage of parasitemia can be calculated by:
 - Counting number of infected and noninfected RBCs
 - Number of white blood cells in microscopic field used as internal standard to aid in estimated parasite density and percentage when thick smears are examined
- Malaria is a nationally notifiable disease.

- State health authorities are notified when diagnosis of malaria made.
- The CDC maintains a 24-hour malaria hotline to assist clinicians with the management of suspected and confirmed malaria cases
 - The numbers to call are: 770-488-7788 Monday to Friday, 8:00 a.m. to 4:30 p.m.
 - Off-hours, weekends, federal holidays: 770-488-7100 and ask to have the malaria clinician on call to be paged

Treatment

- Patients, particularly nonimmune, may deteriorate rapidly.
- Hospitalization of patients during initial phase of treatment is prudent.
 - May have severe illness before manifesting high degrees of parasitemia
 - Patients who manifest any of symptoms or signs of severe malaria and have any degree of parasitemia on blood smear should be treated as case of severe malaria.
 - The World Health Organization promulgated criteria for diagnosis of severe malaria (Table 82.4).
 - Cases meeting these criteria are treated with IV therapy.
 - IV quinidine gluconate is currently only available parenteral drug recommended for severe malaria in the United States.
 - Administered as a loading dose of 6.25 mg base/kg (= 10 mg salt/kg), over 1 to 2 hours
 - Followed by continuous infusion administered at 0.0125 mg/kg/minute base (= 0.02 mg salt/kg/minute)
 - Quinidine levels maintained in range of 3 to 8 mg/L
 - After 24 hours of IV therapy, if patient is able to take oral drugs
 - Treatment can be switched to oral quinine/
 - 10 mg salt/kg every 8 hours for a total of 7 days of therapy
 - All patients with severe malaria are also treated with IV doxycycline (100 mg every 12 hours) or clindamycin (5 mg base/kg every 8 hours).
 - In addition to quinidine until oral therapy tolerated

TABLE 82.4

WORLD HEALTH ORGANIZATION CRITERIA FOR SEVERE MALARIA

Criteria for severe malaria requiring parenteral therapy:

- Impaired consciousness/coma
- Severe normocytic anemia
- Renal failure
- Pulmonary edema
- Acute respiratory distress syndrome
- Circulatory shock
- Disseminated intravascular coagulation
- Spontaneous bleeding
- Acidosis
- Hemoglobinuria
- Jaundice
- Repeated generalized convulsions
- Parasitemia of more than 5%

- If hospital pharmacy unable to obtain IV quinidine quickly
 - Contact Eli Lilly at 1-800-821-0538
 - Assistance from company to arrange rapid shipment of drug available between hours of 6 a.m. and 6 p.m.
- The CDC may also be contacted for advice at malaria hotline.
- Two aspects of quinidine therapy in this setting are very important to remember.
 - First is the possibility of ventricular arrhythmias.
 - Prolongation of the Q-T_C interval is commonly seen during quinidine therapy
 - Careful monitoring of ECG and electrolytes is mandatory
 - Avoid combining with other drugs that prolong Q-T_C interval.
 - Second is propensity of quinidine and quinine to cause hypoglycemia
 - Given likelihood of hypoglycemia in severe malaria due to the disease itself, serum glucose must be carefully monitored and supplemented as necessary
 - Quinidine is administered in the ICU, with the assistance of a cardiologist if needed.
- Recommended by the CDC that exchange transfusion be considered where parasitemia exceeds 10% or when severe complications present.
 - Benefits have not been proven in randomized trial; exchange transfusion has potential benefit of both reducing parasite burden and circulating cytokines and toxins.
 - Exchange transfusion is recommended until parasitemia is below 1%.

ROCKY MOUNTAIN SPOTTED FEVER (RMSF)

- A disease that presents with nonspecific signs and symptoms
 - For which there is no specific rapid diagnostic test
 - When not treated appropriately has high mortality
 - Important for practicing clinician to have a high index of suspicion for RMSF and to be familiar with its epidemiology, clinical manifestations, and treatment

Epidemiology

- RMSF is caused by *Rickettsia rickettsii*.
 - In the United States, intracellular bacterium is primarily transmitted by:
 - Dog tick, *Dermacentor variabilis*, in eastern states
 - Wood tick *Dermacentor andersoni*, in Rocky Mountain States
 - Ticks are also primary reservoir for *R. rickettsii*.
 - Most cases of RMSF occur in the southeastern United States.
 - More than half of all reported cases are from North Carolina, South Carolina, Tennessee, Oklahoma, and Arkansas.
 - Cases have been reported in all 48 continental states except Vermont and Maine.
 - Most cases occur between April and September.
 - Children are at highest risk of RMSF.
 - Peak incidence is between 5 and 9 years of age.

- Males are reported to be at higher risk.
 - More cases among girls than boys
- Most bites are unnoticed.
 - Tick must be attached for 6 to 10 hours for feeding and infection to take place.

Clinical Manifestations and Pathogenesis

- Rickettsial organisms primarily target and infect endothelial cells.
 - Primary pathology consists of diffuse cell injury and increased vascular permeability caused by cell-to-cell spread of organisms after initial hematogenous and lymphatic seeding.
 - Infection occurs in virtually all internal organs.
 - Vascular injury occurs in lung, heart, brain, gastrointestinal tract, skin, and elsewhere.
- Symptoms typically begin 2 to 14 days after tick bite.
 - Virtually all experience classical triad of fever, headache, and rash.
 - Rash is present in only about 50% of cases within first 3 days.
 - Rash usually appears by second to fifth day but is absent in about 10%.
 - Rash is often faint in initial stages and more difficult to detect in patients with dark skin.
 - Begins as blanching, pink maculopapular exanthema
 - Most commonly beginning at wrists and ankles
 - Develops into palpable lesions that spread centrally
 - Often becomes petechial and may involve the palms and soles
 - Associated symptoms occurring in more than 50% of patients are:
 - Myalgias
 - Nausea/vomiting
 - Abdominal pain
 - Serum AST often elevated
 - Thrombocytopenia and hyponatremia in up to 50% of cases
- Central nervous system abnormalities occur in about 25% and carry poor prognosis.
 - CSF abnormalities are observed in one-third of patients and consist of:
 - Pleocytosis
 - Elevated protein levels
 - CSF glucose usually normal
- Fulminant form of disease, with death occurring in the first 5 days, described
 - Glucose-6-phosphate dehydrogenase deficiency linked to this form of disease
 - Neurologic deficits and limb loss most serious sequelae observed in survivors

Diagnosis

- Delay in diagnosis and seeking medical attention is associated with poor outcome.
- Factors likely to lead to delay in diagnosis include:
 - Absence of rash or delayed appearance of rash

- No history of tick bite
- Presentation early in course of disease
- *R. rickettsii* isolated in culture or demonstrated by immunohistochemistry in tissue specimens
- Methods not routinely available
- Empiric therapy should not await result of laboratory testing
- Serology likewise useful for confirmation of diagnosis
- Diagnosis made on basis of epidemiologic and clinical findings described above

Treatment

- Recommended therapy for RMSF is doxycycline
- Administered at a dose of 100 mg twice daily
 - Continued for 7 days and a minimum of 3 days after patient has defervesced
- Treatment of suspected RMSF instituted promptly with doxycycline either IV or orally
- Doxycycline for RMSF is not contraindicated in children.

SECTION XII ■ CARDIOVASCULAR DISEASE AND DYSFUNCTION (OTHER CV DISEASE): ACS IN THE ICU

CHAPTER 83 ■ NON-ST ELEVATION ACUTE CORONARY SYNDROME: CONTEMPORARY MANAGEMENT STRATEGIES

OVERVIEW

Definition of Terms

- Acute coronary syndrome (ACS) ranges from ST-segment elevation myocardial infarction (STEMI) to non-ST-segment elevation MI (N-STEMI) and unstable angina (UA). Acute myocardial ischemia may revert to the presymptomatic state or evolve into a non-Q-wave (nontransmural) or Q-wave (transmural) MI (Fig. 83.1).
- The boundaries between UA, N-STEMI, and STEMI are not always well defined. These are different and dynamic clinical manifestations of a continuous pathogenetic spectrum.
- N-STE-ACS is represented by UA and N-STEMI.

Unstable Angina

- Anginal pain is the pivotal symptom; its intensity, duration, and exercise-related threshold are graded according to the Canadian Cardiovascular Society (CCS) classification (Table 83.1). UA may have three clinical presentations (Table 83.2).

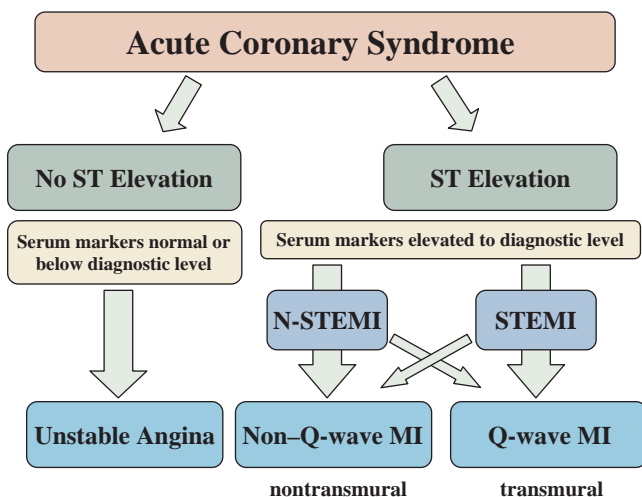

FIGURE 83.1. The interrelationship of the components of ACS on presentation, during evolution and at final outcome [Adapted from Braunwald E, Antman EM, Beasley JW, et al. ACC/AHA 2002 guideline update for the management of patients with unstable angina and non-ST-segment elevation myocardial infarction—summary article: a report of the American College of Cardiology/American Heart Association task force on practice guidelines (Committee on the Management of Patients With Unstable Angina). *J Am Coll Cardiol.* 2002; 40(7):1366–1374].

- A low threshold for angina (CCS III and IV) is an essential feature of UA. The presence of angina at rest is associated with a worse prognosis and a higher rate of events.
- Extracardiac conditions that intensify or precipitate myocardial ischemia (secondary UA) such as anemia, fever, infection, hypotension, uncontrolled hypertension, hypoxemia, and thyrotoxicosis must be excluded.
- The resting ECG may show transient ST-segment depression and/or T-wave inversion, ST-segment elevation or, rarely, may remain normal. The serum markers (troponin I, troponin T, and CK-MB) may remain between normal biological ranges and levels diagnostic of MI (twice the upper normal limit).
- Prinzmetal variant angina is an atypical ischemic coronary syndrome characterized by sudden onset angina occurring almost exclusively at rest, particularly in the first hours of the day, associated with ST-segment elevation on the ECG. Caused by a focal spasm of a coronary artery, it may be associated with subendocardial and/or transmural myocardial ischemia, acute MI, or severe cardiac arrhythmias—including ventricular tachycardia and fibrillation, and sudden death.

Non-ST-Segment Elevation Myocardial Infarction

- N-STEMI may have symptoms and a clinical pattern indistinguishable from UA. Resting ECG more frequently shows ST-segment depression or T-wave inversion (Fig. 83.2) that may be persistent. ST-segment elevation is sometimes observed but, by definition, never sustained. The serum biomarkers

TABLE 83.1

PRINCIPAL PRESENTATIONS OF UNSTABLE ANGINA

New-Onset Angina	New-onset angina of at least CCS Class III severity.
Increasing Angina	Previously diagnosed angina that has become distinctly more frequent, longer in duration, or lower in threshold (i.e., increased by ≥ 1 CCS class to at least CCS Class III severity).
Postinfarction Angina	Patients with recent myocardial infarction (within 2 wk) in whom biomarkers of myocardial necrosis have returned within normal range.

From Myler RK, Shaw RE, Stertzer SH, et al. Unstable angina and coronary angioplasty. *Circulation.* 1990;82(3 Suppl):II88–II95.

TABLE 83.2**GRADING OF ANGINA PECTORIS ACCORDING TO THE CANADIAN CARDIOVASCULAR SOCIETY CLASSIFICATION**

I	Ordinary physical activity does not cause angina, such as walking 2 blocks or climbing stairs. Angina occurs with strenuous, rapid, or prolonged exertion at work or recreation.
II	“Slight limitation of ordinary activity.” Angina occurs on walking or climbing stairs rapidly; walking uphill; walking or stair climbing after meals; in cold, in wind, or under emotional stress; or only during the few hours after awakening. Angina occurs on walking more than 2 blocks on level ground and climbing more than 1 flight of ordinary stairs at a normal pace and under normal conditions.
III	“Marked limitations of ordinary physical activity.” Angina occurs on walking 1–2 blocks on the level and climbing 1 flight of stairs under normal conditions and at a normal pace.
IV	“Inability to carry on any physical activity without discomfort—anginal symptoms may be present at rest.”

Modified from Braunwald E, Antman EM, Beasley JW, et al.; American College of Cardiology; American Heart Association. Committee on the Management of Patients with Unstable Angina. ACC/AHA 2002 guideline update for the management of patients with unstable angina and non–ST-segment elevation myocardial infarction—summary article: a report of the American College of Cardiology/American Heart Association task force on practice guidelines (Committee on the Management of Patients with Unstable Angina). *J Am Coll Cardiol.* 2002;40(7):1366–1374.

always rise to levels diagnostic for MI, which is the essential difference between UA and N-STEMI.

- **Epidemiology of N-STEMI.** Among those who reach the hospital alive: 13% will die, 8% are left with UA, 1.5% to 3% have new strokes, and 17% to 20% are rehospitalized for a further episode of ACS over the next 6 months. The risk is greatest during the first 15 to 30 days from symptom presentation.

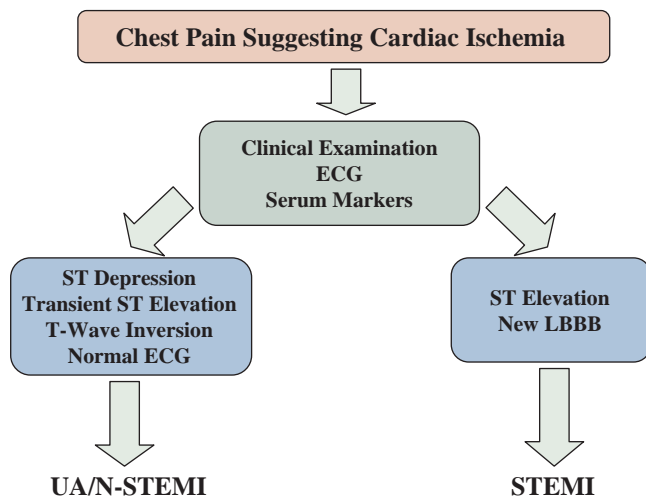

FIGURE 83.2. The differentiation of unstable angina/non–ST-segment elevation myocardial infarction from ST-segment elevation myocardial infarction.

- Pathogenesis of N-STEMI-ACS:

- N-STEMI-ACSs are usually caused by a sudden reduction of myocardial perfusion resulting from a nonocclusive thrombus, a consequence of disruption or erosion of an atherosclerotic plaque. Distal microembolization of thrombus and disrupted plaque components may further reduce perfusion of the distal microvasculature.
- The vulnerable plaque, more prone to rupture, has a necrotic lipid core infiltrated by inflammatory cells, with intraplaque hemorrhage and abundant vasa vasorum on the adventitial site, surrounded by a thin fibrous cap. Expression of proteases and proteolytic inhibitors that weaken the fibrous cap may play a critical role in plaque rupture.
- The severity of obstruction and volume of affected myocardium determine the pattern of clinical presentation. Complete occlusion may manifest with a STEMI if a substantial volume of myocardium is involved, although the same occlusion in the presence of extensive collateralization may manifest as an N-STEMI or UA.
- After clinical stabilization of low-risk ACS patients, exercise stress testing may be appropriate. Early-onset symptoms during exercise, a short exercise time, a fall in blood pressure during exertion, ST-segment elevation, new postexercise ST-segment depression and/or prolonged ST-segment depression are the characteristics of a strongly positive test. Angiography defines the nature and extent of the coronary disease and enables the planning of appropriate revascularization.

EARLY EVALUATION AND RISK STRATIFICATION

Immediate Concerns

- ACS constitutes a clinical emergency, early recognition and initiation of treatment is mandatory. Every patient with chest pain should be comprehensively evaluated, including a history and clinical examination of the cardiovascular system, the immediate recording of a resting ECG, and urgent evaluation of the serum markers of myocardial injury.
- Particular attention must be paid to the factors that influence the patient's risk stratification. These factors are found among the clinical features, the magnitude of ECG change, and the elevation of serum markers of myocardial necrosis. Among those without ST elevation on the ECG, an ACS is diagnosed by the presence of a clinical syndrome of acute ischemia with either pain at rest or a crescendo pattern of ischemic pain with minimal exertion, plus electrocardiographic and/or marker evidence of acute ischemic injury. The predictive accuracy of ST elevation for a final diagnosis of MI is very high, but for N-STEMI, <50% are suspected as infarction on initial presentation.

Symptoms and Physical Examination

- Usually well recognized, the pain varies from mild compressive discomfort to sharp, severe pain located in the anterior chest, particularly substernally, or predominantly involve the mandible, neck, shoulders, either or both arms, the back, or epigastrium.

- Generally of short duration, pain may last >30 minutes without resulting in MI. Spontaneous in onset and unrelated to the usual stressors, it may occur with no—or less than the usual amount of—provocation and may be more severe or more prolonged. Repeated attacks of chest pain, ongoing chest pain before admission, or pain that recurs on treatment is associated with a worse outcome.
- Less frequently, ACS may present with atypical pain or features of an acute transient reduction in cardiac output—tachycardia, hypotension, and poor peripheral circulation, pulmonary venous congestion, breathlessness or pulmonary edema, or rarely a potentially lethal ventricular tachyarrhythmia.
- Shortness of breath, perspiration, palpitations, nausea or vomiting may be present but do not predict the severity of coronary involvement.
- Male gender, age >50 years, early menopause in women, as well as a history of smoking, dyslipidemia, hypertension, diabetes mellitus, and/or a family history of coronary disease all increase the likelihood of ACS.
- There may be no abnormal findings on physical examination; however, a fourth heart sound, mitral regurgitant murmur, or signs of pulmonary congestion are suggestive of transient ischemic myocardial dysfunction.
- Heart failure (HF) is a frequent complication that significantly worsens prognosis; with three to four times the 6 month mortality, longer hospital stays and higher readmission rates. The development of HF during hospitalization—as opposed to HF at admission—is associated with worse outcome and increased frequency of percutaneous coronary intervention (PCI). Those who undergo revascularization have lower cumulative 6-month mortality rates than those who do not.

Electrocardiogram

- The presence of ECG changes, especially when occurring at rest and associated with angina, are a powerful indicator of higher risk. When the other elements of baseline risk are under control, ST deviation conveys the same risk for death whether this deviation is upwards or downwards (Fig. 83.3). New-onset T-wave changes—especially T-wave inversion, although less specific—are also important markers of subendocardial ischemia.

FIGURE 83.3. Probability of 30-day mortality among patients with ACS and different ECG patterns at admission [From Savonitto S, Ardissino D, Granger CB, et al. Prognostic value of the admission electrocardiogram in acute coronary syndromes. *JAMA*. 1999;281:707–713].

- The normalization of ECG alterations and anginal relief are very important within minutes after sublingual nitrate administration; persistence of pain and ECG alterations for >20 minutes despite repeated nitrates is a marker of increased risk for MI.

Biochemical Markers

- Not all N-STE-ACS patients have elevated serum markers; especially when obtained very shortly after onset, these markers may be within normal limits. All patients with normal serum marker results on presentation must have a second assessment 4 to 6 hours later, or 8 to 12 hours after the onset of symptoms, whichever is longer. Elevated levels of creatine kinase (CK), creatine kinase MB iso-enzyme (CK-MB), troponin T or I, and myoglobin are indicators of myocardial injury (Table 83.3).
- Myoglobin, a very sensitive indicator of infarction, is the earliest to appear in the serum. Its clinical usefulness is limited by the high incidence of false-positive results. CK in conjunction with CK-MB, CK-MB alone, and the troponins are all sensitive and specific markers of myocardial injury/infarction that appear from about 4 hours after the onset of the ischemic event. Whereas CK and CK-MB are cleared within 2 to 3 days, elevated troponin may persist up to 14 days, making them poor markers of early reinfarction.
- A “multimarker strategy” that evaluated CK-MB, troponin I or T, and myoglobin is much superior to any “single-marker” strategy or evaluation without myoglobin in reaching an earlier diagnosis and identifying those at higher risk of death or MI by 30 days. Elevated levels of troponin T or I or CK-MB on admission indicate a poorer outcome (Fig. 83.4). The later appearance of an elevated troponin level, suggesting ongoing ischemia, is also associated with higher risk. In all instances, the risk predictors should complete, not replace, clinical judgment.
- Elevated troponin is a powerful and independent predictor of thrombotic complications, including MI and death. They can be used as part of the measures to identify higher risk and the potential for gain from PCI. Newer-generation assays have higher sensitivity and diagnostic accuracy; even very minor increases predict a higher risk of cardiac complications and death.
- Certain biomarkers reflect an upregulation of the inflammatory/thrombotic systems—for example, high-sensitivity C reactive protein (hsCRP), interleukin 6 (IL-6), CD40 ligand, and platelet-monocyte complexes. The acute phase reactant biomarkers are also elevated as a consequence of myocyte injury. hsCRP is a powerful predictor of death in the following 1 to 2 years. Elevation of both hsCRP and troponin signifies a substantially higher risk of death than either marker alone; the patient is at very low risk of future cardiac events in the absence of both markers. A single B-type natriuretic peptide measured after presentation with an ACS has associations with short-term and long-term risk of death and HF; changes over time also predict long-term outcomes.

Imaging Modalities

- Echocardiographic ultrasounds may be extremely useful in evaluation of left ventricular function, especially with

TABLE 83.3**ADVANTAGES AND DISADVANTAGES OF BIOCHEMICAL CARDIAC MARKERS FOR THE EVALUATION AND MANAGEMENT OF PATIENTS WITH SUSPECTED ACS**

Marker	Advantages	Disadvantages
CK-MB	<ol style="list-style-type: none"> 1. Rapid, cost-efficient, accurate assays 2. Ability to detect early reinfarction 	<ol style="list-style-type: none"> 1. Loss of specificity in setting of skeletal muscle disease or injury, including surgery 2. Low sensitivity during very early MI (<6 h after symptom onset) or later after symptom onset (>36 h) and for minor myocardial damage (detectable with troponins)
CK-MB Isoforms	<ol style="list-style-type: none"> 1. Early detection of MI 	<ol style="list-style-type: none"> 1. Specificity profile similar to that of CK-MB 2. Current assays require special expertise
Myoglobin	<ol style="list-style-type: none"> 1. High sensitivity 2. Useful in early detection of MI 3. Detection of reperfusion 4. Most useful in ruling out MI 	<ol style="list-style-type: none"> 1. Very low specificity in setting of skeletal muscle injury or disease 2. Rapid return to normal range limits sensitivity for later presentations
Cardiac Troponins	<ol style="list-style-type: none"> 1. Powerful tool for risk stratification 2. Greater sensitivity and specificity than CK-MB 3. Detection of recent MI up to 2 wk after onset 4. Useful for selection of therapy 5. Detection of reperfusion 	<ol style="list-style-type: none"> 1. Low sensitivity in very early phase of MI (<6 h after symptom onset) and requires repeat measurement at 8 to 12 h, if negative 2. Limited ability to detect late minor reinfarction

Modified from Braunwald E, Antman EM, Beasley JW, et al.; American College of Cardiology; American Heart Association. Committee on the Management of Patients with Unstable Angina. ACC/AHA 2002 guideline update for the management of patients with unstable angina and non-ST-segment elevation myocardial infarction—summary article: a report of the American College of Cardiology/American Heart Association task force on practice guidelines (Committee on the Management of Patients with Unstable Angina). *J Am Coll Cardiol*. 2002;40(7):1366–1374.

increasing emphasis on early reperfusion and prevention of left ventricular remodeling. It also excludes nonischemic causes of chest pain, ECG alterations, and elevated biomarker levels. It is noninvasive, cheap, and portable; myocardial contrast echocardiography to assess perfusion also holds promise.

- Single-photon emission computed tomography or magnetic resonance imaging can detect wall motion abnormalities in patients with recent or established infarction, but their role remains to be determined.
- Stress echocardiography and/or myocardial perfusion imaging should be reserved for the patient with a particular clinical

problem, when such specialized facilities are available locally. Coronary angiography is advised if the functional test demonstrates ischemia.

ESTIMATION OF THE LEVEL OF RISK AND RISK SCORES

- The patient with N-STE-ACS is at risk of major cardiovascular complications and death, the extent of this risk is dependent on acute and pre-existing risk factors (Table 83.4). These risk factors also predict future cerebrovascular and peripheral vascular complications. Early risk stratification plays a central

FIGURE 83.4. Relationship between cardiac troponin levels and risk of mortality in patients with ACS. [From Antman EM, Tanasijevic MJ, Thompson B, et al. Cardiac specific troponin I levels to predict the risk of mortality in patients with acute coronary syndromes. *N Engl J Med*. 1996;335:1342–1349].

TABLE 83.4**RISK INDICATORS OF A POOR OUTCOME IN ACS**

Event-Related	<ul style="list-style-type: none"> • Ongoing or recurring chest pain • ST-segment depression/new ischemia on ECG • Elevated serum biomarkers of cardiac injury/infarction • Hemodynamic instability
Preexisting	<ul style="list-style-type: none"> • Age over 65 y • Three or more risk factors for CAD, especially diabetes mellitus • Aspirin use within 7 d • Known CAD • Prior left ventricular dysfunction

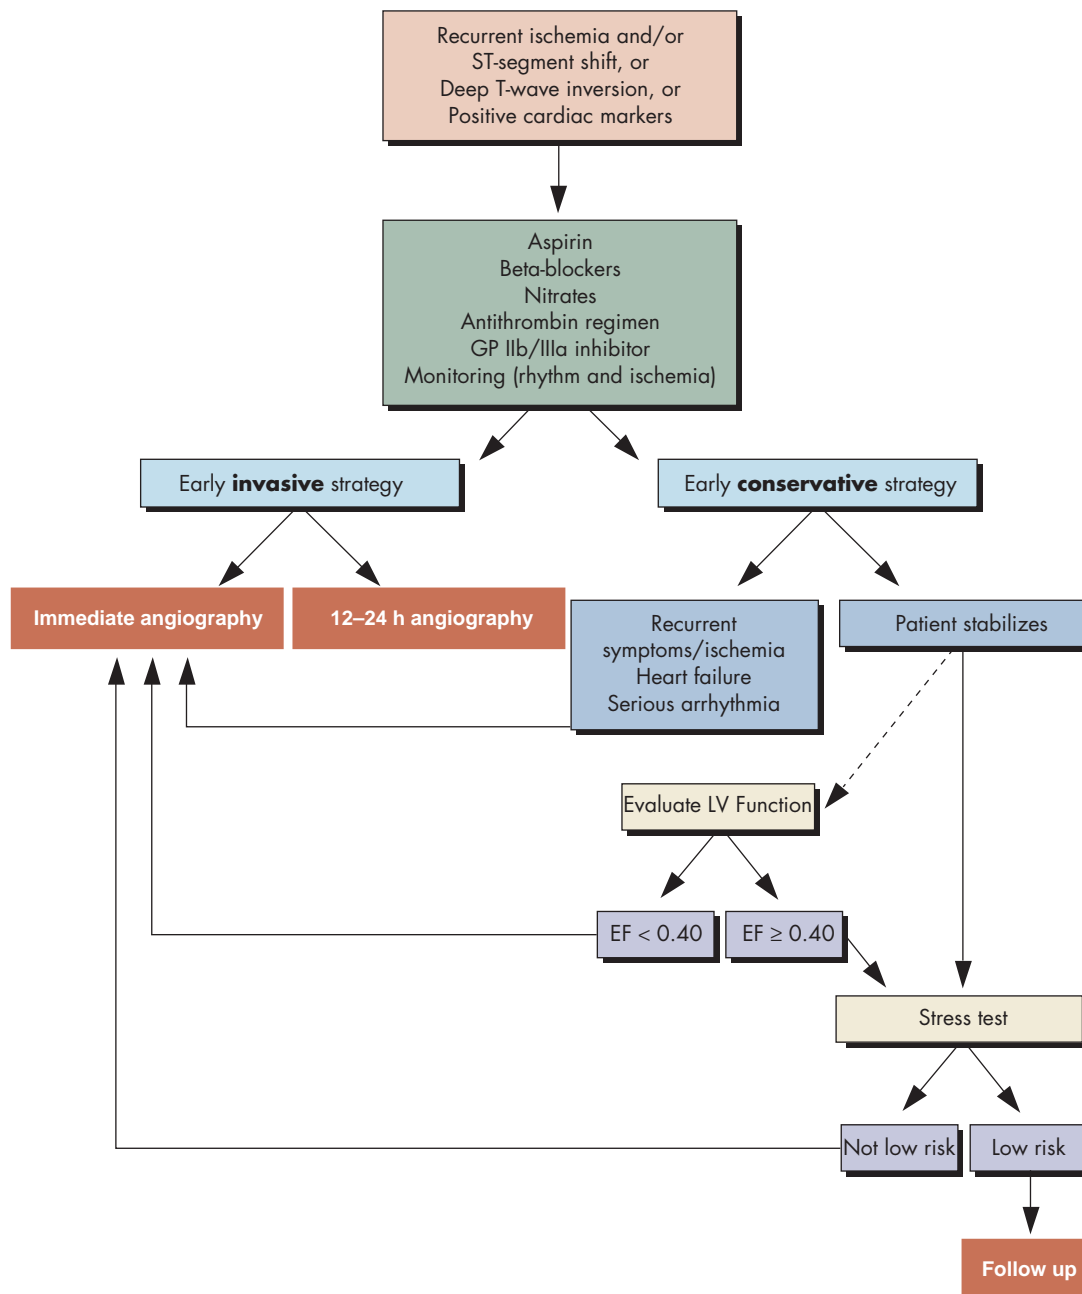

FIGURE 83.5. Acute ischemia pathway [From Braunwald E, Antman EM, Beasley JW, et al. ACC/AHA 2002 guideline update for the management of patients with unstable angina and non-ST-segment elevation myocardial infarction—summary article: a report of the American College of Cardiology/American Heart Association task force on practice guidelines (Committee on the Management of Patients With Unstable Angina). *J Am Coll Cardiol.* 2002;40(7):1366–1374].

role, as the benefit of newer, more aggressive, and costly treatment strategies seem to be proportional to the risk of adverse clinical events (Figs. 83.5 to 83.7).

- Different scores are now available based on initial clinical history, ECG, and laboratory tests that enable early risk stratification on admission (Table 83.5). All these scores were developed for short-term prognosis; however, a significant proportion of adverse events in N-STE-ACS patients occur after the first 30 days, and it is not known whether these risk scores can also predict their occurrence.

HOSPITAL CARE AND MANAGEMENT STRATEGIES: EARLY PHARMACOLOGIC TREATMENT

Control of Pain

- Although analgesics have no influence on the pathophysiological process, narcotic analgesia with IV morphine sulphate and/or sedation with oral benzodiazepines assist in alleviating

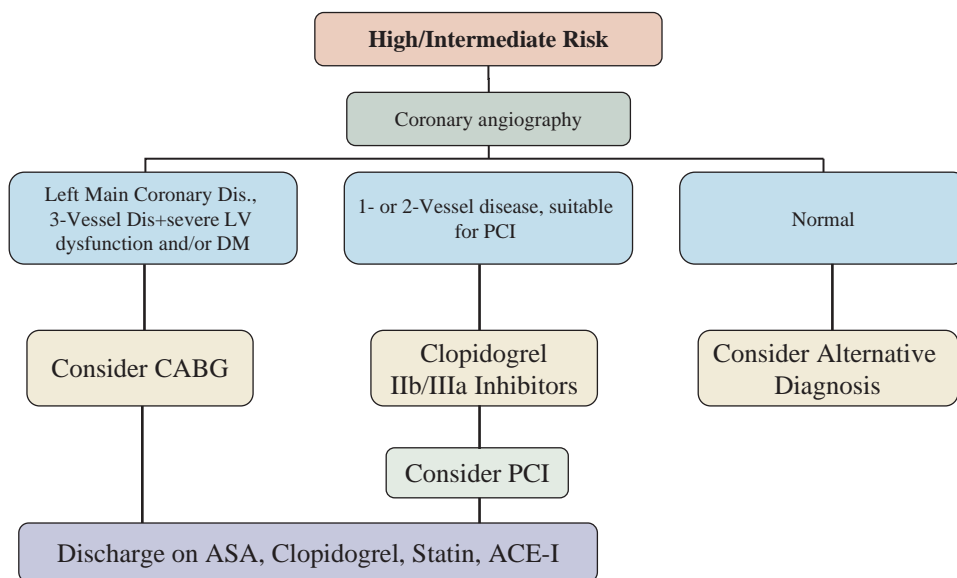

FIGURE 83.6. Algorithm for the management of NSTE-ACS patients at high-intermediate risk undergoing coronary angiography.

pain and anxiety. Morphine may induce nausea and vomiting, it is advisable to premedicate with IV metoclopramide.

- It is important to be aware of other analgesic treatments such as tramadol, a synthetic analogue of codeine, which may have been administered by paramedical staff during transport to the hospital. Intramuscular injection may perturb certain serum markers of cardiac injury/infarction, have variable absorption, and are, in general, more painful and less humane than IV injections.

Anti-ischemic Drugs

- Nitrates act by reducing preload and afterload, promoting coronary vasodilation, relieving coronary vasospasm or vasoconstriction, and by putative effects upon platelet aggregability. These effects combine to improve myocardial blood flow, relieve ischemia and cardiac ischemic pain but do not improve the outcome in ACS. They may be administered sublingually, orally, or intravenously in standard doses (Table 83.6).
- Beta-blockers reduce myocardial oxygen demand and diminish ischemia. Although large trials demonstrate the benefit of β -blockade following acute MI, there is limited evaluation in N-STE-ACS. The dose should be titrated to a resting heart

rate of 50 to 60 beats/minute, while maintaining an adequate blood pressure and peripheral perfusion.

- Calcium channel blockers are a diverse group of compounds that cause smooth muscle relaxation by blocking cellular calcium entry, this results in coronary vasodilation and afterload reduction. They should be reserved for the control of intractable chest pain or hypertension that cannot be alleviated by other means. Furthermore, the use of any calcium channel blocker is contraindicated when there is left ventricular dysfunction.
- The dihydropyridine group of calcium channel blockers may increase the resting heart rate and should be used only in combination with β -blockade. Short-acting dihydropyridine calcium channel blockers are detrimental in UA and should not be used at all.
- The nondihydropyridine group—diltiazem and verapamil—reduce the resting heart rate, and thus tend to diminish myocardial oxygen demand. Diltiazem reduces reinfarction and postinfarction angina in non-Q-wave MI, but does not improve mortality. Although β -blockers are preferred in all other patients, diltiazem may be used alone as an alternative therapy if β -blockade is not possible. Although verapamil

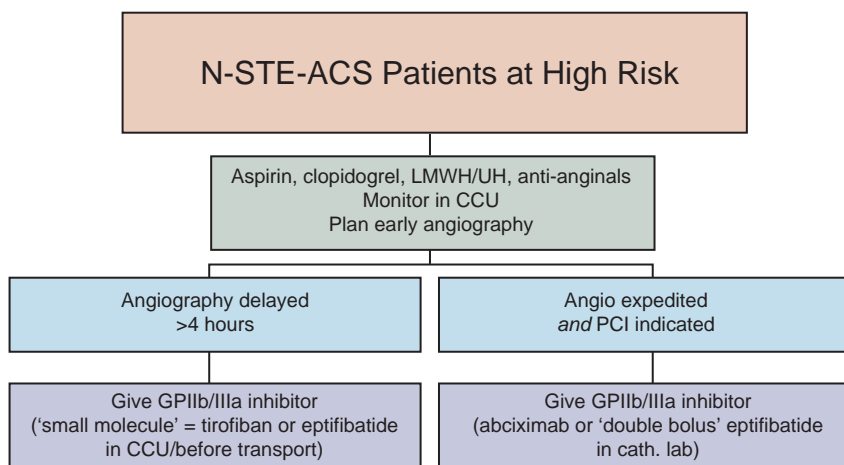

FIGURE 83.7. Algorithm for the treatment of high-risk patients with unstable angina/non-ST-segment elevation myocardial infarction.

TABLE 83.5**RISK SCORES FOR N-STE-ACS**

TIMI (0–7)	Age ≥ 65 y	1
	3 or more risk factors for CAD	1
	Use of ASA (last 7 d)	1
	Known CAD (stenosis $\geq 50\%$)	1
	More than 1 episode rest angina in <24 h	1

has similar effects to diltiazem, its effects in ACS have not been evaluated.

Antiplatelet Therapy (see Table 83.7)

- Aspirin irreversibly inhibits cyclooxygenase-1, thus reducing the generation of thromboxane A₂, a potent mediator of platelet aggregation. The most recent update of the Anti-thrombotic Trialists' Collaboration, based on 287 studies in 13,500 patients, demonstrates a highly significant reduction in the risk of MI/stroke/vascular death as a result of antiplatelet treatment versus control. Overall, the event rates were 13.2% in control patients and 10.7% with antiplatelet therapy, a 22% relative risk reduction. In acute MI, and in other high-risk patients, the absolute and relative risk reductions were greater: 23 per 1,000 fewer vascular deaths and 13 per 1,000 fewer MIs. The bleeding risk doubles for aspirin doses above 160 mg daily, with no improved efficacy. Without specific contraindications—intolerance or allergy; active bleeding; hemophilia; severe hypertension; retinal, genitourinary, or gastrointestinal bleeding; active peptic ulcer—aspirin should be given to all patients with N-STE-ACS as soon as possible and continued indefinitely. Additional antiplatelet treatment requires evidence of benefit on top of aspirin, rather than as an alternative to aspirin.
- Thienopyridines (ticlopidine and clopidogrel) inhibit adenosine diphosphate-mediated platelet aggregation, clopidogrel has superseded ticlopidine due to superior safety and more rapid onset of action. The blockade of adenosine diphosphate receptors is irreversible but relatively slow to manifest, several days for ticlopidine, and a substantial number of individuals appear to be resistant to the antiplatelet action of thienopyridines. For this reason, a high loading dose of 300 to 600 mg of clopidogrel or 500 mg of ticlopidine can be used to obtain a rapid onset of action. In N-STE-ACS, the AHA/ACC guidelines recommend approximately 9 months of treatment with clopidogrel.
- Thienopyridines reduce the risk of stent thrombotic occlusion and are now part of standard treatment for at least 4 weeks in all patients undergoing elective PCI. With drug eluting stents, at least 6 months and perhaps 12 months of clopidogrel and aspirin are required.
- As the antiaggregation effects of aspirin and thienopyridines are mediated by different mechanisms, an additive benefit may exist. The CURE trial tested clopidogrel in 12,562 N-STE-ACS patients on top of background treatment and aspirin. A 2.1% absolute risk reduction (20% relative risk reduction) occurred in the frequency of nonfatal MI, stroke, or cardiovascular death. Although the absolute benefits were greatest in the first 3 months of treatment, the relative risk reduction was the same beyond 3 months. Approximately 1% more patients experienced major bleeding.
- The association of aspirin and clopidogrel increases the risk of bleeding during major surgery and coronary surgery (CABG), thus clopidogrel should be interrupted 5 to 7 days before elective surgery. If early diagnostic catheterization is scheduled within 24 to 36 hours, clopidogrel can be initiated after coronary angiography when it is clear that CABG will not be undertaken; in the case of immediate percutaneous revascularization, the therapy can be initiated with a loading dose immediately. In candidates for very urgent CABG, a small molecule Gp IIb/IIIa inhibitor—eptifibatide or tirofiban—can be used before surgery.

TABLE 83.6**DOSAGES OF NITROGLYCERIN AND NITRATES IN ANGINA**

Agent	Route	Dosage
Nitroglycerin	<ul style="list-style-type: none"> • Sublingual tablets • Spray • Transdermal • Intravenous 	<ul style="list-style-type: none"> • 0.3–0.6 mg up to 1.5 mg • 0.4 mg as needed • 0.2–0.8 mg/h every 12 h • 5–200 mcg/min
Isosorbide dinitrate	<ul style="list-style-type: none"> • Oral • Oral, slow release 	<ul style="list-style-type: none"> • 5–80 mg, 2 or 3 times daily • 40 mg 1 or 2 times daily

TABLE 83.7**COMMONLY USED ANTIPLATELET AND ANTICOAGULANT AGENTS IN UNSTABLE ANGINA AND N-STEMI—DRUG DOSES AND SPECIAL PRECAUTIONS**

Agent	Dose	Precautions
Oral antiplatelet agent		
Aspirin	Initially 300 mg p.o.; then 75–150 mg daily	<ul style="list-style-type: none"> • GI bleeding
Clopidogrel (Plavix/Iscover)	Initial loading dose of 300 mg (or 600 mg); then 75 mg daily	<ul style="list-style-type: none"> • Peptic ulceration • Aspirin allergy • Increased bleeding risk • Antiplatelet therapy contraindicated
Heparins		
Unfractionated heparin	60 U/kg IV bolus to a maximum of 4,000 units; then 12 units/kg/h infusion to a maximum of 1,000 units/h	<ul style="list-style-type: none"> • Monitor PTT: keep at 50–70 s
Low-molecular-weight heparin	120 IU/kg subcutaneously every 12 h	<ul style="list-style-type: none"> • Any abnormal bleeding
Dalteparin (Fragmin)	1 mg/kg subcutaneously every 12 h	<ul style="list-style-type: none"> • Any major surgery <30 d
Enoxaparin (Clexane)		<ul style="list-style-type: none"> • Thrombocytopenia • Risk of bleeding • As above
Glycoprotein IIb/IIIa inhibitors		
Eptifibatide (Integrilin)	180 μ g/kg IV over 1–2 min; then 2 μ g/kg/min infusion over 72 h or until hospital discharge, whichever occurs first When initiating immediately before PCI, as above but repeat 180 μ g/kg IV bolus 10 min after the first bolus	<ul style="list-style-type: none"> • Bleeding disorder • Thrombocytopenia • Surgery <6 wk • Abnormal bleed <30 d • Active GI ulceration • Puncture of a noncompressible vessel • Prior stroke, organic CNS pathology • Any systolic BP >180 mm Hg during the acute event • As above • 1/2 dose in renal insufficiency
Tirofiban (Aggrastat)	0.4 μ g/kg/min IV over 30 min; then 0.1 μ g/kg/min infusion for 48–108 h	<ul style="list-style-type: none"> • As above
Abciximab (ReoPro)	0.25 mg/kg IV bolus 10–60 min before PCI, then 10 μ g/min IV infusion for 12 h	

- Glycoprotein IIb/IIIa Receptor Antagonists. Platelet aggregation involves the GP IIb/IIIa receptor linked to fibrinogen or von Willebrand factor. IV GP IIb/IIIa receptor antagonists have been extensively tested in patients with ACS and, in a meta-analysis of all the major randomized trials, the absolute risk reduction for death or MI at 30 days was 1% (11.8% control vs. 10.8% with Gp IIb/IIIa). The absolute treatment benefit was largest in high-risk patients—in particular, those with evidence of troponin release or those undergoing acute PCI. Among those without troponin elevation or PCI, no significant benefits were observed.
- Abciximab may reduce the composite of death, MI, or urgent target vessel revascularization within 30 days in patients with N-STEMI treated with PCI and clopidogrel.
- Tirofiban given several hours before coronary angiography may improve myocardial perfusion, a higher myocardial contrast echocardiographic score, and lower rates of post-procedure troponin elevation in high-risk ACS patients.
- Upstream GPI therapy may be more effective than downstream use in moderate- to high-risk patients managed with an invasive strategy in whom immediate catheterization is not planned.

Anticoagulation Therapy

- Thrombin (factor IIa) is a highly potent stimulus fibrin generation and platelet activation. In addition, it leads to monocyte chemotaxis, mitogenesis, increased permeability of the vascular wall, and secretion of cytokines and growth factors from smooth muscle cells. Effective antithrombotic treatment requires the inhibition of both platelet function and thrombin.
- Unfractionated heparin has been widely used but suffers from practical difficulties in maintaining antithrombin activity within the therapeutic range, which are influenced by acute-phase proteins and binding to antithrombins. Heparin, either unfractionated or low-molecular-weight heparin (LMWH), reduces absolute rates of death or MI.
- Direct antithrombins may provide significant advantages over the indirect inhibitors (unfractionated and LMWH), though hirudins are only approved for treatment of heparin-induced thrombocytopenia and not licensed for ACS. LMWHs partially inhibit factor Xa, but newer specific inhibitors of Xa have been developed—for example, bivalirudin and fondaparinux. Bivalirudin reduces bleeding compared to treatment with GP IIb/IIIa inhibitors. Fondaparinux may substantially reduce major bleeding and improve long-term mortality and morbidity compared to LMWH.
- Ximelagatran is an orally administered, direct thrombin antagonist. It does not require anticoagulation monitoring, and is administered as a fixed dose and may reduce the frequency of death, nonfatal MI, and severe recurrent ischemia. As an alternative to warfarin in the management of atrial fibrillation, it demonstrates similar efficacy but less bleeding. A potential hazard involves alterations in liver enzymes to at least three times the upper limit of normal, which appears to resolve with or without cessation of drug treatment.

HMG-CoA Reductase Inhibitors

- Intensive therapy with atorvastatin, 80 mg, compared with pravastatin, 40 mg, should begin in the early post-ACS phase.

This reduces risk of death, MI, stroke, or rehospitalization for recurrent ACS; consistent with greater early pleiotropic effects. A number of potential early benefits of statins independent of LDL have been postulated and include favorable effects on inflammation, endothelial function (including flow-mediated dilation), and the coagulation cascade. This early benefit may be associated with the more profound reduction in CRP achieved.

- To achieve goals of LDL <70 mg/dL and CRP <2 mg/L associated with relatively lower rates of death and recurrent ischemic complications, better control of traditional risk factors and even more potent pharmacologic therapy are necessary. Dose adjustment is not required in patients who achieve very low LDL concentrations, <40 mg/dL. Statins may be of greatest benefit when combined with aspirin and clopidogrel.

HOSPITAL CARE AND MANAGEMENT STRATEGIES: INVASIVE STRATEGIES

The Role of Coronary Angiography

- Presently, coronary angiography represents the only reliable tool for the assessment of coronary anatomy in patients with N-STE-ACS. Patients with high-risk coronary lesions—left main disease, three vessel disease, and proximal left anterior descending coronary artery disease—represent about 50% of all patients with N-STE-ACS.
- Despite the use of risk scores and biomarkers of myocardial damage, it is frequently impossible to identify these high-risk patients who are most likely to benefit from revascularization both in terms of survival and symptom improvement (Table 83.8).
- Thus, the concept of low- and high-risk patients suggested by the various scores derived by investigational studies and registry is rather relative. According to the TIMI risk score, about 50% of patients with N-STE-ACS are in the low risk subgroup (score <3); nevertheless about 25% of these patients develop a major event—death, nonfatal MI, or urgent revascularization—within 14 days from

TABLE 83.8

HIGH-RISK FEATURES FAVORING AN EARLY INVASIVE STRATEGY

- Recurrent angina/ischemia at rest or with low-level activities despite intensive anti-ischemic therapy
- Elevated troponin level
- New or presumably new ST-segment depression
- Recurrent angina/ischemia with symptoms of heart failure, an S₃ gallop, pulmonary edema, worsening rales, or new or worsening mitral regurgitation
- High-risk findings on noninvasive stress testing
- Left ventricular systolic dysfunction (ejection fraction <40% on a noninvasive study)
- Hemodynamic instability
- Sustained ventricular tachycardia
- Percutaneous coronary intervention within

FIGURE 83.8. Odds of nonfatal myocardial infarction (MI) from randomization to end of follow-up in a meta-analysis of 7 trials of routine versus selective invasive management of acute coronary syndromes. $P = 0.51$ for heterogeneity across the trials. CI, confidence interval; OR, odds ratio. [From Bavry AA, Kumbhani DJ, Rassi AN, et al. Benefit of early invasive therapy in acute coronary syndromes: a meta-analysis of contemporary randomized clinical trials. *J Am Coll Cardiol.* 2006;48:1319–1325].

hospitalization. Thus, all patients with N-STE-ACS should be regarded at risk to develop major coronary events.

Early Conservative versus Invasive Strategies

- An early invasive approach appears to improve long-term survival and reduce late nonfatal MI and rehospitalization for symptom recurrence versus conservative strategies. The issue

is not whether but when a patient with N-STE-ACS should undergo coronary angiography and eventually revascularization.

- The goal in N-STE-ACS should be to perform early invasive therapy within 48 hours from hospital admission (Fig. 83.8). Obviously, coronary angiography should be anticipated if clinical instability occurs.
- The best revascularization strategy (PCI or CABG) should be evaluated for each case according to coronary anatomy, clinical symptoms, and associated diseases.

CHAPTER 84 ■ ST ELEVATION MYOCARDIAL INFARCTION (STEMI): CONTEMPORARY MANAGEMENT STRATEGIES

OVERVIEW OF ST ELEVATION MYOCARDIAL INFARCTION

Definition of Terms

- The definition of acute myocardial infarction (MI) is **death of cardiac myocytes** caused by prolonged ischemia. Electrocardiographic (ECG) changes are associated with elevation of the biomarkers of myocardial damage. The standard biomarker for myocardial damage is cardiac troponin (I or T), which has high specificity and sensitivity, and creatine kinase (CK)-MB mass, which is less tissue-specific but more specific for irreversible injury.

- Acute evolving MI in the presence of clinically appropriate symptoms:
 - **ST elevation MI (STEMI)**, new ST-segment elevation at the J-point with the cutoff points ≥ 0.2 mV in V_1 through V_3 and ≥ 0.1 mV in other leads, usually indicates transmural MI.
 - **Non-ST elevation MI (N-STEMI)**, ST-segment depression or T-wave abnormalities with elevated biomarkers, usually indicates subendocardial MI.
- Clinically established MI defined by any Q wave in leads V_1 through V_3 , or a Q wave ≥ 0.03 s in leads I, II, aVL, aVF, V_4 , V_5 , or V_6 .
- Recently, a global task force redefined the ESC/ACC criteria for the diagnosis of MI from various perspectives

TABLE 84.1**NEW DEFINITION OF MYOCARDIAL INFARCTION****Criteria for acute MI**

The term *MI* should be used when there is evidence of myocardial necrosis in a clinical setting consistent with myocardial ischemia. Under these conditions, any of the following criteria meets the diagnosis for MI:

- Detection of rise and/or fall of cardiac biomarkers (preferably troponin) with at least one value above the 99th percentile of the URL together with evidence of myocardial ischemia with at least one of the following:
 - Symptoms of ischemia
 - ECG changes indicative of new ischemia (new ST-T changes or new LBBB)
 - Development of pathological Q waves in the ECG
 - Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality
 - Sudden, unexpected cardiac death, involving cardiac arrest, often with symptoms suggestive of myocardial ischemia and accompanied by presumably new ST elevation, or new LBBB, and/or evidence of fresh thrombus by coronary angiography and/or at autopsy, but death occurring before blood samples could be obtained, or at a time before appearance of cardiac biomarkers in the blood
- For PCI and CABG in patients with normal baseline troponin values, elevation of cardiac biomarkers above the 99th percentile URL are indicative of periprocedural myocardial necrosis. By convention, increases of biomarkers $>3 \times$ 99th percentile URL has been designated as defining PCI-related MI and elevations of biomarkers $>5 \times$ 99th percentile URL plus either new pathological Q waves or new LBBB or angiographically documented new graft or native coronary artery occlusion, or imaging evidence of new loss of viable myocardium, have been designated as defining CABG-related MI.
- Pathological findings of an acute MI

Criteria for prior MI

Any one of the following criteria meets the diagnosis for prior MI:

- Development of new pathological Q waves with or without symptoms
- Imaging evidence of a region of loss of viable myocardium that is thinned and fails to contract, in the absence of a nonischemic cause
- Pathological findings of a healed or healing MI

MI, myocardial infarction; URL, upper reference limit; ECG, electrocardiogram; LBBB, left bundle branch block; PCI, percutaneous coronary intervention; CABG, coronary artery bypass grafting.

(Table 84.1). Clinically, the various types of MI, according to this new definition, can be classified as shown in Table 84.2.

Pathogenesis of ST Elevation Myocardial Infarction and Its Complications

- ST elevation represents transmural ischemia in response to total and prolonged occlusion (less frequently spasm) of a major coronary artery.
- Dysfunction or disruption of critical myocardial structures may require an immediate combination of pharmacologic, catheter-based, and surgical treatments.
- This may lead to **ventricular remodeling**, referring to changes in size, shape, and thickness of the left ventricle involving both infarcted and noninfarcted segments. An extra load is placed on the residual functioning myocardium, which results in compensatory hypertrophy. Additionally, cardiac dysrhythmias may result from electrical instability, pump failure/excessive sympathetic stimulation, and conduction disturbances.

Early Evaluation

Immediate Concerns and Questions to be Addressed at the Initial Evaluation

- Rapid diagnosis and early risk stratification can improve outcomes (Table 84.3). A working diagnosis of acute MI is usually based on the history of severe **chest pain** lasting for

TABLE 84.2**CLINICAL CLASSIFICATION OF DIFFERENT TYPES OF MYOCARDIAL INFARCTION****Type 1**

Spontaneous MI related to ischemia due to a primary coronary event such as plaque erosion and/or rupture, fissuring, or dissection

Type 2

MI secondary to ischemia due to either increased oxygen demand or decreased supply (e.g., coronary spasm, coronary embolism, anemia, arrhythmias, hypertension, or hypotension)

Type 3

Sudden unexpected cardiac death, including cardiac arrest, often with symptoms suggestive of myocardial ischemia, accompanied by presumably new ST elevation, or new LBBB, or evidence of fresh thrombus in a coronary artery by angiography and/or autopsy, but death occurring before blood samples could be obtained, or at a time before the appearance of cardiac biomarkers in the blood

Type 4a

MI associated with PCI

Type 4b

MI associated with stent thrombosis as documented by angiography or at autopsy

Type 5

MI associated with CABG

MI, myocardial infarction; LBBB, left bundle branch block; PCI, percutaneous coronary intervention; CABG, coronary artery bypass grafting.

TABLE 84.3**AIMS OF ACUTE MANAGEMENT OF ST ELEVATION MYOCARDIAL INFARCTION**

- Rapidly establish a working diagnosis after presentation.
- Treat acute dysrhythmic and hemodynamic complications, including cardiac arrest.
- Provide prompt pain relief and adequate arterial oxygen concentration.
- Initiate reperfusion therapy to limit the extent of infarction and minimize the complications of pump failure and dysrhythmias.
- Treat complications of acute myocardial infarction.
- Provide risk assessment for longer-term management and to initiate secondary prevention.

20 minutes or more, not responding to nitroglycerin (Fig. 84.1). Important clues are a previous history of coronary artery disease and radiation of the pain to the neck, lower jaw, or left arm. The pain may not be severe and, particularly in the elderly, other presentations such as **fatigue**, **dyspnea**, **syncope**, and feeling faint or “poorly” are common.

- Physical signs may include hypotension or a narrow pulse pressure, irregularities of the pulse, bradycardia or tachycardia, and a third heart sound. The presence and severity of basal pulmonary rales is a pivotal tool for an early risk stratification of STEMI patients (Table 84.4).

- Certain patients, including the elderly and diabetics, may present **without typical symptoms**.
- Perform immediate ECG; if ST-segment elevations or new or presumed new left bundle branch block are present, reperfusion therapy should be initiated as soon as possible. During the early evolution of infarction, the ECG may be without significant ST elevation. It is important to institute continuous ST monitoring or perform repeat ECGs to ensure that such evolution is detected promptly. However, even in proven infarction, it may never demonstrate the classic features of ST-segment elevation and new Q waves.
- **Alternative diagnoses** are presented in Table 84.5. Myocardial perfusion scintigraphy or magnetic resonance imaging may be used to detect the presence of ischemia or infarction, and a normal result also effectively excludes significant MI.
- First blood sample for **biomarkers** may be negative. It is not reasonable to wait for the next results before initiating a reperfusion regimen. Elevated biomarkers are sometimes helpful in deciding to initiate reperfusion therapy (e.g., left bundle branch block). When the history, ECG, and serum biomarkers are not diagnostic of acute MI, the patient can proceed safely to stress testing for underlying coronary artery disease.

Hemodynamic Compromise and Cardiac Arrest

- Resuscitation may be required for ventricular fibrillation (VF) or ventricular tachycardia (VT) with diminished cardiac output. With extensive MI and/or heart failure, additional

circulatory support may be necessary, including an intra-aortic balloon pump, as a bridge to revascularization.

Early In-Hospital Care and Management Strategies

Pharmacologic Treatment in the Acute Phase of ST Elevation Myocardial Infarction

- **Pain management** is a key element, directed toward relief of myocardial ischemia and necrosis symptoms, heart's metabolic demands, anxiety, and apprehension. **Morphine**

TABLE 84.5**DIFFERENTIAL DIAGNOSIS OF ST ELEVATION MYOCARDIAL INFARCTION****Life threatening**

- Aortic dissection
- Pulmonary embolus
- Perforating ulcer
- Tension pneumothorax
- Boerhaave syndrome (esophageal rupture with mediastinitis)

Other cardiovascular and nonischemic entities

- Pericarditis
- Atypical angina
- Early repolarization
- Wolff-Parkinson-White syndrome
- Deeply inverted T waves suggestive of a central nervous system lesion or apical hypertrophic cardiomyopathy
- Left ventricular hypertrophy with strain
- Brugada syndrome
- Myocarditis
- Hyperkalemia
- Bundle branch blocks
- Vasospastic angina
- Hypertrophic cardiomyopathy

Other noncardiac entities

- Gastroesophageal reflux and spasm
- Chest wall pain
- Pleurisy
- Peptic ulcer disease
- Panic attack
- Biliary or pancreatic pain
- Cervical disc or neuropathic pain
- Somatization and psychogenic pain disorder

sulfate remains the analgesic agent of choice for pain for patients with pulmonary edema and promotes peripheral arterial and venous dilation.

• **Fibrinolysis**

- Prompt and effective reperfusion by pharmacologic therapy is the cornerstone of treatment for STEMI and can diminish infarct size and major cardiac complications (Table 84.6).
- Limitations of fibrinolysis: The major limitation is that reperfusion is gradual and incomplete or inadequate in a significant proportion of patients. This ranges from about 40% showing failure to achieve thrombolysis in myocardial infarction (TIMI) 3 flow within the first 3 hours of reperfusion therapy when streptokinase is used, to 20% to 30% with tissue plasminogen activator (tPA) or tenecteplase (TNK) (Table 84.7).
- The principal hazards are **stroke and intracranial hemorrhage**; about four extra strokes, two fatal, occur per 1,000 patients treated. Accelerated tPA (alteplase) results in fewer deaths than streptokinase but at the risk of additional strokes. Single-bolus agents provide logistic advantages and

TABLE 84.6**CONTRAINDICATIONS TO FIBRINOLYTIC THERAPY****Absolute contraindications**

- Hemorrhagic stroke or stroke of unknown origin at any time
- Ischemic stroke in preceding 6 mo
- Central nervous system damage or neoplasms
- Recent major trauma/surgery/head injury (within preceding 3 wk)
- Gastrointestinal bleeding within the last month
- Known bleeding disorder
- Aortic dissection

Relative contraindications

- Transient ischemic attack in preceding 6 mo
- Oral anticoagulant therapy
- Pregnancy or within 1 wk postpartum
- Noncompressible punctures
- Traumatic resuscitation
- Refractory hypertension (systolic blood pressure >180 mmHg)
- Advanced liver disease
- Infective endocarditis
- Active peptic ulcer

TABLE 84.7

COMPARISON OF APPROVED FIBRINOLYTIC AGENTS

	Streptokinase	Alteplase	Reteplase	Tenecteplase-tPA

MU, mega units; TIMI, thrombolysis in myocardial infarction.

^aBolus 15 mg, infusion 0.75 mg/kg × 30 min (maximum 50 mg);, then 0.5 mg/kg, not to exceed 35 mg over the next 60 min to an overall maximum of 100 mg.

^bThirty milligrams for weight <60 kg; 35 mg for 60–69 kg; 40 mg for 70–79 kg; 45 mg for 80–89 kg; and 50 mg for 90 kg or more.

minimize delay in the prehospital and emergency room settings; both reteplase-PA or weight-adjusted TNK have equivalent efficacy to accelerated tPA. TNK has a lower rate of noncerebral bleeds and a lesser need for blood transfusion.

- Prehospital fibrinolysis: Myocardial salvage is highly dependent on the time from the beginning of symptoms to reperfusion. Efficacy of thrombolysis decreases exponentially in patients treated >3 hours after the onset of chest pain. Prehospital thrombolysis results in decreased mortality and likely superior myocardial salvage compared with in-hospital thrombolysis and possibly also primary percutaneous coronary intervention (PCI).
- Fibrinolysis combined with newer antithrombotic agents: To improve the rates of TIMI 3 flow by pharmacologic reperfusion therapy, glycoprotein (GP) IIb/IIIa inhibitor and antithrombin (bivalirudin) have been tried with thrombolytics. Neither combination has been shown to offer any advantage; in patients older than 70 years, the combination increased the risk of intracranial hemorrhage and extracranial bleeding.
- Anti-ischemic drugs
 - Oxygen: Even with uncomplicated MI, some patients are modestly hypoxemic initially, presumably from ventilation/perfusion mismatch and excessive lung water. Nitrates reduce preload and afterload through peripheral arterial and venous dilation, improve coronary flow by relaxation of epicardial coronary arteries, and dilate collateral vessels, potentially creating a more favorable subendocardial-to-epicardial flow ratio. Nitrates in all forms should be avoided in patients with initial systolic blood pressures <90 mmHg or ≥30 mmHg below baseline, marked bradycardia or tachycardia, or known or suspected right ventricular (RV) infarction.
 - β -Adrenergic blockers within 24 hours of suspected STEMI onset are associated with reduced risk of reinfarction and VF but increased risk of cardiogenic shock. In general, consider starting β -blocker therapy in hospital only when the hemodynamic condition after STEMI has been stabilized.
- Antiplatelet therapy
 - Aspirin should be given to the patient with suspected STEMI as early as possible and continued indefinitely, regard-

less of the strategy for reperfusion or whether additional antiplatelet agents are administered; known true aspirin allergy is the only exception.

- Thienopyridine: A thienopyridine (e.g., ticlopidine or clopidogrel) should be substituted when aspirin is contraindicated because of hypersensitivity or major gastrointestinal intolerance. Combination therapy, clopidogrel and low-dose aspirin, improves infarct-related coronary artery patency after fibrinolytic therapy in STEMI, safely reduces in-hospital mortality and major vascular events, and is recommended for all patients after stent implantation. Prasugrel, a new thienopyridine derivative, is 10 times more potent but results in low and similar rates of bleeding when compared with clopidogrel.
- Platelet glycoprotein IIb/IIIa receptor antagonists: Adjunctive treatment with GP IIb/IIIa (abciximab, tirofiban, and eptifibatide) blockade reduces the incidence of acute ischemic events by 35% to 50% among the broad population of patients undergoing primary PCI. GP IIb/IIIa inhibitors decrease coronary thrombus, improve TIMI flow grade, enhance epicardial reperfusion when combined with thrombolysis, improve 30-day clinical outcomes after MI (Fig. 84.2) including reinfarction, speed resolution of ST-segment elevation, and improve coronary artery flow reserve and myocardial blush grade. Abciximab in STEMI is associated with a significant reduction in 30-day and long-term mortality in patients treated with primary PCI but not fibrinolysis where a higher risk of major bleeding complications is observed.
- Antithrombotic therapy
 - Unfractionated heparin (UFH): In fibrinolytic therapy, recommendations for UFH therapy depend on the agent chosen. The nonspecific fibrinolytic agents (streptokinase, anistreplase, and urokinase) produce a systemic coagulopathy, including production of fibrinogen degradation products and depletion of factors V and VIII; the need for adjunctive systemic anticoagulation is less compelling. When primary PCI is chosen as the route of reperfusion, weight-adjusted boluses of heparin in the range of 70 to 100 U/kg are recommended based on angioplasty observations that an activated clotting time of at least 250 to 350 seconds is associated with a lower rate of complications. When

FIGURE 84.2. Randomized trials demonstrating the clinical benefits of abciximab in the setting of ST elevation myocardial infarction (STEMI). D, death; MI, myocardial infarction; TVR, target vessel revascularization; PTCA, percutaneous transluminal coronary angioplasty.

GP IIb/IIIa antagonists are used, the UFH bolus should be reduced to 50 to 70 U/kg to achieve a target activated clotting time of 200 seconds.

- **Low-molecular-weight heparin (LMWH).** In the setting of STEMI, LMWH may be an attractive alternative to UFH as ancillary therapy to patients with and without fibrinolysis. The two LMWHs studied most extensively are enoxaparin and dalteparin.
- **Direct antithrombin agents:** Compared to UFH, a 25% reduction in reinfarction results with either hirudin or bivalirudin treatment in STEMI, but univalent thrombin inhibitors such as argatroban, efegatran, and inogatran are less efficacious. Bivalirudin alone is as safe and effective long term as heparin or heparin and GP IIb/IIIa in STEMI.
- **Fondaparinux** binds antithrombin III, inducing a conformational change that increases its anti-Xa activity more than 300 times, resulting in dose-dependent inhibition of factor Xa. In STEMI, particularly those not undergoing primary PCI, fondaparinux seems to reduce mortality and reinfarction without increasing bleeding and strokes.
- **Other pharmacologic agents**
 - **Angiotensin-converting enzyme inhibitors** should be given to patients with impaired left ventricular (LV) function or congestive heart failure (CHF) in the early phase of an MI and should be started in the first 24 hours after STEMI.
 - **Calcium antagonists:** Immediate-release nifedipine does not reduce the incidence of reinfarction or mortality and may be particularly detrimental in patients with hypotension or tachycardia. Immediate-release verapamil initiated several days after STEMI, in noncandidates for β -blockade, may reduce reinfarction and death, provided LV function was well preserved. Verapamil is detrimental to patients with CHF or bradyarrhythmias during the first 24 to 48 hours after STEMI. Patients with non-Q-wave MI or with Q-wave MI, preserved LV function, and no evidence of CHF may benefit from immediate-release diltiazem.
 - **Inodilators** may be used when severe hypotension occurs. Positive inotropic agents, especially **phosphodiesterase inhibitors** and adrenergic agonists such as dobutamine, are associated with increasing myocardial oxygen demand and the potential to induce malignant dysrhythmias and myocar-

dial ischemia, contributing to further cell death or necrosis. **Levosimendan** is a calcium sensitizer that, by virtue of its unique mechanism of action and its negligible effect on myocardial oxygen demand, is the only inodilator that has been associated with favorable short-term outcomes in patients with acute MI.

- **Magnesium:** Magnesium can continue to be administered for repletion of documented electrolyte deficits and life-threatening ventricular arrhythmias such as torsades de pointes.
- **Lidocaine:** Although it has been demonstrated that lidocaine can reduce the incidence of VF in the acute phase of MI, this drug significantly increases the risk of asystole. The routine prophylactic use of this drug is therefore not justified.
- **Glucose-insulin-potassium,** administered routinely, may favorably influence metabolism in the ischemic myocardium and therefore confer a clinical benefit.

Early In-Hospital Care and Management Strategies: Invasive Strategies

Primary Percutaneous Coronary Intervention

- Percutaneous coronary intervention (PCI) without prior thrombolytic therapy is associated with several potential advantages and disadvantages (Table 84.8). Primary PCI results in better acute arterial patency compared to lytics, further improving survival and reducing the hazards of excess cerebral and systemic bleeding and recurrent ischemia, especially in high-risk patients (Fig. 84.3).
- Primary PCI improves LV function with less reperfusion injury, cardiogenic shock, and myocardial rupture than fibrinolytic therapy.

Facilitated Percutaneous Coronary Intervention

- Facilitated PCI refers to treatment with low-dose thrombolytic therapy, platelet GP IIb/IIIa inhibitors, or both, **before** PCI to provide the earliest possible pharmacologic reperfusion before an attempt at definitive mechanical revascularization. Primary PCI is superior to facilitated PCI with lower

TABLE 84.8

ADVANTAGES AND DISADVANTAGES OF PRIMARY PERCUTANEOUS CORONARY INTERVENTION VERSUS THROMBOLYSIS

Advantages of primary PCI versus thrombolysis

- Immediate definition of coronary anatomy
- Early risk stratification
- Superior acute vessel patency and TIMI flow grade
- Less reocclusion, recurrent ischemia, and reinfarction
- Better survival in high-risk patients
- Less reperfusion injury and myocardial rupture
- Lower risk of intracranial hemorrhage
- Useful in thrombolytic ineligible patients
- Shorter length of hospital stay

Disadvantages of primary PCI versus thrombolysis

- Skilled interventional cardiologists and catheterization laboratory must be available
- Logistic delays

PCI, percutaneous coronary intervention; TIMI, thrombolysis in myocardial infarction.

rates of death, stroke, cardiogenic shock, or CHF within 90 days and less bleeding.

- Conversely, thrombolytics (half-dose reteplase and abciximab) given to high-risk patients with STEMI in **noninterventional centers** prior to immediate transfer for PCI improves outcomes.

Rescue Percutaneous Coronary Intervention

- Rescue PCI is performed in patients without response to thrombolytic treatment within 90 minutes after therapy (<50% ST-segment resolution and/or symptom regression). Current guidelines recommend it only for certain high-risk subgroups of patients. Rescue PCI has better event-free survival than repeated thrombolysis or conservative treatment.

* : $p < 0.001$

** : $p = 0.003$

***: $p = 0.002$

Transport for Primary Percutaneous Coronary Intervention

- For hospitals without on-site PCI facilities, patient transfer needs to be considered. Several trials compare immediate transfer to on-site thrombolytic therapy in STEMI patients at community hospitals without PCI capability (Fig. 84.4); complications during transfer (death, ventricular dysrhythmias, and second- or third-degree heart block) were rare.
- For transfer times of 2 hours or less from a community hospital to the start of PCI, there is a significant reduction in death, reinfarction, and stroke compared with thrombolysis. This benefit may not apply to transfer for primary PCI in low-volume centers or to situations in which transfer delays exceed 2 to 3 hours. The time from symptom onset to first balloon inflation must be minimized, requiring that the transferred patient is delivered directly to an experienced “ready and waiting” catheterization laboratory.

The Crucial Role of Time in Reperfusion Therapies

- The shorter the time is from symptom onset to treatment, the greater the survival benefit with either reperfusion therapy. The choice between therapies should take into account reperfusion treatment times (Figs. 84.5 and 84.6). Within the **first 2 hours**, the reduction in mortality is twice as large as beyond 2 hours (Fig. 84.7).
- The European guidelines for the management of acute MI recommend that for those patients with clear-cut changes of acute infarction, no more than **20 minutes** should elapse between hospital arrival and the administration of thrombolytic therapy (or prehospital administration) or no more than **60 minutes** between hospital arrival and balloon inflation for primary PCI.
- A second and critically important reason for minimizing prehospital delay is to treat early VF. At least as many deaths may be saved by prompt resuscitation therapy in early acute MI as are saved by reperfusion therapy.

FIGURE 84.3. Meta-analysis of 23 randomized trials of primary percutaneous coronary intervention (PCI) versus thrombolysis. (Modified from Keeley EC, Grines CL. Primary coronary intervention for acute myocardial infarction. *JAMA*. 2004;291[6]:736–739.)

FIGURE 84.4. Randomized trials comparing on-site fibrinolysis and transfer for primary percutaneous coronary intervention (PCI).

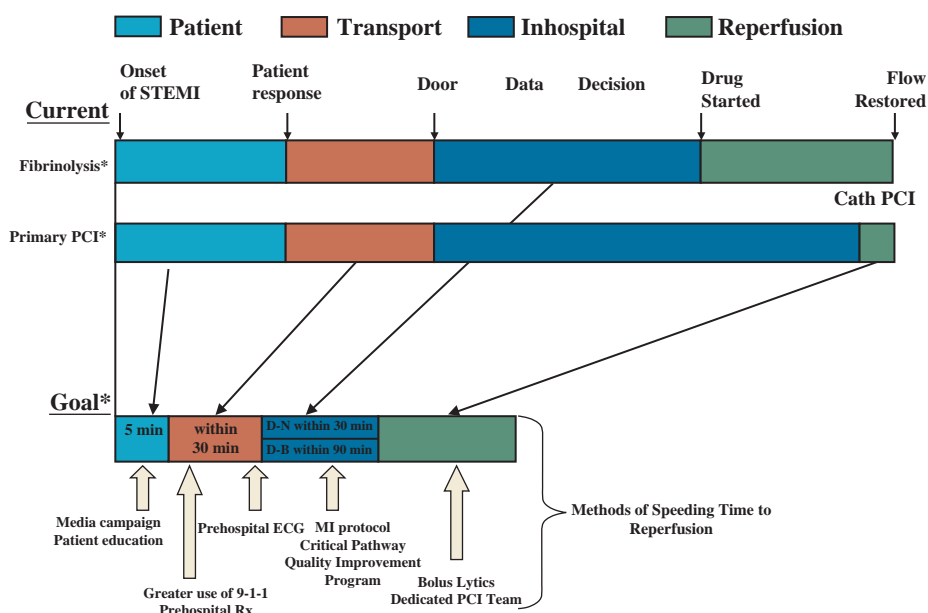

FIGURE 84.5. Major components of time delay between onset of symptoms from ST elevation myocardial infarction (STEMI) and restoration of flow in the infarct-related artery. PCI, percutaneous coronary intervention. (Modified from Antman EM, Anbe DT, Armstrong PW, et al. American College of Cardiology; American Heart Association Task Force on Practice Guidelines; Canadian Cardiovascular Society. ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [committee to revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction]. *Circulation*. 2004;110[9]:e82–e292.)

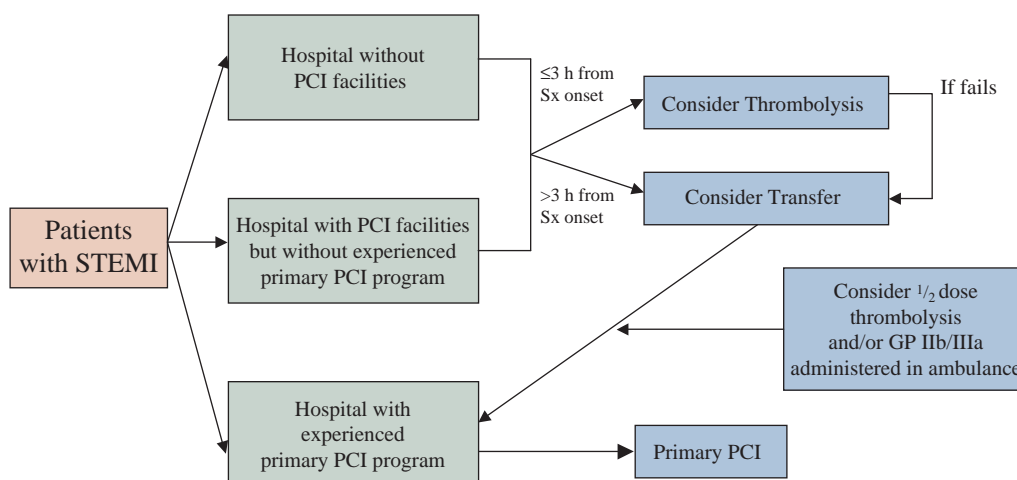

FIGURE 84.6. Possible strategies for the acute management of ST elevation myocardial infarction (STEMI) patients based on the hospital availability of an experienced primary percutaneous coronary intervention (PCI) program. GP, glycoprotein.

FIGURE 84.7. Time dependency of myocardial salvage expressed as percentage of initial area at risk. The initial parts of the curve up to 2 hours were reconstructed based on the experimental studies. The other parts of the curve showing myocardial salvage from 2 to 12 hours from the symptom onset are reconstructed according to the data of scintigraphic studies. Efficacy of reperfusion is expressed as follows: +++, very effective; ++, effective; +, moderately effective; ±, uncertainly effective; -, not effective. PCI, percutaneous coronary intervention. (From Schomig A, Ndrepepa G, Kastrati A. Late myocardial salvage: time to recognize its reality in the reperfusion therapy of acute myocardial infarction. *Eur Heart J.* 2006;27:1900–1907.)

- The relationship between **mortality and time delay** from symptom onset to treatment is stringent with thrombolytic therapy in STEMI. It is much weaker with primary PCI (Fig. 84.8); however, the benefits of primary PCI may diminish with excessive delays in opening the infarct-related artery

FIGURE 84.8. Time dependence of myocardial salvage according to time-to-treatment interval in patients with ST elevation myocardial infarction (STEMI) treated by percutaneous coronary intervention (PCI) or thrombolysis. **A:** Myocardial salvage expressed as percentage of the left ventricle (LV). **B:** Myocardial salvage expressed as proportion of the initial area at risk salvaged by reperfusion therapy. (From Schomig A, Ndrepepa G, Kastrati A. Late myocardial salvage: time to recognize its reality in the reperfusion therapy of acute myocardial infarction. *Eur Heart J.* 2006;27:1900–1907.)

(Fig. 84.9). With thrombolytic therapy, there is an inverse relationship between the rate of achieving normal blood flow and the time-to-treatment interval and an increased risk for mechanical complications, such as myocardial rupture. Therapy is more often complicated by reocclusion of the infarct-related artery, reinfarction, and worse long-term survival as compared to primary PCI. With primary PCI, mechanical complications are rare.

Coronary Artery Bypass Surgery

- Coronary artery bypass surgery (CABG) may be indicated when PCI has failed or is not feasible, with sudden occlusion of a coronary artery during catheterization, in cardiogenic shock, or in association with surgery for a ventricular septal defect or mitral regurgitation due to papillary muscle dysfunction and rupture.
- CABG is also indicated if coronary angiography demonstrates lesions, such as left main stenosis or three-vessel disease with poor LV function, for which surgery improves prognosis.

LONG-TERM POST-MYOCARDIAL INFARCTION

Pharmacologic Treatment

- Pharmacologic therapies aimed at limiting risk factors and coronary plaque instability with lipid-lowering therapies and inhibiting post-MI remodeling with neurohumoral antagonists can significantly improve long-term outcomes including death, reinfarction, and worsening CHF (Table 84.9). Clinical trials have also shown the benefits of antiplatelet, anticoagulant, and newer platelet inhibitors in

FIGURE 84.9. Relationship between 30-day mortality and time from study enrollment to first balloon inflation. PTCA, percutaneous transluminal coronary angioplasty. (Modified from Berger PB, Ellis SG, Holmes DR Jr, et al. Relationship between delay in performing direct coronary angioplasty and early clinical outcome in patients with acute myocardial infarction: results from the Global Use of Strategies to Open Occluded Arteries in Acute Coronary Syndromes [GUSTO-IIb] trial. *Circulation*. 1999;100:14–20.)

limiting recurrent myocardial ischemia and its consequences (Table 84.10).

Special Issues

Acute Congestive Heart Failure and Cardiogenic Shock

- Acute CHF arises from a sudden injury or structural failure and constitutes approximately 10% of CHF admissions. Etiologies include acute coronary syndromes (ACSs), acute valvular dysfunction, pericardial disease, new arrhythmia, myocarditis, and malignant hypertension.

TABLE 84.9

AMERICAN COLLEGE OF CARDIOLOGY/AMERICAN HEART ASSOCIATION GUIDELINES FOR MANAGEMENT OF ST ELEVATION MYOCARDIAL INFARCTION

Acute therapy	Discharge therapy
Aspirin	Aspirin
Clopidogrel	Clopidogrel
β -Blocker	β -Blocker
ACE inhibitor	ACE inhibitor
Heparin (UFH or LMWH)	Aldosterone antagonist
GP IIb/IIIa Inhibitor (if receiving PCI)	Statin
	Smoking cessation
	Cardiac rehabilitation

ACE, angiotensin-converting enzyme; UFH, unfractionated heparin; LMWH, low-molecular-weight heparin; GP, glycoprotein; PCI, percutaneous coronary intervention.

Table made with data from Antman EM, Anbe DT, Armstrong PW, et al. American College of Cardiology/American Heart Association Task Force on Practice Guidelines; Canadian Cardiovascular Society. ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (committee to revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction). *Circulation*. 2004;110(9):e82–e292.

- Patients with ACS accompanied by CHF have **considerable mortality** and clearly benefit from emergent revascularization (Fig. 84.10). Medical management includes the standard therapies for ACS (antiplatelet therapy and anticoagulation); β -blockers are contraindicated in the presence of systolic CHF but are probably helpful in diastolic CHF.
- For patients with hypotension or hypoperfusion, serious consideration should be given to placement of a **pulmonary artery catheter**. An **intra-aortic balloon pump** is the most physiologic for improving cardiac output in the setting of ACS as it improves coronary perfusion while increasing blood pressure and decreasing afterload (Fig. 84.11). All currently available inotropes may worsen ischemia and are proarrhythmic.
- Cardiogenic shock remains the leading cause of death in patients hospitalized with acute MI. **Early mechanical revascularization** for cardiogenic shock in acute MI is a class I recommendation by the American College of Cardiology and the American Heart Association for patients younger than 75 years with ST elevation left bundle branch block acute MI due to a significant mortality benefit over initial medical stabilization followed by late or no revascularization (Fig. 84.12).

Other Possible In-Hospital Complications

- Mitral regurgitation may be present in 50% of patients within 30 days of MI, with a graded positive association between the severity of mitral regurgitation, including mild cases, and CHF or death.
- Deep vein thrombosis and pulmonary embolism: These complications are now relatively uncommon after MI, except in patients kept in bed for comorbidities or complications of MI. When they occur, they should be treated with therapeutic doses of LMWH followed by oral anticoagulation for 3 to 6 months.
- Intraventricular thrombus and systemic emboli: Echocardiography may reveal intraventricular thrombi, especially in patients with a large anterior MI. If the thrombi are mobile or protuberant, they should be treated initially with intravenous UFH or LMWH and subsequently with oral anticoagulants for at least 3 to 6 months.

TABLE 84.10
LARGE-SCALE CLINICAL TRIALS OF THERAPY FOR AMI SURVIVORS

Study	Reference	Patient population (n)	Treatment	Background therapy	Average duration	All-cause mortality risk reduction	Re-infarction
Antiplatelet ATC	BMJ. 1994; 308:81–106	AMI (20,000)	Aspirin	None	4.5 y	25% $p < 0.02$	34% $p < 0.02$

FIGURE 84.10. Impact of presence of heart failure (HF) at admission or development of HF during hospitalization (H) in all patients with acute coronary syndromes (ACSs). STEMI, ST elevation myocardial infarction; N-STEMI, non-ST elevation myocardial infarction; UA, unstable angina. (Modified from Steg PG, Dabbous OH, Feldman LJ, et al.; Global Registry of Acute Coronary Events Investigators. Determinants and prognostic impact of heart failure complicating acute coronary syndromes: observations from the Global Registry of Acute Coronary Events [GRACE]. *Circulation*. 2004;109:494–499.)

- Pericarditis: Acute pericarditis is associated with a worse outcome, giving rise to chest pain that may be misinterpreted as recurrent MI or angina. The pain is distinguished by its sharp nature and relationship to posture and respiration, and may be confirmed by a pericardial rub. It may be treated

by high-dose oral or intravenous aspirin, nonsteroidal anti-inflammatory agents, or steroids. A hemorrhagic effusion with tamponade is uncommon but especially associated with anticoagulant treatment. Recognized echocardiographically, it may be treated by pericardiocentesis if needed.

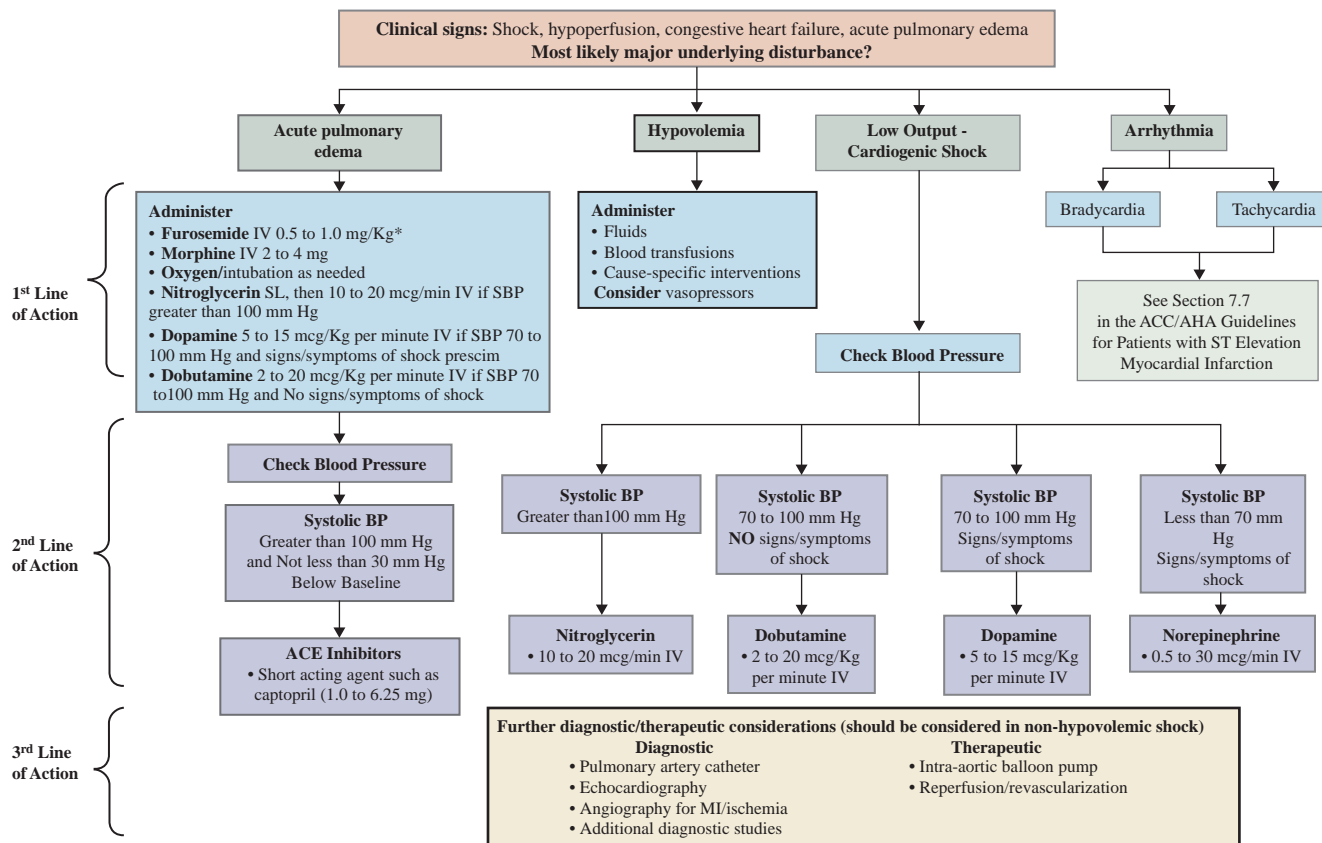

FIGURE 84.11. Emergency management of complicated ST elevation myocardial infarction (STEMI). The emergency management of patients with cardiogenic shock, acute pulmonary edema, or both is outlined. HF, heart failure; IV, intravenous; SL, sublingual; SBP, systolic blood pressure; BP, blood pressure; ACE, angiotensin-converting enzyme; MI, myocardial infarction. (Modified from Antman EM, Anbe DT, Armstrong PW, et al. American College of Cardiology; American Heart Association Task Force on Practice Guidelines; Canadian Cardiovascular Society. ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [committee to revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction]. *Circulation*. 2004;110[9]:e82–292.)

FIGURE 84.12. Mortality of medical stabilization vs. emergency revascularization by percutaneous coronary intervention (PCI) in ST-elevation myocardial infarction (STEMI) patients with shock. (Modified from Hochman JS, Sleeper LA, Webb JG, et al.; SHOCK Investigators. Early revascularization in acute myocardial infarction complicated by cardiogenic shock. *N Engl J Med.* 1999;341:625–634.)

- Late ventricular dysrhythmias: VT and VF occurring on the first day have a low predictive value for recurring dysrhythmias. Dysrhythmias developing later are liable to recur and are associated with a high risk of death. VT or VF during the first week postinfarction is associated with more extensive myocardial damage; a careful assessment of coronary anatomy and ventricular function should always be undertaken. If induced by ischemia, revascularization by PCI or surgery should be considered; otherwise a variety of therapeutic approaches are available including the use of β -blockers, amiodarone, electrophysiologically guided antidysrhythmic therapy, and/or insertion of an implantable converter defibrillator.
- Postinfarction angina and ischemia: The routine use of elective PCI after fibrinolytic therapy in the absence of spontaneous or provokable ischemia does not improve LV function or survival. In treating angina or recurrent or inducible ischemia, however, revascularization by PCI or CABG has a definite role. It may also be of value in managing dysrhythmias associated with persistent ischemia.
- Right ventricular (RV) infarction encompasses a spectrum of disease states ranging from asymptomatic mild RV dysfunction through cardiogenic shock. Most patients demonstrate a return of normal RV function over a period of weeks to months, which suggests that RV stunning, rather than irreversible necrosis, has occurred. Only 10% to 15% of patients show classic hemodynamic abnormalities. A common clinical presentation is profound hypotension after administration of sublingual nitroglycerin, with the **degree of hypotension often out of proportion** to the ECG severity of the infarct.
 - RV infarction with hemodynamic abnormalities accompanying inferior STEMI is associated with a significantly higher mortality and should be considered in high-priority candidates for reperfusion. The high mortality rate is similar to that for patients with LV shock.
 - The treatment of patients with RV ischemic dysfunction is different compared to management of LV dysfunction. It includes maintenance of **RV preload**, reduction of RV afterload, **inotropic support** of the dysfunctional RV, and early

reperfusion. Because of their influence on preload, drugs routinely used in management of LV infarctions, such as nitrates and diuretics, may reduce cardiac output and produce severe hypotension when the RV is ischemic.

- Although **volume loading** is a critical first step in the management of hypotension associated with RV ischemia/infarction, inotropic support—in particular, with **dobutamine**—should be initiated promptly if cardiac output fails to improve after 0.5 to 1 L of fluid has been administered. Excessive volume loading may further complicate the right-sided filling pressure increase and RV dilatation, resulting in decreased LV output secondary to shift of the interventricular septum toward the LV.

Indications for Hemodynamic Monitoring

- It is important to accurately **assess the severity of LV dysfunction** because maneuvers performed in the coronary care unit may worsen this state. More than half of the patients with a moderate reduction in resting cardiac output and an increase in LV filling pressure have no clinical signs of LV dysfunction.
- Correlation of the chest radiograph and clinical evaluation with hemodynamic measurements have demonstrated that the presence of **cardiomegaly, gallop rhythms, and pulmonary edema** may help predict which patients with MI will develop shock.
- There is an unfortunate tendency to institute potent therapeutic measures in patients with MI before precise hemodynamic indices are known. Intravenous furosemide, for example, may create a decline in pulmonary artery occlusion pressure without compromising the cardiac output if ventricular filling pressures are elevated and there is pulmonary congestion. However, if the clinical diagnosis of CHF is incorrect and the pulmonary artery occlusion pressure is normal, diuretic therapy may actually decrease the cardiac output and cause deterioration of an already compromised myocardial flow reserve. This can be particularly detrimental in patients who present with RV infarction.

CHAPTER 85 ■ EVALUATION AND MANAGEMENT OF HEART FAILURE

- The World Health Organization developed classification nomenclature for the cardiomyopathies based on anatomic and physiologic findings: restrictive, hypertrophic, and dilated. This chapter focuses on the dilated cardiomyopathies (DCM); nearly half are secondary to ischemic heart disease, and all remaining etiologies are primary muscle diseases. The hallmark findings of DCM are a dilated left ventricle (LV) and a low LV ejection fraction (EF). Nearly 25% have no pre-existing risk factors. A small number of DCMs are secondary to toxins such as alcohol, anthracyclines, and cocaine; endocrine diseases such as diabetes mellitus and thyroid disease; human immunodeficiency virus and Lyme disease infections; sarcoidosis; thiamine deficiency; peripartum cardiomyopathy; hemochromatosis; and underlying collagen vascular diseases.

CELLULAR DETERMINANTS OF MYOCARDIAL CONTRACTION

The Contractile Proteins

- The interaction of the proteins actin, myosin, and the troponin complex is responsible for myocardial contraction. Engagement of actin and myosin occurs when calcium (Ca^{2+}) levels in the cytosol increase in the presence of adenosine triphosphate (ATP), as regulated by a complex that consists of troponin C and other proteins (Fig. 85.1).
- Removal of Ca^{2+} from the cytosol results in dissociation from troponin C, with subsequent cessation of actin–myosin cross-

linkage, signaling the end of contractile activity and the start of relaxation—a process known as *inactivation*.

Calcium and Cyclic Adenosine Monophosphate

- Alterations in the delivery, use, myofibrillar sensitivity to Ca^{2+} and removal of Ca^{2+} from the myofibril and the myocyte cytosol constitutes the basis for abnormalities in both contractility and relaxation. Entry of Ca^{2+} from extracellular locations occurs through either voltage-dependent, gated “slow channels” activated by membrane depolarization or via sodium–calcium ($\text{Na}^+/\text{Ca}^{2+}$) exchange across the sarcolemma.
- Calcium and cyclic adenosine monophosphate-mediated (cAMP-mediated) transfer of phosphates to phospholamban increases Ca^{2+} influx by additional voltage-dependent channels which triggers Ca^{2+} release from the sarcoplasmic reticulum (SR), termed Ca^{2+} -dependent Ca^{2+} release for contractile activity (Fig. 85.2).
- Altered Ca^{2+} kinetics are responsible for the increases in contractility observed in other circumstances. The increased contractility of postextrasystolic beats, increased heart rate, and during manipulation with cardiac glycosides, phosphodiesterase inhibitors, sympathomimetic amines, and caffeine are dependent on changes in intracellular Ca^{2+} and/or cAMP levels.
- Absolute Ca^{2+} levels and hormonal changes such as hyperthyroidism increase contractility via increased troponin C affinity for Ca^{2+} , increased ATPase activity with concomitant increased cAMP levels, and changes in intracellular Ca^{2+} handling.

FIGURE 85.1. A schematic representation of tropomyosin, troponin complex, actin, myosin, and calcium during relaxation (A), activation (B), and contraction (C). During relaxation, the myosin is prevented from interacting with actin by tropomyosin. Activation by the interaction of calcium with troponin C confers a configurational change in tropomyosin, allowing the interaction of myosin and actin.

FIGURE 85.2. The role of calcium in excitation and contraction in the human myocyte. During depolarization, Ca^{2+} enters from the extracellular space through the voltage-dependent, gated slow channel, the so-called L-type channel. This entry is facilitated by β -receptor stimulation of a protein receptor, which in turn stimulates adenylyl cyclase (AC), producing cyclic adenosine monophosphate (cAMP) and phosphorylation of the calcium channel. However, this intrusion of calcium into the cell does not moderate the interaction of actin and myosin. Rather, it acts as a trigger for the release of calcium from the sarcoplasmic reticulum (SR) Ca^{2+} release or ryanodine receptor channel. During repolarization, the sarcoplasmic reticulum (SR) Ca^{2+} ATPase (SERCA) mediates the uptake of cytosolic calcium into the SR. cAMP-mediated phosphorylation of phospholamban prevents the inhibition by phospholamban of SERCA activity. The $\text{Na}-\text{Ca}^{2+}$ exchange pump is the dominant mechanism of Ca^{2+} extrusion out of the cytosol into the extracellular space.

- Individual muscle units in the failing and hypertrophied ventricle have depressed function. The myocardial depression accompanying anoxia, acidosis, hypothyroidism, barbiturate use, administration of local and general anesthetics, Ca^{2+} antagonists, and ischemia all result from abnormalities in the Ca^{2+} -dependent mechanisms described here.

and hypertrophic cardiomyopathy. Impairment of relaxation occurs secondary to increased levels of Ca^{2+} within the myocyte in diastole, owing to diminished genetic expression of the SR uptake pump, decreased phospholamban activity and transcription, down-regulation or uncoupling of β -receptors, and G-protein inhibition of β -receptor function.

CELLULAR DETERMINANTS OF RELAXATION

- Inactivation signals the end of actin–myosin interaction with the rate and extent of Ca^{2+} removal affecting the rate and extent of relaxation. SR Ca^{2+} ATPase (SERCA) mediates the uptake of cytosolic Ca^{2+} into the SR. Primarily after adrenergic stimuli, cAMP-dependent phosphorylated phospholamban increases SR uptake of Ca^{2+} .
- In addition, the $\text{Na}^+-\text{Ca}^{2+}$ exchange pump—also requiring ATP—allows the efflux of Ca^{2+} into the extracellular space from the cytosol (see Fig. 85.2). As the myofibril shortens, its affinity for Ca^{2+} decreases, limiting Ca^{2+} effects and affecting relaxation. All of these mechanisms can be facilitated or inhibited by drugs or neurohumoral factors.
- The process of relaxation has been extensively studied in DCM, left ventricular hypertrophy (LVH), ischemia,

MEDIATORS OF CONTRACTILITY

β -Receptors and Guanine Nucleotide Regulatory Proteins

- Adrenergic stimulation of cardiac myocytes is an important regulator of both Ca^{2+} influx and cAMP levels within the cell (see Fig. 85.2). β -receptor stimulation activates adenylyl cyclase (AC) which increases cAMP resulting in increased Ca^{2+} influx and increased contractile force. These Ca^{2+} channels are known as “receptor-operated channels.”
- The coupling between β -receptors and AC occurs through guanine cyclic nucleotides, also known as G proteins, which have both stimulatory and inhibitory influences on AC. The G-protein complex (GPC) in its active form contains guanosine triphosphate. G proteins also stimulate cardiac contractility by α -receptor stimulation via a cAMP-independent

mechanism. cAMP-dependent mechanisms have delays in response of 2 to 20 seconds, as opposed to G-protein pathway delays in response of 150 milliseconds.

- Inhibitory G proteins, activated by acetylcholine receptors, inhibit Ca^{2+} influx via cyclic guanosine monophosphate (cGMP). A cGMP system activates cGMP protein kinase, which inhibits calcium inward currents previously stimulated by cAMP.
- In addition to changes in receptor function, molecular alterations in β -receptor production occurs in various disease states. In DCM, both β_1 -receptor mRNA and absolute receptor levels are depressed; also β -receptor kinase levels are elevated, evidence of dysfunctional (uncoupled) β receptors. This may explain catecholamine insensitivity observed in failing hearts after cardiopulmonary bypass and possibly sepsis.

Nitric Oxide

- Nitric oxide (NO) has cholinergic depressant effects on cardiac contractility mediated via cGMP. Antagonists of NO (methylene blue, oxyhemoglobin, and L-arginine) enhance the positive inotropic action of the β agonist isoproterenol.
- Tumor necrosis factor- α (TNF- α) may cause the myocardial depression seen in septic shock. N-methyl-L-arginine blocks the myocardial effect of TNF by inhibition of NO synthesis. Methylene blue, an inhibitor of guanylate cyclase, also blocks TNF-induced cardiomyocyte depression.

Endothelin

- Endothelins and the closely related vasoactive intestinal constrictor are potent vasoconstrictors and positive inotropes, acting via a yet incompletely defined mechanism. Endothelins may sensitize the myofibrils to calcium; high-affinity receptors have been isolated in mammalian atria and ventricles. Found ubiquitously in mammalian tissues, their intracardiac site of genesis is unknown but believed to be the endothelium of the coronary arteries and microvasculature.
- Endothelin causes an increase in intracellular pH that increases myofibrillar sensitivity for Ca^{2+} , and subsequently increases contraction. This effect is completely inhibited by pretreatment with amiloride, blocking Na^+/H^+ exchange across the sarcolemmal membrane and prevents increase in intracellular pH. The effect of endothelin may be mediated via G proteins participating in signal transduction after binding of endothelin to its sarcolemmal receptor.

THE CELLULAR BASIS OF HEART FAILURE

- Heart failure, either acute or chronic, results from loss of myocytes or loss of intrinsic contractility within individual myocytes. Several functional abnormalities involving excitation-contraction coupling of contractile proteins within myocytes and myocardial energetics have been identified.
- The importance of Ca^{2+} in the regulation of myocardial contraction cannot be overstated. In heart failure, there is a blunted rise of depolarization, causing slower activation and a slower rate of fall during repolarization. This is likely mediated by impaired reuptake of Ca^{2+} into the SR because Ca^{2+} -adenosine triphosphatase activity (SERCA2) is reduced. The

activity of SERCA2 activity is inhibited by phosphorylation of phospholamban through cAMP stimulated by β -adrenergic receptors.

- The calcium release channel (CRC) of the SR mediates release of Ca^{2+} into the cytosol during contraction and is critical for activation of the contractile elements. The CRC is hyperphosphorylated by protein kinase A in heart failure, resulting in a high rate of Ca^{2+} leakage from the SR throughout the cardiac cycle. The $\text{Na}^+/\text{Ca}^{2+}$ exchanger has increased activity in heart failure, perhaps as a compensation for reduced SERCA2, and decreased mRNA and protein levels of the voltage-dependent Ca^{2+} channel.
- **Contractile protein alteration in the failure heart:** Both troponin I and T, and myosin heavy and light chains revert to fetal phenotypes in chronic heart failure.
- **Regulation of interstitial collagen:** Collagen provides stents along which myocytes are aligned. The quantity and nature of the collagen are determined by the balance between synthesis and degradation; the latter is regulated by matrix metalloproteinases. In heart failure, there is a maladaptation of collagen stents, perhaps mediated by increased activity of matrix metalloproteinases.
- **Adaptations to changes in load or myocardial injury:** In these situations, the ventricle can maintain cardiac output by increasing ventricular preload (so-called Frank-Starling effect) (Fig. 85.3), activation of neurohumoral systems such as the renin-angiotensin-aldosterone system, release of norepinephrine, or myocardial remodeling via chamber dilatation, and augmentation of myocardial mass.
- At the cellular level, there are increases in number of mitochondria, cell size, and amount of collagen within the extracellular matrix. When the injury or stress exceeds the ability of these adaptive mechanisms to compensate, myocardial contractility decreases. The transition to failure involves inadequate hypertrophy to maintain contractility, re-expression of fetal genes and decreased expression of adult genes, alteration in proteins involved in excitation-contraction coupling, myocardial death by necrosis or apoptosis, and changes in myocardial energetics.

Frank Starling Relationship

FIGURE 85.3. Typical Frank-Starling curves for normal and depressed myocardium. For a given end-diastolic volume, stroke volume is decreased with depressed contractility.

- **Neurohormonal abnormalities in heart failure:** Low cardiac output decreases renal perfusion pressure and stimulates the renin-angiotensin system. Angiotensin II is a potent vasoconstrictor; the discovery of angiotensin-converting enzyme (ACE) inhibitors to interrupt this pathway was a major breakthrough in heart failure therapy. Another was the realization that chymase, CAGE, and cathepsin G, enzymes located in the myocardium, could also cleave angiotensin I into angiotensin II. This discovery cemented the idea that the heart was a neuroendocrine organ.
- Elevated levels of aldosterone are also seen in patients with LV systolic dysfunction. Mechanisms of increased aldosterone are renin-angiotensin stimulation, decreased hepatic clearance, and sodium-restricted diets. Elevated aldosterone leads to sodium and water retention; plasma volume is increased. Low cardiac output also causes the adrenal gland to produce more norepinephrine. Higher levels of circulating catecholamines in heart failure predict a higher mortality.
- Elevated levels of norepinephrine, angiotensin II, and aldosterone result in maladaptive changes in LV structure. These neurohormones lead to dilatation of the LV and changes in cardiocyte architecture, collagen type and content, and β -adrenergic receptor abnormalities. Collectively, these changes in LV architecture are known as remodeling.
- Eccentric hypertrophy results from expression of embryonic genes with contractile protein units assembled in series, rather than in parallel, as seen in concentric hypertrophy. Factors that lead to the hypertrophic response include growth factors, peptides, and cytokines, with the most comprehensively studied substances being insulin growth factor I, angiotensin II, endothelin, and those that activate a form of guanosine triphosphate-binding protein (ras) signaling pathways, cytokines including interleukin-6, and heteromeric (G_q).
- Abnormal amounts of neurohormones are produced in heart failure as part of compensatory mechanisms to alleviate the adverse effects of low cardiac output.
 - Vasoconstrictors, including endothelin and angiotensin II, keep perfusion pressure up. Aldosterone stimulates renal retention of sodium and water but at the cost of potassium secretion, vascular and myocardial fibrosis, baroreceptor dysfunction, and prevention of myocardial norepinephrine uptake.
 - Activated arterial baroreceptors causes nonosmotic stimulation of arginine vasopressin from the supraoptic nucleus of the hypothalamus stimulating both V_{1a} vascular smooth muscle receptors and V_2 receptors on the collecting duct. V_2 receptor stimulation increases aquaporin-2 water channel trafficking in the collecting duct; causing increased water reabsorption and hyponatremia.
 - The adrenal gland also produces more norepinephrine to increase heart rate; however, prolonged exposure leads to intracellular migration and down-regulation of β -adrenergic receptors; remaining β receptors are less responsive to isoproterenol.
- Neurohormones beneficial in heart failure include the natriuretic peptides made in response to LV dilatation, especially brain natriuretic peptide (BNP). This hormone has natriuretic and vasodilatory properties to counteract the deleterious effects of aldosterone and angiotensin II. BNP levels are elevated in heart failure and become more elevated as they become more symptomatic (New York Heart Association Functional Class increases). Levels may be more elevated in decompensated heart failure compared to the compensated state. Other substances with vasodilatory properties include bradykinin, nitric oxide, and prostaglandins; ACE inhibitors have a secondary effect of blocking bradykinin degradation.
- Once LV dysfunction is present, cytokine over-expression of interleukins and TNF- α promote LV dilatation and remodeling; contributing to the progression of heart failure. Elevated TNF- α levels are found in advanced heart failure, and a trend toward higher mortality with higher TNF- α levels has been observed.
- **Remodeling** is a complex process in response to either acute or chronic injury to cardiocytes. Myocardial remodeling takes longer to develop with different patterns of gene activation for several peptide growth factors. There are two distinct patterns, concentric (increased mass without ventricular dilatation) in pressure overload and eccentric hypertrophy (increased mass and ventricular dilatation) in volume overload. In both cases, wall stress is returned toward normal, at least initially.
- **Concentric hypertrophy**, seen with aortic stenosis or chronic untreated hypertension, is characterized by increased elastic stiffness and an elevated end diastolic pressure (EDP) for a given volume. Pressure overload is characterized by parallel replication of myofibrils and thickening of individual myocytes
- **Eccentric hypertrophy**, as seen with mitral or aortic insufficiency, is characterized by increased ventricular volume but little or no change in elasticity; this results in little increase in pressure at increased volumes. Volume overload results in increased diastolic stress with a series replication of sarcomeres, elongation of myocytes, and ventricular dilatation.
- The term *remodeling* encompasses LV dilatation, eccentric hypertrophy, apoptosis, changes in valvular structure, and arrhythmias.
 - With increase in chamber size, geometry is altered; the LV loses its elliptical shape and develops a more spherical shape. The spherical LV has been associated with higher end-systolic wall stress and abnormal distribution of fiber shortening.
 - Mitral regurgitation, due to misalignment of papillary muscles and subvalvular structures and distortion at the mitral annulus secondary to LV enlargement, frequently accompanies LV remodeling. Left atrial enlargement and pulmonary venous hypertension are frequent sequelae of mitral regurgitation.
 - Electrocardiographic abnormalities and arrhythmias are also common problems in heart failure, including left bundle branch block, P-R interval prolongation, atrial flutter and atrial fibrillation, and ventricular tachycardia (VT). Syncope, an ominous predictor for sudden cardiac death, may be secondary to VT or atrial arrhythmias, with rapid ventricular response.

DIASTOLIC DYSFUNCTION IN HEART FAILURE

- LV diastolic function is dependent on many intrinsic and extrinsic factors. Relaxation can be further divided into the *extent of relaxation* and the *rate of relaxation*. Alterations in the extent, rate, or both characterize the abnormalities of relaxation and result in characteristic hemodynamic patterns.

- **LV compliance and the diastolic left ventricular pressure–volume relationship:** A nonlinear relationship normally exists between pressure and volume during ventricular diastole. Shifts are reflected by a change in slope (LV stiffness) or intercept of the relationship resulting from various disease states.
- **Extent of relaxation** reflects LV compliance and is the major determinant of end-diastolic volume and end-diastolic pressure (EDP). Abnormalities in extent of relaxation affect the end-diastolic pressure–volume (EDP–V) relationship to the greatest extent.
- LV geometry (i.e., thickness, size, and chamber dimension) in large part determines the LV EDP–V relationship, as determined by mathematic approximations based on Laplace’s law. *Coronary vascular turgor* decreases LV diastolic compliance through its erectile effect on LV stiffness by increasing LV wall volume, resulting in a higher EDP for a given volume. This effect seems to be independent of pericardial influences and predominates in the late diastolic filling period.
- **Load-dependent relaxation** phenomena are alterations in elastic properties and the rate of relaxation of the myocardium, mediated via changes in the load sensed by the LV during relaxation. These cause instantaneous changes in LV compliance and the rate of relaxation independent of heart rate when LV muscle is abruptly stretched.
- **Manifestations of viscosity:** The clinical importance of viscoelasticity has been disputed.
 - **Stress relaxation**—a decrease in the distending pressure of the ventricle over time
 - **Creep**—a rightward shift in the diastolic P–V relationship
- LV hypertrophy results in abnormalities of relaxation that are characteristic of the manner in which the hypertrophy developed and of the type of hypertrophy formed. Elevated EDP is seen in chronic pressure overload hypertrophy.
- Ischemia affects the extent of relaxation as evidenced by upward shift in the EDP–V relationship. These effects are independent of pericardial, right ventricular (RV), or lung interactions, implying a change in the intrinsic myocardial elastic properties. As previously discussed, changes in diastolic properties secondary to changes in myocardial Ca^{2+} handling and in hydrogen ion accumulation and repeated systolic stretch of the ischemia segment interact to produce the observed changes.
 - The changes in compliance appear restricted to the region of active ischemia.
 - The remaining normal areas of myocardium appear to utilize the Frank–Starling mechanism to maintain stroke volume (SV) in compensation for the effects of abnormal contractility or an upward shift of the regional diastolic P–V relationship within the ischemic areas.
- In addition, the constraining effect of the pericardium and the degree of ventricular interaction affect the extent of relaxation.
- **Rate of relaxation:** Abnormalities occur early in diastole and therefore do not alter EDP and EDV and tend to have minimal effect on the EDP–V relationship.
 - Changes in the diastolic P–V relationship that depend on the rate at which the LV deforms are known as viscoelasticity, a property that the myocardium shares with most biomaterials. This property is manifest when filling rates are highest, occurring during the first half of diastole or after atrial contraction.

- The determinants of relaxation rate are many, and their interactions complicated. Increases in heart rate and inotropy result in increased rates of relaxation. Alterations in end-diastolic loading conditions result in changes in the rate of relaxation during experimental conditions. Nonuniformity of relaxation refers to distribution of load and electric inactivation during diastole in space and time. Ventricular suction, or the ability of the ventricle to generate pressures below equilibrium diastolic pressures, may alter the rate and extent of LV filling. Ischemia can alter the rate and the extent of relaxation.

Extrinsic Influences on the Diastolic Pressure–Volume Relationship

- External loads can also profoundly influence ventricular compliance properties. Specifically, the RV, the pericardium, and the lungs all may acutely induce shifts of the LV diastolic P–V relationship. It is likely that each of these influences may be exerted when both ventricles are dilated and when the lungs are hyperinflated during ventilator therapy.
- The influence of the pericardium in the diastolic P–V relationship is a function of both its stiffness and its ability to constrain the entire heart. An increase in size of one ventricle therefore causes an increase in the EDP for a given volume (i.e., a shift upward in the P–V relationship) (Fig. 85.4). Although this effect is present with the pericardium open, the coupling is much stronger when it is closed.
- Little normal pericardial effect is observed at normal filling pressures. The constraining effect is dependent on its intrinsic compliance and how it affects LV pressures; dilatation of the LV (i.e., a high LV filling pressure) amplifies the pericardium’s influence.
- The intact pericardium allows interaction between the atria and the LV and between the RV and LV. The effect of left atrial pressure is approximately one-fourth that of the RV pressure in determining the LV diastolic pressure. Ventricular interaction is an important mechanism underlying acute reductions in LV compliance; this may be why improved LV compliance is observed with vasoactive medications that reduce volume return to the RV, such as nitrates.
- Acute pulmonary hypertension alters LV geometry and upward shifts the LV diastolic P–V relationship with changes in RV afterload, largely mediated via a reduction in the LV septum to the free wall dimension and an increase in intrapericardial pressure. The LV septal/free wall axis appears disproportionately reduced when compared with either the base-to-apex or the anteroposterior axis.
- The special case of acute right ventricular failure: The established mechanisms for acute RV failure are shown in Table 85.1. An inverse relationship between RV stroke volume and pulmonary input resistance, vascular load, has been demonstrated. The RV tolerates up to triple the normal pulmonary artery pressure (PAP) by both the heart rate (chronotropic) response and the Frank–Starling mechanism (preload reserve) to maintain cardiac output. ATP and creatine phosphate levels are normal up to this point (Table 85.2); further increases in PAP create afterload mismatch with a disproportionate increase in end-systolic volume compared with end-diastolic volume (i.e., stroke volume and ejection fraction decrease as

FIGURE 85.4. Diastolic portions of left ventricular pressure-area loops. Representative loops are depicted during both control and a microvascular injury (MVI) of the lungs at different right ventricular preloads or right ventricular end-diastolic pressures of 5, 10, and 15 mm Hg. The loops during both control and MVI are shifted upward by increasing right ventricular end-diastolic pressure (RVEDP), although left ventricular end-diastolic area is reduced at a given RVEDP during MVI.

a result). At this particular point, the RV is performing largely pressure work and very little flow work.

- As the RV dilates within an intact pericardium, RV end-diastolic pressure increases the intrapericardial pressure. This external pressure is exerted on the LV and affects its distensibility; this effect is independent of any change in heart rate.

- The transeptal pressure gradient decreases or, in fact, reverses with leftward shift of the septum further impairing LV filling. There is an inverse relationship between the transeptal pressure gradient and the LV septal-free wall dimension.

Evaluation and Treatment

TABLE 85.1

CAUSES OF RIGHT VENTRICULAR FAILURE

Increased pressure load

Pulmonary embolism
 Pulmonary disease (hypoxic pulmonary vasoconstriction, destruction of pulmonary vascular bed)
 Chronic airflow obstruction (emphysema, chronic bronchitis)
 Interstitial lung disease
 Neuromuscular chest wall restriction
 Primary pulmonary hypertension
 Elevated pulmonary venous pressure
 Left ventricular failure
 Mitral stenosis and insufficiency
 Adult respiratory distress syndrome
 Positive-pressure ventilation
 Pulmonic valve stenosis

Increased volume load

Atrial septal defect
 Ventricular septal defect
 Tricuspid valve insufficiency

Decreased contractility

Ischemia
 Right coronary artery occlusion
 Systemic hypotension (poor right coronary perfusion)
 Right ventricular contusion (chest trauma)
 Mediastinal radiation
 β -Blockade

- Growing public health and economic concerns have led to publication of guidelines by the Heart Failure Society of America, joint guidelines by the American Heart Association and the American College of Cardiology, with endorsement of the latter by the Heart Rhythm Society (Fig. 85.5).
- Treatment goals are set for Stage A (at risk), Stage B (asymptomatic abnormalities in cardiac structure and function), and Stages C and D with overt heart failure.
- The guidelines also give recommendations for initial evaluation of patients with both systolic and diastolic heart

TABLE 85.2

MYOCARDIAL ADENOSINE TRIPHOSPHATE AND CREATINE PHOSPHATE IN OPEN PERICARDIA EXPERIMENTS ($N = 8^a$)

	ATP ($\mu\text{mol/g}$ wet weight)	CP ($\mu\text{mol/g}$ wet weight)
Baseline	5.52 ± 1.33	9.49 ± 3.24
Doubling of mean PAP	5.41 ± 1.28	8.78 ± 3.28
Tripling of mean PAP	5.12 ± 0.60	9.19 ± 1.20
RVF	3.63 ± 1.73^b	3.11 ± 3.22^b

ATP, adenosine triphosphate; CP, creatine phosphate; PAP, pulmonary artery pressure; RVF, right ventricular failure.

^a $p < 0.05$, compared with baseline and doubling and tripling of mean PAP.

^b Values are expressed as mean \pm standard deviation.

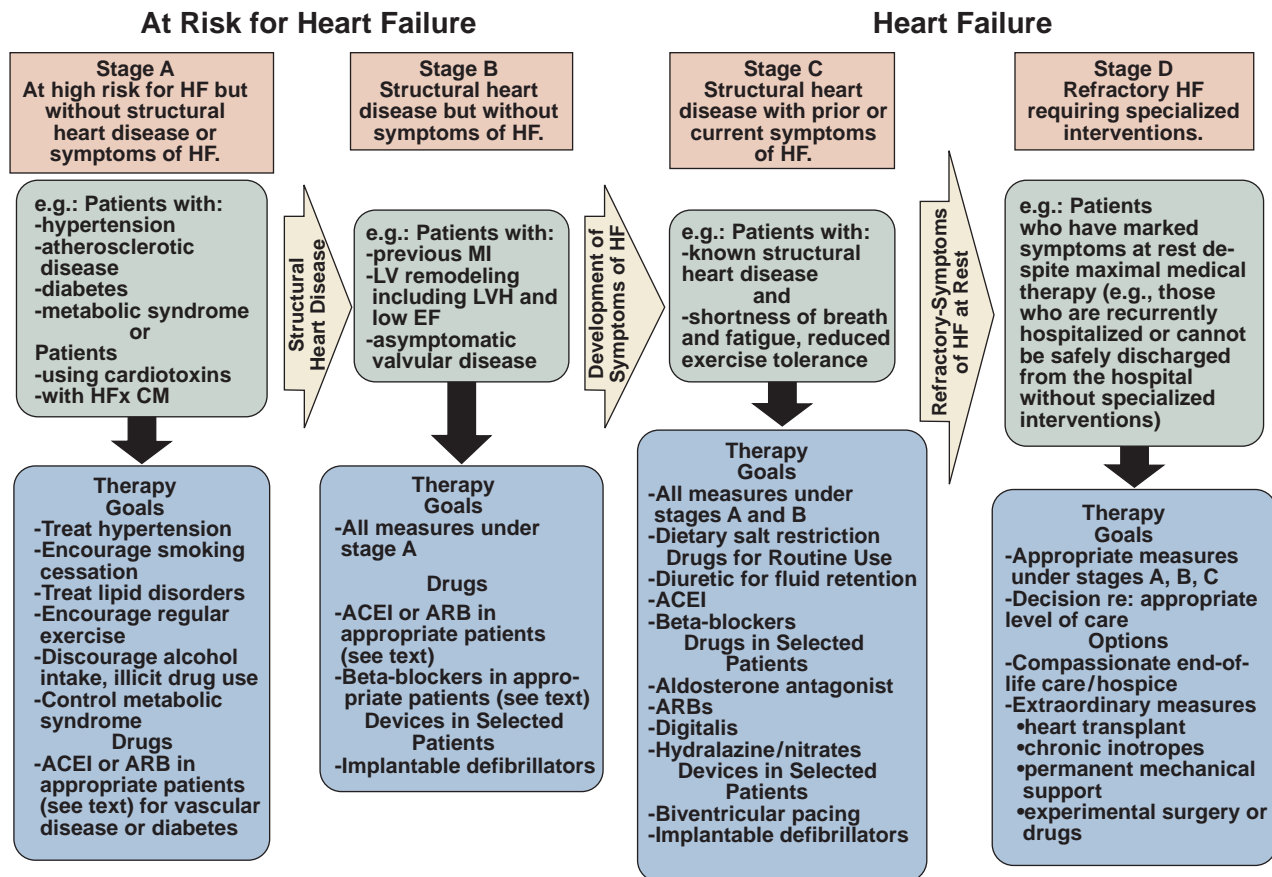

FIGURE 85.5. American College of Cardiology/American Heart Association 2005 guideline update for the diagnosis and management of chronic heart failure in the adult—summary article. A report of the American College of Cardiology Heart Association, Task Force in Practice Guidelines. (Writing Committee to Update the 2001 Guidelines for the Evaluation and Management of Heart Failure. *J Am Coll Cardiol.* 2005;46:1116–1143.)

failure, chronic outpatient management for the wide range of New York Heart Association (NYHA) classes, and inpatient management of acute decompensated heart failure (ADHF).

- Initial evaluation—patients presenting with new-onset heart failure—should have a thorough history and physical examination, with special attention to risk factors and noncardiac disorders that may aggravate their condition. Behaviors or therapies that may cause heart failure or exacerbate LV dysfunction should also be sought.
- Twelve-lead electrocardiogram, complete blood count, blood urea nitrogen, creatinine, electrolytes, fasting lipid panel and glucose, hemoglobin A_{1C} in diabetics, and thyroid-stimulating hormone, should be obtained; baseline BNP may be useful.
- If common etiologies are not present, test for HIV, hemochromatosis, sleep apnea, amyloidosis, pheochromocytoma, and rheumatologic disorders. Endomyocardial biopsy should be considered only if the results would influence therapy.
- Posteroanterior and lateral chest radiographs and echocardiography assess for pulmonary congestion, LV dimensions, LVEF, LVH, and valvular and wall motion abnormalities. Radionuclide ventriculography may also be performed to assess LVEF, LV volumes, and RV ejection fraction.

- In patients with angina pectoris or ischemia, coronary angiography should be performed unless contraindicated to evaluate for revascularization. Noninvasive imaging to determine myocardial viability is reasonable in patients with known coronary disease but without angina.

Prognosis in Heart Failure

- The overall 5-year survival is 50%, whereas the 1-year survival for end-stage heart failure is 75%. Negative prognostic factors include the presence of an S₃, low pulse pressure, elevated jugular venous pulse, and high NYHA class. Other important comorbidities include diabetes mellitus, renal insufficiency, and depression.
- Cardiac testing plays an important role in prognostication:
 - EF is a very important marker for prognosis and as a target for new therapies such as implantable cardioverter defibrillator (ICD) and biventricular pacing.
 - Peak oxygen consumption is an objective prognostic measurement (Fig. 85.6); mortality rates vary from 20% per year if peak VO₂ is ≥14 but <18 mL/kg/minute to 60% per year if peak VO₂ is ≤10 mL/kg/minute.
 - Distance covered in the 6-minute walk is predictive of morbidity and mortality.

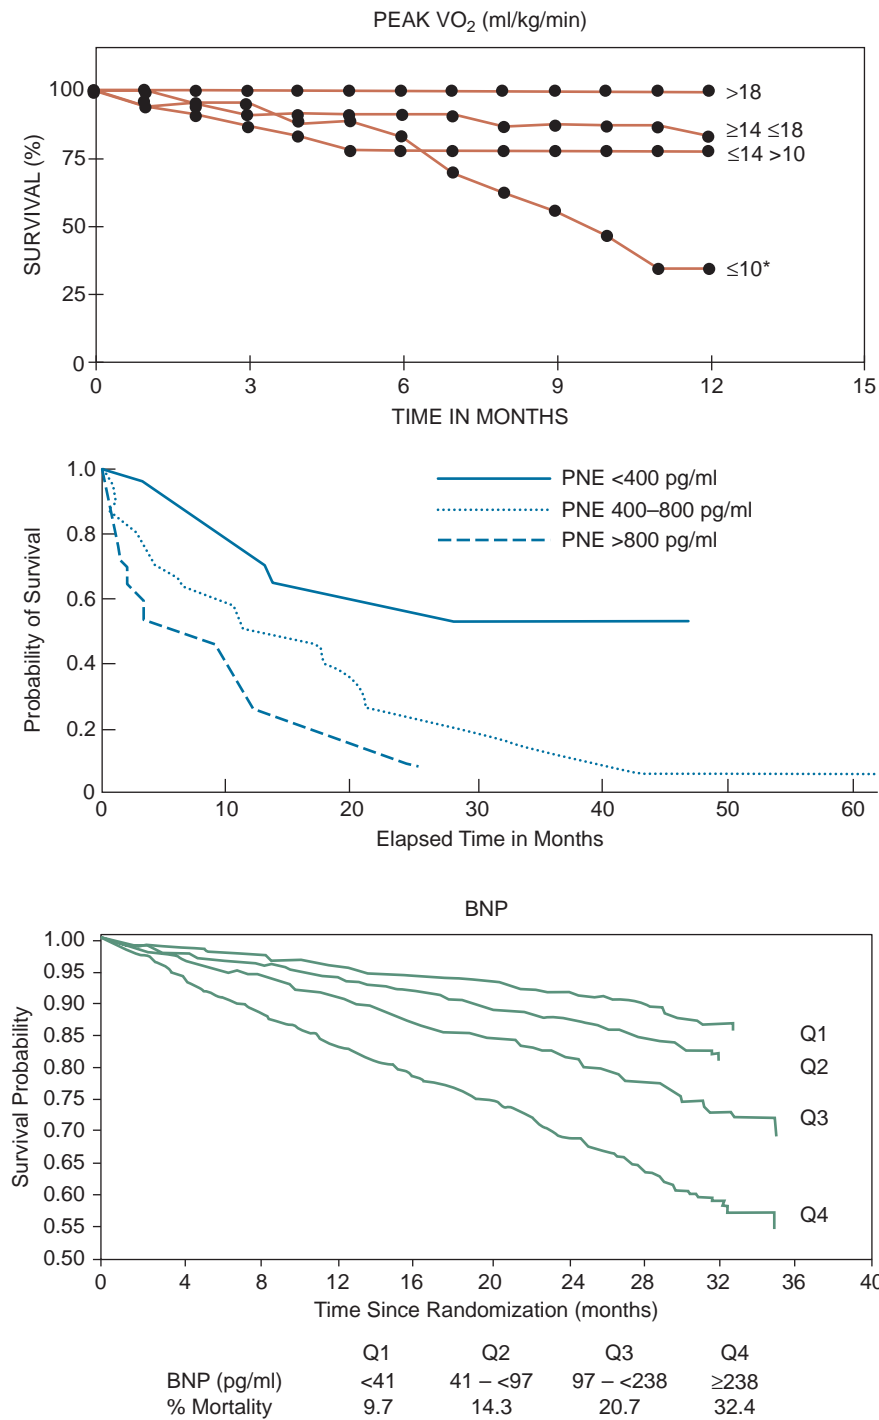

FIGURE 85.6. Survival curves for heart failure patients by peak VO₂ (upper panel), plasma norepinephrine (middle), and brain natriuretic peptide (BNP, lower panel). Survival is best with peak VO₂ >18 mL/kg/min, plasma norepinephrine <400 pg/mL, and BNP <100 pg/mL. (Reproduced from Mancin DM, Eisen H, Kausmaul W, et al. *Circulation*. 1991;83:778–786; Cohn JN, Levin B, Olivari MT, et al. *N Engl J Med*. 1984;311:819–823; and Anand IS, Fisher LD, Chiang Y, et al. Changes in brain natriuretic peptide and norepinephrine over time and mortality and morbidity in the Valsartan Heart Failure Trial (Val-HeFT) *Circulation*. 2003;107:1278–1283.)

- Hemodynamic variables measured at catheterization, such as cardiac index, systemic and pulmonary vascular resistances, PAP, and pulmonary capillary wedge pressures, are important indicators of prognosis and aid diagnosis. Stroke work index is an especially important predictor, as it incorporates both flow and pressure work.
- Inverse relationships exist between survival and plasma norepinephrine, renin, vasopressin, aldosterone, atrial and B-type natriuretic peptides, and endothelin-1 (see Fig. 85.6). Plasma norepinephrine, pro-BNP, and BNP are independent factors affecting prognosis, but only BNP has become a routine laboratory test in suspected heart failure patients
- Multivariate models can be used in critically ill patients to assess the severity of acute decompensated heart failure.
- Acute Physiology and Chronic Health Evaluation (APACHE) II score predicts mortality in acute heart failure and after ventricular assist device implantation (Fig. 85.7); survivors had lower APACHE II scores than nonsurvivors.
- The Acute Decompensated Heart Failure Registry acuity model for heart failure identifies three predictors: blood urea nitrogen ≥43 mg/dL, serum creatinine >2.5 mg/dL, and systolic blood pressure (SBP) <115 mm Hg to partition patients into one high-risk group (three factors present,

FIGURE 85.7. Kaplan-Meier survival curves for non-left ventricular assist device (LVAD)-treated heart failure patients demonstrates a strong relationship between survival and APACHE II scores (**left panel**) and survival curves for heart failure patients with APACHE II scores between 11 and 20 for both LVAD and non-LVAD-treated patients (**right panel**). (Right panel from Gracin N, Johnson MR, Spokes D, et al. The use of Apache II scores to select candidates for left ventricular assist device placement. *J Heart Lung Transplant.* 1998;17:1017–1023.)

crude mortality 21.9%), three intermediate-risk groups (varying combinations of risk factors present, crude mortality 5.5%–12.4%), and one low-risk group (no risk factors present, crude mortality 2.14%).

THERAPEUTIC TRIALS AND FINDINGS

Angiotensin-converting Enzyme Inhibitors

- ACE inhibitors are the foundation therapy for heart failure as they delay development of both heart failure symptoms and hospitalizations and increase survival. ACE inhibitors should be prescribed for all patients with asymptomatic LV systolic dysfunction and asymptomatic valvular heart disease (stage B) and in patients with symptomatic and/or refractory heart failure (stages C and D) unless the patient is intolerant to ACE inhibitors. In stage A patients, ACE inhibitors are indicated for those with diabetes mellitus and LVH. Patients experiencing angioedema, intolerable cough, or other untoward effects of ACE inhibitors should be prescribed angiotensin II receptor blockers (ARBs).
- ACE inhibitors increase survival in patients with LV systolic dysfunction (LVEF $\leq 35\%$) and symptoms of heart failure, especially NYHA class IV, by reducing progression of disease. They also improve NYHA functional class with treatment.
- Asymptomatic patients with LV dysfunction have a reduced risk in the combined end point of death plus development of heart failure with ACE inhibitors and fewer hospitalizations for heart failure or death.
- In acute myocardial infarction (MI) with LV systolic dysfunction (LVEF $< 40\%$), ACE inhibitors decrease all-cause mortality, the development of severe heart failure, fatal and

nonfatal major cardiovascular events, congestive heart failure end points requiring hospitalization, and recurrent MIs.

- Trials of ACE inhibitors in survivors of MI showing improved survival with the ACE inhibitors and less development of LV systolic dysfunction.

Angiotensin II Receptor Blockers

- ARBs are better tolerated with less cough but have no difference on all-cause mortality, sudden death, or increases in serum creatinine compared to ACE inhibitors. ARBs decrease cardiovascular death or admission to hospital for heart failure in patients intolerant to ACE inhibitors. Combination therapy with ACE inhibitors has the most drug-related adverse events.
- In chronic heart failure and in heart failure after MI (LVEF $< 40\%$ and NYHA classes II through IV heart failure), ARBs may decrease the combined end point of mortality and morbidity in addition to ACE inhibitors or β -blockers. For those already on ACE inhibitors but still experiencing heart failure symptoms, ARBs decrease the combined outcome of cardiovascular death or hospitalization for heart failure.
- With preserved LV systolic dysfunction (NYHA classes II through IV and baseline LVEF $> 40\%$) there is no benefit of ARB therapy in terms of cardiovascular death or admission to hospital for heart failure.

β -Adrenergic Receptor Antagonists

- β -Blockers, in addition to ACE inhibitors, decrease LV size and improve EF. However, not just any β -blocker can be used in heart failure patients.

- Carvedilol, a nonselective β -blocker and an α -blocker, decreases hospitalization and improves quality of life in patients with NYHA classes II and III heart failure. In patients with severe heart failure (LVEF of $<25\%$ and NYHA classes IIIB to IV) already receiving standard heart failure therapy (ACE inhibitors or ARBs plus diuretic), carvedilol reduces mortality and the combined end point of death or hospitalization. After acute MI with LV dysfunction, it reduces all-cause mortality, cardiovascular mortality, and recurrent, nonfatal MIs.
- Selective β_1 antagonists, bisoprolol and extended-release metoprolol, decrease all-cause mortality and sudden death in symptomatic heart failure patients. Short-acting metoprolol does not have the same affect on survival.
- Bucindolol, a nonselective β -blocker and a weak α -blocker, does not improve survival. This is possibly due to its sympatholytic activity, which decreases norepinephrine levels. Bucindolol appears to worsen mortality in African Americans and those with NYHA class IV versus class III heart failure.

Aldosterone Receptor Antagonists

- ACE inhibitors may only transiently suppress aldosterone production. As aldosterone promotes retention of sodium, sympathetic activation, inhibition of the parasympathetic nervous system, myocardial and vascular fibrosis, and loss of magnesium and potassium, blockade of aldosterone receptors may alter progression of LV dysfunction. Spironolactone in addition to standard therapy decreases mortality, though use is limited by hyperkalemia and renal insufficiency.

Other Vasodilators

- When digoxin and diuretics were the standard of care, vasodilators were explored as therapeutic options in heart failure. Prazosin 20 mg/day was equivalent to placebo; however, the combination of hydralazine (300 mg/day) and isosorbide dinitrate (160 mg/day) reduced mortality.
- This combination was later compared to and found inferior to ACE inhibitor therapy, especially in Caucasians.
- African Americans have similar survival with ACE inhibitors and combination vasodilator therapy, possibly due to a less active renin-angiotensin system and lower NO bioavailability than other racial groups. Combination therapy—hydralazine plus isosorbide dinitrate—improves survival in NYHA classes III and IV African Americans who remain symptomatic with heart failure despite standard therapy, including ACE inhibitors or ARBs in ACE-intolerant patients, β -blockers, digoxin, spironolactone, and diuretics.

Digoxin

- After acceptance of ACE inhibitors for heart failure, the efficacy of digoxin became controversial. However, in the era prior to β -blockers, digoxin was shown to be efficacious for treatment of heart failure.
- When digoxin is withdrawn from patients managed with either diuretics or diuretics and ACE inhibitors, however, maximal exercise and functional capacity worsens, treatment failure increases, time-to-treatment failure

decreases, LV EF decreases, and both weight and heart rate increase.

- In patients with LV EF $<45\%$ on diuretics and ACE inhibitors, the addition of digoxin has no effect on mortality but decreases total hospitalizations and hospitalizations for worsening heart failure.

ACUTE DECOMPENSATED HEART FAILURE

- ADHF has a variety of presentations; common symptoms include fatigue, shortness of breath, and congestion of the lungs and abdominal organs that can mimic other disease states. Patients with preserved systolic function and systemic hypertension comprise the majority of hospitalized patients; a minority have poor end-organ perfusion, low EF, and hypotension. Despite advances in therapeutics, both pharmacologic and devices, risk of death, and rehospitalization remain high.
- Hospitalization constitutes the bulk of the cost in caring for patients with heart failure.
- BNP is a useful diagnostic test as values over 400 (normal range: 0–100 pg/mL) have a high probability for heart failure, whether systolic or diastolic in origin.
- The Heart Failure Society of America guidelines recommend hospitalization for altered mentation, worsening renal function, hypotension, resting dyspnea, hemodynamically significant arrhythmias, and acute coronary syndromes. Hospitalization should be considered when congestion has worsened with evidence of weight gain of ≥ 5 kg, and when there are signs and symptoms of abdominal or pulmonary congestion, even in the absence of weight gain. Other considerations include major electrolyte abnormalities, repeated ICD discharges, and associated comorbid conditions.
- Blood urea nitrogen level >43 mg/dL at admission is the best single discriminator between survivors and nonsurvivors of hospitalization for ADHF. The second best predictor is SBP <115 mm Hg.
- Use of pulmonary artery catheters to help guide clinical management may not improve hospital mortality or length of stay in either the intensive care unit or in hospital and are associated with complications including hematoma at the insertion site, arrhythmias, and infection. When used, nesiritide is more effective than nitroglycerin to lower pulmonary capillary wedge pressure from baseline.
- Current guidelines for inpatient management of ADHF include identification of precipitating factors and etiology, optimizing volume status, treating with recommended vasodilator therapy, and minimizing side effects. Educating patients about lifestyle changes, including sodium and fluid restriction, and self-management techniques are recommended general measures. Precipitating factors include development of arrhythmias, acute infections, and nonadherence with medications and dietary restrictions.
- Optimization of medical therapy involves daily weights and accurate recordings of intake and output. Intravenous (IV) loop diuretics are recommended; with inadequate diuresis continuous IV infusion of loop diuretics or addition of other diuretics, such as metolazone, should be considered. In those not responding to the foregoing measures and without symptomatic hypotension, IV nitroglycerin, nitroprusside, or nesiritide may be used additionally.

- IV inotropes should be reserved for those with advanced heart failure and evidence of end-organ dysfunction and/or decreased peripheral perfusion, especially if SBP is <90 mm Hg.
- Ultrafiltration is an alternative to diuretics for volume removal, does not require central venous access, and can be performed through a 16-gauge 35-cm peripheral catheter. It is well tolerated and can also be used in conjunction with diuretics.

NONPHARMACOLOGIC AND NONSURGICAL THERAPY FOR CHRONIC HEART FAILURE

- Electrophysiologic therapy is a new addition to the heart failure management arsenal and is having enormous impact. Combination therapy with defibrillators and biventricular pacing reduces mortality to a greater degree in ischemic versus nonischemic cardiomyopathy.
- Automatic implantable cardioverter defibrillators were first shown to be effective at improving long-term survival after symptomatic VT or cardiac arrest, in ischemic cardiomyopathy with EF <30%, and asymptomatic inducible VT. Other indications include nonischemic cardiomyopathy patients with QRS duration >120 msec, with LVEF <35%, and having had an admission for heart failure in the previous year.
- Indications for automatic implantable cardioverter defibrillators for primary prevention of sudden cardiac death in heart failure are:
 - Prior MI \geq 40 days old, with EF 30% to 40%, and NYHA class II or III on optimal therapy.
 - Prior MI \geq 40 days old, with EF 30% to 35%, and NYHA class I on optimal therapy.
 - Nonischemic cardiomyopathy, with EF 30% to 35%, and NYHA class II or III on optimal therapy.
- Biventricular pacing is achieved by implantation of a LV lead, generally via the coronary sinus to the great cardiac vein, in addition to a RV lead. This strategy is based on the fact that most patients with intraventricular conduction delay have dyssynchronous LV contraction, which reduces cardiac efficiency (decreased contractile force and impaired myocardial energetics).
 - It improves NYHA class, exercise tolerance, dp/dt, EF, cardiac index, and mortality.
 - Cardiac resynchronization reverses remodeling the LV.

CARDIAC TRANSPLANTATION AND LEFT VENTRICULAR ASSIST DEVICES

- When patients continue to experience advanced heart failure symptoms despite maximization of medical therapy, cardiac transplantation and left ventricular assist devices (LVADs) may be considered.
- There are currently three LVADs available for use in the United States.
 - The Abiomed system is available for temporary use as either right, left, or biventricular assist systems. It is most commonly used after high-risk coronary artery bypass surgery in patients who fail to wean from the cardiopulmonary bypass machine. Cannulae are placed in the atria, and the pumps

are external to the body. Because the cannulae are implanted in the atria, removal is feasible should the patient recover. Additionally, one ventricular system may be removed at a time; this system requires full anticoagulation.

- The Thoratec Heart Mate device is approved for use as a bridge to transplantation and as destination therapy in those not considered transplant candidates. The outflow cannula is placed in the proximal ascending aorta, and the inflow cannula is placed in the LV apex. Cannulae are named with respect to the pump that is commonly implanted in the left upper abdominal quadrant preperitoneally. This device does not require anticoagulation, although antiplatelet therapy with aspirin is recommended.
- The World Heart LVAD is implanted in a fashion similar to that of the Heart Mate device and is currently approved by the Food and Drug Administration as a bridge to transplantation. Currently, a clinical trial is under way for its potential use as destination therapy. This device requires full anticoagulation with warfarin, aspirin, and clopidogrel.
- There have been 40,192 cardiac transplantation procedures between 1988 and August 31, 2006; 2,125 of these procedures were performed in 2005. Kaplan–Meier survival rates for heart transplantation procedures performed between 1997 and 2004 ranged from 85.7% to 90.6% at 1 year; 75.2% to 81.8% at 3 years; and 68.8% to 72.6% at 5 years. Ranges are given as the data were based on the United Network of Organ Sharing status at the time of transplantation.
- Criteria to be considered for transplantation include advanced symptoms despite maximization of medical therapy—including tailoring therapy via hemodynamic monitoring with pulmonary artery catheterization—and a peak oxygen consumption <15.0 mL/kg/minute during exercise testing.
- Exclusion criteria include fixed pulmonary hypertension with >4 Wood units not responsive to vasodilator therapy; tobacco, alcohol, or illicit drug use; other life-threatening illnesses such as cancer or advanced peripheral arterial disease; noncompliance with physician visits, diet, and medications; psychiatric or personality disorders likely to become exacerbated by, or that would interfere with, posttransplant care; and lack of social support.

THERAPEUTIC GUIDELINES FOR SYMPTOMATIC LEFT VENTRICULAR SYSTOLIC DYSFUNCTION

- Polypharmacy has become standard therapy for patients with symptomatic systolic dysfunction.
- ACE inhibitors are recommended for all patients; those with contraindications (other than renal insufficiency or hyperkalemia) or intolerable side effects should be treated with ARBs. After the introduction of ACE inhibitor or ARB therapy, β -adrenergic receptor blockade should be started consisting of either carvedilol or long-acting metoprolol (Toprol XL).
- β -Blockers should be instituted in patients with euvolemia, starting with low doses and titrating the dose up every 2 weeks as tolerated, to doses achieved in clinical trials; achievement of these doses may take 8 to 12 weeks. For patients being discharged from the hospital with ADHF,

low-dose β -blockers may be instituted in-hospital once euvolemia has been achieved. In patients on stable doses of β -blockers who then experience an acute decompensation requiring hospitalization, continuation of β -blocker therapy is recommended.

- Aldosterone antagonists are recommended for patients with NYHA class III or IV symptoms in addition to standard therapy, including diuretics. They are not recommended in patients with creatinine clearance <30 mL/minute, serum potassium >5.0 mmol/L, or serum creatinine >2.5 mg/dL. Guidelines recommend frequent monitoring of serum potassium levels after initiation of or change in dose of aldosterone antagonists.
- Hydralazine and oral nitrate combination may be considered in those not tolerating ACE inhibitors or ARBs. The combination of hydralazine and oral nitrates is recommended for African American patients—in addition to ACE inhibitors and β -blockers—who remain NYHA class III or IV despite these drugs.

- Loop and distal tubule diuretics should be viewed as necessary adjuncts to relieve sodium and water retention.
- Guidelines recommend that digoxin should be considered for symptomatic patients receiving standard therapy and that the dose should be 0.125 mg in the majority of patients. Serum digoxin level should be <1.0 ng/mL.
- Amiodarone and other antiarrhythmic medications should not be used for primary prevention of sudden death, but amiodarone may be considered in those with ICDs to decrease the frequency of repetitive ICD discharges should this become an issue.
- Patients with mild heart failure symptoms (NYHA class II) should restrict their sodium intake to 2 to 3 g daily. Those with more advanced symptoms (NYHA classes III to IV) should restrict their sodium intake to 2 g daily. Patients with severe hyponatremia—serum sodium <130 mEq/L—should restrict their fluid intake to <2 L/day, as should individuals in whom fluid balance is difficult to maintain despite sodium restriction and high-dose diuretics.

CHAPTER 86 ■ CARDIAC MECHANICAL ASSIST DEVICES

Cardiac mechanical assist devices are used during periods of hemodynamic instability and persistent low cardiac output in an attempt to restore normal hemodynamic parameters and preserve vital organs. There is a stepwise progression of therapy with respect to cardiac assist interventions beginning with inotropic and vasodilator drugs, then intra-aortic balloon pump, and ultimately mechanical ventricular assist device (VAD) placement. In this chapter, we briefly discuss these devices with special emphasis on their indications, contraindications, placement, complications, and potential pitfalls.

INTRA-AORTIC BALLOON PUMP

- Indications: 10% to 15% of acute myocardial infarctions have shock that may require temporary hemodynamic support with an intra-aortic balloon pump (Fig. 86.1). Other indications include unstable angina, prophylaxis for high-risk surgery or percutaneous coronary intervention, acute mitral insufficiency, ventricular septal rupture after an ischemic event, postcardiotomy failure: inability to separate patient from cardiopulmonary bypass after cardiac surgical procedure, and traumatic myocardial contusion with low cardiac output.
- Contraindications:
 - *Aortic insufficiency*: Leaking of the aortic valve makes the use of an intra-aortic balloon pump potentially detrimental. During periods of diastolic augmentation, enhanced reversal of flow actually exacerbates the aortic insufficiency.

- *Atheromatous aorta*: Patients who are known to have severe atheromatous disease of the aorta are poor candidates for balloon pump therapy. There is the risk of atheroembolization, either distally or retrograde into the cerebral vasculature, during pump use or manipulation.
- *Severe peripheral vascular disease or aortic dissection*: The balloon pump is typically inserted in a retrograde fashion from the groin. This relative contraindication of peripheral vascular disease can be overcome by the use of alternate insertion techniques.

Techniques of Insertion

- The most commonly used method of intra-aortic balloon pump insertion is via the retrograde approach from percutaneous access to the femoral artery (Fig. 86.2) with or without a vascular sheath. When a groin incision is present related to coronary artery bypass cannulation or some other intervention, it is possible to insert the balloon pump via direct arterial access.
- For patients who have their balloon pump for an extended period of time or need to ambulate during balloon pump use, the balloon pump may be placed directly through the axillary artery. A sheath is not routinely used for placement. In more extreme circumstances, such as coexisting peripheral vascular disease and postcardiotomy failure, placement may require an antegrade approach either directly into the arch or through a small graft sewn onto the ascending aorta or arch and tunneled to the chest wall.

FIGURE 86.1. Intra-aortic balloon pulsation (IABP). Example of standard 7.5 French 40-mL IABP.

Verification of Location

- The balloon pump should be positioned just distal to the left subclavian artery in the descending thoracic aorta (Fig. 86.3). The location may be verified by fluoroscopy, chest roentgenogram, or transesophageal echocardiography if performed concurrently with balloon pump insertion. The tip should be high in the left chest in appropriate relation to the aortic arch.
- Also important is selecting the appropriate-sized balloon pump for the patient. They range in size from those appropriate for a small infant to those used in large adults (Fig. 86.4). The standard adult size is 40 mL; the manufacturer's labeling, recommendations, and the patient's habitus should be considered.

Mechanism of Action

- There are two complementary effects of an intra-aortic balloon pump. Both of these mechanisms augment left ventricular function and serve in complementary fashion to help those patients with right ventricular dysfunction.

FIGURE 86.3. Chest radiograph showing intra-aortic balloon pulsation (IABP) device in place. Marked distal tip of IABP.

FIGURE 86.2. Intra-aortic balloon pulsation (IABP). Insertion from femoral approach. A: Artery is accessed and wire advanced. B: Sheath inserted over wire. C: IABP advanced over wire and through sheath to appropriate level.

FIGURE 86.4. Different sizes of intra-aortic balloon pulsation (IABP) devices.

- The first is the diastolic augmentation of coronary blood flow. The balloon pump is carefully timed to the cardiac cycle so that the pump inflates during aortic valve closure and thus enhances the diastolic pressure in the proximal aorta. This allows increased coronary blood flow and enhanced myocardial oxygen delivery.
- The second action involves the afterload reduction at the time of cardiac systole, thereby allowing enhanced runoff for the failing ventricle. The balloon should be properly timed to deflate during aortic valve opening, thereby creating a pocket of reduced afterload and thus enhancing the ability of the heart to eject the blood during systole. This action serves to lower the left ventricular end systolic volume.
- It is a common misperception that a balloon pump is not beneficial or indicated, for right ventricular dysfunction. In clinical practice, patients with right ventricular dysfunction benefit from the diastolic augmentation of coronary blood flow in the right coronary artery. Additional benefit is derived from the reduced left ventricular end-diastolic pressure and left atrial pressure, thereby allowing increased forward flow and decreased afterload for the failing right ventricle.

Complications

- Although complications related to balloon pump insertion and use are relatively infrequent, they can be quite serious.
- During insertion of the balloon pump, direct trauma to the arterial insertion site may occur. It is important that insertion occurs relatively high in the thigh in the femoral artery, near the inferior edge of the inguinal ligament. A misplaced balloon may shear off a major arterial branch, and placement through a smaller-caliber artery may cause complete occlusion and ischemia. In arteries that are not particularly calcified, the balloon pump may be placed without a vascular sheath, which reduces the maximal diameter of obstruction in the artery and perhaps reduces the potential for thrombus.
- Improper proximal location of the balloon pump risks impingement of the arch vessels, causing cerebral ischemia from atheroembolization or thromboembolism from micro-

thrombi forming on the balloon pump itself. When too distal, the pump may impede the visceral arteries.

- When it is placed as part of a cardiopulmonary bypass procedure, blood is equally oxygenated in the arterial and venous vessels, and there is no pulsatile flow at the time of insertion. This makes differentiating artery from vein difficult and has led to inadvertent placement of balloon pumps via the femoral vein into the right atrium. Hemodynamic instability at the time of insertion may also lead to suboptimal confirmation of balloon pump location.
- In more chronic management of the balloon pump, ranging from several days to weeks or months, infectious complications become more predominant. In addition to meticulous sterile insertion techniques, balloon pumps also require daily attention from the nursing staff. Attention to the insertion site for signs of erythema or purulence and close monitoring of the patient's temperature are mandatory. When a patient's hemodynamic status fails to stabilize with balloon pump therapy, a VAD is the next course of progressive therapy.

VENTRICULAR ASSIST DEVICES

Preoperative Considerations

- Indications for VADs include unstable hemodynamic measurements and failure to stabilize measurements with other less-invasive therapies. Common hemodynamic parameters for device placement are listed in Table 86.1.
- In the preoperative assessment, determine the likelihood that right ventricular support will be needed as a course of therapy. Several scoring systems are commonly used; most center on the calculation of right ventricular stroke work and other hemodynamic indices.
 - Use caution if the central venous pressure is greater than the pulmonary capillary wedge pressure or if the patient's central venous pressure is >20 mm Hg after optimization.
 - Dependence on the right ventricle to support a left-sided device in such instances may prove to be difficult. Patients who are very debilitated at the time of implantation, with organ deterioration (elevated liver enzymes, abnormal coagulation parameters, and renal dysfunction) caused by right heart dysfunction, are more likely to require right-sided support devices.
- Select the device based on the goal of therapy; devices may be implanted as a *bridge to recovery*, a *bridge to transplantation*, or as a *destination therapy*.

TABLE 86.1

HEMODYNAMIC PARAMETERS SUGGESTING NEED FOR MECHANICAL SUPPORT

Hemodynamic parameters	Values
Pulmonary capillary wedge pressure	>20 mm Hg
Central venous pressure	>20 mm Hg
Cardiac index	<2.0 L/m ²
Mean arterial pressure	<60 mm Hg

- The lines between bridge to recovery and bridge to transplantation can sometimes become blurred when the neurologic status of patients cannot be defined prior to implantation. These patients have been termed *bridge to decision*, where a short-term device may be appropriate to stabilize hemodynamics until the neurologic status and overall candidacy for transplantation are better elucidated.
- Destination therapy refers to permanent device implantation, intended to remain in use for the duration of the patient's lifetime for patients who are not transplant candidates because of age or end organ dysfunction.

Preparation of the Patient

- Before the operative implantation of the VAD, it is often useful to have a period of volume optimization, or a preoperative “tune-up.” This is done to ensure that right ventricular function is as well preserved as possible for placement of a left VAD.
- This may include diuretic and inotropic therapy. In cases where the decision for biventricular support is difficult, a 24- to 48-hour period of intra-aortic balloon pumping may be a useful prognostic indicator. This helps to demonstrate the response of the right ventricular function to a reduced left ventricular end-diastolic pressure.
- During this period of optimization, it is ideal to use an arterial pressure monitor and a pulmonary artery catheter to allow fine tuning of medications and volume status.
- Antimicrobial prophylaxis is essential during the period of preoperative optimization. This usually involves selective skin decontamination with Hibiclens scrub; additionally, Bac-troban (mupirocin) is often used to reduce the number of pathogens in the nasal passages.
- Red cell augmentation may be performed in semielective implants, as frequently there is a 5- to 7-day delay before implantation. Erythropoiesis-stimulating drugs, such as erythropoietin, can be combined with iron supplementation to achieve a significant increase of hematocrit.

Classification of Ventricular Assist Devices

- Flow type
 - **Pulsatile:** In these devices, the intermittent relocation of a pusher plate or blood sack emits a pulsatile wave similar to that of the natural heart (Fig. 86.5).
 - **Axial flow:** The term *nonpulsatile* is frequently applied to these devices, although this is a misnomer. These pumps actually have a central blade that rotates at a rapid rate, similar to a jet engine in an airplane (Fig. 86.6). The native function of the left ventricle does intermittently augment the inflow to the pump, which generates a pulsatile output at appropriate speeds.
 - **Centripetal flow:** These pumps have a continuous spinning impeller that generates a flow similar to axial pumps. However, the more advanced pumps, currently in development, may be magnetically levitated to function without bearings (Fig. 86.7).
- Mechanism
 - **Pneumatic:** These pumps are operated by air, where intermittent external application of compressed gas through a tube to a blood sac emits the pulse of the pump (Fig. 86.8).

FIGURE 86.5. HeartMate XVE, an example of a pulsatile pusher plate device. (Thoratec Corp, Pleasanton, CA, with permission.)

FIGURE 86.6. HeartMate II, an example of an axial flow device. (Thoratec Corp, Pleasanton, CA, with permission.)

FIGURE 86.7. WorldHeart Levacor, magnetically levitated, centrifugal pump (in development).

- **Electric:** Electric pumps are driven by batteries or alternating current via an adapter. They may have the axial flow motor or the pusher plate-driven motor.
- **Location**
 - **Paracorporeal:** These pumps are placed outside of, but in continuity with, the body, usually connected via transcatheter cannulas that are surgically implanted into the heart (Figs. 86.8 and 86.9).
 - **Intracorporeal.** This term typically refers to those pumps that are placed completely within the body with only a drive line exiting the skin (Fig. 86.10). The main pumping mechanism is within the body, rather than external to it.

FIGURE 86.8. Thoratec pVAD, an example of pneumatically actuated ventricular assist device as biventricular support.

FIGURE 86.9. Thoratec pVAD, a paracorporeal device.

- **Percutaneous:** *Percutaneous* refers to a small group of pumps that are indicated for extremely short-term use and are inserted transcutaneously, either via the femoral vein and then transseptally into the left atrium or retrograde across the aortic valve (Fig. 86.11).
- **Potential duration of support based on device type**
 - **Short term:** These devices are placed to resolve immediate hemodynamic instability as either a bridge to recovery, a bridge to decision, or for use during a short-term procedure. Their use is intended for hours to weeks.
 - **Medium term:** These devices are inserted with the intention of being used to allow recovery of the native heart function or as a short-term bridge to transplantation. They are indicated for weeks to months.
 - **Long term:** These devices are intended to be used for either long-term bridge patients who will require an extended period of time to acquire donor hearts or for those patients who may potentially have the device as destination therapy.

Important Implications for Potential Emergency Situations while the Patient is Supported by Ventricular Assist Devices

- It is important to understand the physiologic implications of each VAD, not only while they are in use but during periods of unintended pump arrest. One of the critical differentiations between the various types of pumps is the presence or absence of valves and the potential for retrograde flow during periods of pump stoppage.
- The presence of valves should prevent retrograde flow; pump arrest merely means that the augmented flow no longer exists. This is a key point to consider during emergency management.
- The pumps with no valves, such as the axial flow devices, will allow volumes in excess of 1.5 L/minute of retrograde flow during periods of pump arrest. This degree of acute aortic insufficiency will frequently lead to ventricular arrhythmias and cardiovascular collapse.
- Knowledge of these internal components and working mechanisms leads to proper decision making during emergencies. Health care providers must know whether the pump can be temporally actuated via an external mechanism (blood sac pumps) by an individual (as opposed to the driver) and whether the pump electronics are defibrillation-compatible.
- Future devices: Most future generations will be designed to have a longer life span so they are better suited for destination therapy. Enhanced battery life will allow for greater independence, and a reduced need for transcutaneous attachment to the device, thus reducing infectious complications. They will focus on total elimination of bearings and metal-to-metal contact through magnetically levitated bearingless designs to resolve issues of anticoagulation and thromboembolic events.

Management of the Post-left Ventricular Assist Device Patient

- Most VAD centers strive to support patients with left-sided devices only and limit the number of patients who require right VADs whenever possible. Patients on single ventricular support are more mobile and more rapidly rehabilitated. A major focus of post-left VAD management is the stabilization of right heart function and prevention of right heart failure.
- To accomplish this goal, the most important factor is the selection of patients who have sustainable right ventricular hemodynamic parameters preoperatively. The previously discussed period of optimization is crucial and ranks just under the requirement that the right heart can support the function of the left VAD.
- Additionally, right heart function is frequently supported for some period of time with inotropic therapy. The most commonly used drugs are dobutamine or milrinone.
- Aggressive attempts are made to lower the pulmonary artery resistance by using nitroso-dilators, such as sodium nitroprusside, nitroglycerin, and inhaled nitric oxide. Inhaled prostacyclin may be a less expensive alternative to inhaled nitric oxide.
- Other more novel options in evolution include the use of orally available, direct-acting drugs on the pulmonary

vasculature, such as the use of sildenafil, a phosphodiesterase type 5 inhibitor.

- After placement of a left VAD, meticulous care of the drive line site is important to reduce the risk of ascending infection. This typically involves diligent immobilization of the drive line and the use of topical treatments, initially several times a day. In cases where infection is noted at the drive line site despite all efforts, topical treatments can be used with success.

Dysfunction and Complications of Left Ventricular Assist Devices

- **Cannula kinking:** In the paracorporeal devices, this is particularly problematic. Shifting of patient position or rolling in the bed can lead to either dislodgement or, more frequently, kinking of the transcatheter cannula. This will lead to flow alarms and sudden dysfunction of the device and can usually be addressed by simply removing the kink in the cannula. Often, centers have found it beneficial to keep a folded towel under the device to keep it off the patient's skin and to keep the cannulas straight. With the intracorporeal devices, this problem is usually secondary to device migration, either from chest closure in the operating room or from postoperative ambulation. With intracorporeal devices, this frequently requires reoperation for adjustment of the device.
- **Thrombosis and embolism:** The Achilles heel of all device therapy remains the poorly understood human coagulation system and the effects of foreign bodies in the bloodstream. Depending on the specific device selected and the type of valves within the device, variable amounts of anticoagulation are recommended by the manufacturer. Regardless of the anticoagulation therapy used, thrombosis, embolism, and bleeding events are a concern with all devices. It is important to treat patients with any new symptom, such as abdominal pain or a cold leg, as if it were a thromboembolic event. With appropriate management of anticoagulation and diligent patient care, these events are relatively infrequent.
- **Mechanical device issues:** The devices themselves may have mechanical issues related to valve dysfunction or problems with either bearings or motor wear. These are addressed in the materials supplied by the manufacturers. All of the devices require some type of ongoing surveillance and assessment for wear and potential mechanical failure.
- **Patent foramen ovale and hypoxemia after left ventricular assist placement:** Patients need to be carefully screened in the operating room with transesophageal echocardiography and provocation maneuvers during a bubble test to identify a patent foramen ovale. With the altered hemodynamics after left VAD placement, the left atrial pressure is suddenly dramatically lower than the right atrial pressure. This allows even the smallest patent foramen ovale to become clinically significant, with right-to-left shunting resulting in hypoxemia.
 - Partial digital occlusion of the main pulmonary artery is a provocative maneuver that may be used during the bubble study to enhance intraoperative detection of patent foramen ovale during device placement.
 - A patent foramen ovale discovered in the operating room prior to placement of the VAD and those discovered after the device is activated in the operating room should be closed at that time.

- **Right heart failure and the potential need for a right VAD:** Despite best efforts, a small percentage of patients will develop refractory right heart failure necessitating device therapy.

- If this occurs in the operating room while the cardiopulmonary bypass cannulas are still in place, a circuit is set up where blood is drawn from the right atrium, oxygenated by the cardiopulmonary bypass circuit, and then returned to the pulmonary artery. Often referred to as a *Berlin bridge*, it may be a beneficial intermediate step as the effect of super-oxygenated blood on the pulmonary artery may result in a reduction in pulmonary resistance over several minutes and obviate the need for a right VAD.
- When right heart dysfunction and failure develop several days after a left VAD placement, some type of short-term device support may be required if the heart remains refractory to initial interventions including pharmacotherapy.
- **Bleeding** is most common during the perioperative period but can also occur with anticoagulation during device use. Individual institutions must make the decision regarding the appropriateness of aprotinin therapy. It has been our standard practice to use a full dose of aprotinin (full Hammersmith protocol; see package insert) at the time of device implantation and with subsequent transplantation because of the tremendous importance of hemostasis.
 - The administration of blood products, especially plasma and platelets, increases pulmonary resistance that, in combination with their volume, can precipitate right heart failure. This outcome should always be considered when using blood product therapy.
 - At the time of the second exposure, a test dose is administered only when cardiopulmonary bypass is immediately available because of the risk of a hypersensitivity reaction.
- **Patient factors** include accidental disconnects, where a patient, in spite of optimal education from physicians and VAD staff, simultaneously disconnects all power sources to his or her device, resulting in pump stoppage. Additionally, traction injuries are common. Particular attention should be given to entering and exiting vehicles and traversing through narrow doorways, as these seem to be particularly problematic for the drive lines of VADs.

TRANSITION FROM INTENSIVE CARE UNIT TO THE FLOOR AND OUTPATIENT MANAGEMENT

- It is beyond the scope of this chapter to discuss personnel management. However, dedicated staff members are essential and must be thoroughly trained to deal with outpatient management of VADs.
- Communication and current knowledge of the device are paramount to the success of the VAD program. This requires the establishment of community resources and alternate caregiver training so that there is redundancy at every level of the system.
- Although minor problems with these patients and their devices are not uncommon, most are easily handled if the support staff are prepared and adequately trained. Mechanical assist devices can enhance not only the quantity but the quality of life for these patients.

CHAPTER 87 ■ VALVULAR HEART DISEASE

IMMEDIATE CONCERNS

- Critically ill patients with valvular heart disease (VHD) presenting to the intensive care unit (ICU) fall into three primary categories:
 - **Acute-onset**, newly acquired VHD
 - **Exacerbation** or complications of pre-existing VHD
 - **Concomitant** VHD critically ill from other causes
- Most patients present with instability secondary to left heart valvular disease, including diminished cardiac output (CO) with tissue hypoperfusion, and pulmonary venous hypertension with pulmonary edema that, if severe, leads to pulmonary hypertension (PHT) and right heart failure. Isolated right-sided valvular lesions present with reduced CO and systemic venous congestion.
- Life-threatening valvular disease generally presents manifestations of congestive heart failure (CHF) that require immediate stabilization. Initial interventions are aimed at controlling circulatory shock and respiratory failure; then 2 levels of diagnosis must be established.
 - Define the type and severity of valvular heart disease.
 - Determine acute precipitating events including cardiac problems such as acute changes in the valvular lesion, endocarditis, myocardial infarction, and cardiac dysrhythmias to systemic problems impacting cardiac performance such as uncontrolled hypertension, noncompliance with diet or medication regimens, infection, pulmonary embolism, endocrine abnormalities—particularly diabetic ketoacidosis or hyperthyroid crisis—and acute renal failure.
- Once both levels of diagnosis have been made, an estimate of the reversibility of the hemodynamic defect is possible, and plans for management can be developed. Specific management decisions depend on the lesion, its inherent physiology, and the presence of complicating factors.
- Invasive measurements such as arterial blood pressure, cardiac filling pressures, CO, mixed venous oxygen saturation, and calculated cardiovascular variables such as left ventricular (LV) stroke work index, systemic vascular resistance, and pulmonary vascular resistance are particularly useful for guiding and assessing the results of management.

CRITICAL ILLNESS CAUSED BY VALVULAR HEART DISEASE

- Detection by physical examination may be made difficult by environmental noise, pulmonary rhonchi, or other factors. With severe aortic or mitral stenosis and a failing LV, cardiac murmurs may be unimpressive or even absent. Clinical signs of common valve lesions are noted in Table 87.1.
- Electrocardiography frequently reveals concomitant ischemic heart disease, left ventricular hypertrophy (LVH), atrial

abnormalities, arrhythmias, or right ventricular (RV) hypertrophy.

- Plain chest film can reveal pulmonary venous or arterial hypertension, pulmonary edema, pleural effusions, and lung parenchymal abnormalities and can evaluate cardiac contour.
- Early echocardiography is imperative in unexplained heart failure; if transthoracic echocardiogram (TTE) is not optimal, transesophageal echocardiography (TEE) should be performed.

CRITICAL ILLNESS IN PATIENTS WITH UNDERLYING VALVULAR HEART DISEASE

- When patients are critically ill from noncardiac causes, VHD is often discovered as murmurs on physical examination, valve calcification or cardiac contour abnormalities on chest radiograph (CXR), or unexplained LVH or atrial abnormality on electrocardiogram (ECG).
- Echocardiography is the most useful diagnostic tool for defining the type and extent of the valvular abnormality. Its impact on the management plan can then be determined by consideration of its severity and specific hemodynamic characteristics. All valve lesions share several common considerations.
 - Antibiotic prophylaxis for endocarditis is important as infections are common in critically ill patients, particularly with invasive procedures or indwelling catheters.
 - Fever and increased work of breathing may increase oxygen demand to a degree not well tolerated and should be treated vigorously.
 - Sinus tachycardia, atrial fibrillation (AF) with rapid ventricular response, and paroxysmal atrial tachycardia reduce LV filling time and may lead to hemodynamic deterioration. Treat aggressively, particularly in severely stenotic lesions.
 - Treatment of dysrhythmias includes correction of electrolyte abnormalities, judicious use of digoxin, and intermittent or constant infusion of β -adrenergic blockers, calcium channel blockers, amiodarone, or other antidysrhythmic drugs. Hemodynamically compromised patients who do not promptly respond may need urgent cardioversion.

CRITICAL ILLNESSES WITH SPECIFIC VALVULAR ABNORMALITIES

Aortic Stenosis

- Etiology: Aortic stenosis (AS) is the most common primary valvular heart disease. Stenosis of the normal tricuspid valve is caused by pathology similar to coronary artery disease. A

TABLE 87.1

CLINICAL SIGNS IN VALVULAR HEART DISEASE

	Aortic stenosis	Aortic regurgitation	Acute mitral regurgitation	Chronic mitral regurgitation	Mitral stenosis
General signs	Nothing remarkable	Look for Marfan syndrome, ankylosing spondylitis, or seronegative arthropathies	Tachypnea, circulatory shock	Tachypnea	Mitral facies (malar flush), tachypnea, peripheral cyanosis
Pulse	Small volume (parvus) and late peaking (tardus) Prominent a wave	Water-hammer pulse, wide pulse pressure Prominent carotid pulsations (Corrigan sign)	Sinus tachycardia	Irregularly irregular in AF	Reduced or normal volume, irregularly irregular in AF
Neck and JVP			Prominent a wave	Absent a wave in AF	Prominent a wave in PHT, absent a wave in AF
Precordium	Sustained, nondisplaced or slightly displaced apical impulse, palpable S ₄ , systolic thrill at the base and at carotids	Diffuse, hyperdynamic and displaced apical impulse	Nondisplaced hyperdynamic apical impulse, systolic thrill	Hyperdynamic, inferolateral displaced apical impulse, parasternal heave (LAE)	Tapping apical impulse (palpable S ₁), palpable P ₂ , and parasternal heave in PHT, diastolic thrill rarely
AUSCULTATION					
S ₁	Soft	Soft in acute AR	Normal/soft	Soft	Loud
S ₂	Narrow split or reverse split S ₂ , absent A ₂ in severe AS	P ₂ loud in acute AR	Accentuated P ₂ /wide paradoxical split	Normal P ₂ /wide paradoxical split	P ₂ loud in PHT
S ₃ /S ₄	Prominent S ₄	S ₃ heard	Present/present	Present/absent	Opening snap
Clicks and added sounds	Systolic ejection click indicates mobile valve			Mid-systolic click in MVP	
Murmur	Systolic soft musical murmur, decreasing intensity in advanced disease	High-pitched, long diastolic murmur in chronic versus low-pitched short diastolic murmur in acute AR along left sternal border, diastolic murmur of early mitral diastolic closure	Early systolic loud radiating toward base (anterior directed jet) or axilla (posterior directed jet)	Holosystolic, soft or harsh and radiating toward axilla/back, late systolic murmur in MVP	Mid-diastolic murmur with late diastolic accentuation best heard at apex
AF, atrial fibrillation; JVP, jugular venous pulse; PHT, pulmonary hypertension; LAE, left atrial enlargement; AR, aortic regurgitation; AS, aortic stenosis; MVP, mitral valve prolapse.					

FIGURE 87.1. Transesophageal echocardiographic appearance of severe calcific aortic stenosis.

fibrocalcific process may involve the bicuspid valve, though the process is slower. Rheumatic aortic valve disease, rare in industrialized societies, may be seen with mitral valve disease.

- **Hemodynamics:** Obstruction causes **concentric hypertrophy** of the LV, which decreases wall stress but increases oxygen demand and dependence on left atrial (LA) contraction for ventricular filling. Subendocardial ischemia in LVH predisposes to ventricular dysrhythmias. Decreased forward flow and associated peripheral vasodilatation with exercise can cause syncope or sudden death. Later, the ventricles dilate and cardiac function is maintained by Frank–Starling mechanisms.
- **Diagnosis:** ECG features include LVH with strain pattern, left bundle branch block, and LA hypertrophy (biphasic P waves in precordial lead V₁). CXR may reveal a boot-shaped heart, calcification of the aortic valve, poststenotic dilatation of the aorta, and pulmonary venous congestion. Echocardiography is the principal modality for confirming AS (Fig. 87.1) and evaluating LV function. Severity is determined by peak gradients and valve area (Table 87.2). Gradients will be lower with severe AS if the flow across the valve is reduced by hypovolemia or by poor LV function. Systolic function may be preserved, but significant diastolic dysfunction, which predisposes patients to pulmonary edema, may be present.
- **Therapeutic considerations:** The triad of syncope, angina, and dyspnea indicate severe AS and require surgical intervention. Coronary angiography is indicated before surgery to rule

out associated coronary artery disease. ICU admission may be required for acute cardiogenic shock, pulmonary edema, severe angina, ventricular dysrhythmias or, less commonly, AF and systemic embolization.

- **Drugs:** Commonly used drugs carry significant risks in AS. β -Blockers, calcium channel blockers, and other antidysrhythmics should be used with caution as patients are sensitive to myocardial depression.
- Treat pulmonary congestion with careful administration of diuretics and nitroglycerin; may cause inadequate preload; digitalis carries the risk of dysrhythmias.
- Increased LV mass and intracavitary systolic pressure decrease tolerance to vasodilatation and tachycardia. Angiotensin-converting enzyme inhibitors and other vasodilators can cause syncope or sudden death and are relatively contraindicated.
- Undesirable hemodynamic effects of sedative drugs should be considered in patients with fixed CO. Narcotics can blunt the hypertensive sympathetic responses without significant myocardial depression and are usually the agents of choice.
- Patients with diastolic dysfunction are extremely sensitive to fluids and can develop pulmonary edema, even when systolic function and ejection fraction are preserved.
- **Monitoring:** Hemodynamic stabilization with drugs and fluids should be carried out with careful monitoring of arterial and cardiac filling pressures. Normal central venous pressure does not ensure adequate filling with a stiff LV. Placement of a pulmonary artery catheter (PAC) provides useful information about LV filling pressures, CO, and mixed venous oxygenation and can be used for transvenous pacing but may precipitate malignant dysrhythmias. Pulmonary capillary wedge pressure can underestimate LV end-diastolic pressure (LVEDP) in patients with markedly reduced ventricular compliance; echocardiography can be useful in such situations. Monitor for ischemia with continuous ECG leads V₅ and II; however the ECG manifestations of LVH may make detection more difficult.
- **Hemodynamic goals:** LVH renders the atrial contraction—and thus sinus rhythm and preload—more crucial for diastolic filling. Severe bradycardia should be avoided as severe AS results in a fixed stroke volume and CO.
- AF should be reversed with prompt cardioversion and initiation of antidysrhythmic therapy with amiodarone and/or β -blocking drugs. Procainamide has an increased risk of myocardial depression and hypotension. If cardioversion is unsuccessful, control of the ventricular rate is essential as decreased diastole increases the risk of ischemia.
- Maintain adequate preload. Severe myocardial dysfunction with low blood pressure and ischemia may require administration of inotropes. Afterload reduction can impair coronary perfusion pressure; vasopressors may be necessary in patients with optimized volume and myocardial contractile status.
- Patients who are refractory to medical management may benefit from insertion of an intra-aortic balloon counterpulsation pump (IABP).
- **Definitive therapy:** Any patient with severe AS who continues to deteriorate despite medical therapy should be seen by a cardiologist and cardiac surgeon for possible balloon valvotomy or open-valve replacement. Balloon valvotomy affords temporary improvement in transvalvular gradient and may

TABLE 87.2

ECHOCARDIOGRAPHIC ASSESSMENT OF AORTIC STENOSIS (AS)

	Mild AS	Moderate AS	Severe AS
Valve area (cm ²)	>1.5	1–1.5	<1
Mean transvalvular gradient (mm Hg)	<25	25–40	>40
Jet velocity of blood flow across the valve (m/s)	<3	3–4	>4

relieve symptoms, thus serving as a bridge to surgery. It is often very effective for young adults and adolescents with bicuspid valves but carries a mortality of 10% in patients with calcific AS.

Aortic Regurgitation

- **Etiology:** Acute aortic regurgitation (AR) results from infective endocarditis, aortic dissection extending into the aortic annulus or aortic root, and trauma. Severe, acute hypertension may also cause sudden-onset AR that often reverses after control of hypertension. Chronic AR causes are diverse and may involve the valve or the aortic root. Primary valvular diseases include congenital bicuspid valve, prolapse of aortic cusp, rheumatic heart disease, calcific degenerative disease, connective tissue diseases, and subacute bacterial endocarditis. Diseases associated with aortic root dilatation include systemic hypertension, Marfan disease (see Fig. 87.2), Ehlers-Danlos disease, granulomatous diseases of the aorta, senile and cystic medial degeneration, annuloaortic ectasia, and syphilis.
- **Hemodynamics:** In chronic AR, the LV dilates and hypertrophies when subjected to volume overload but, as the compensatory limit is reached, the wall stress begins to rise, and systolic function deteriorates. Severe decompensated AR results with decreasing forward-stroke volume and increasing LV end-diastolic volume and LV end-diastolic pressure, and symptoms of heart failure. In acute AR, there is no opportunity for compensation; increased end-diastolic pressures cause pulmonary venous congestion and pulmonary edema. The severity is dependent on the regurgitant orifice size, duration of diastole—as the degree of AR increases with bradycardia—and the diastolic pressure gradient between aorta and LV.
- **Diagnosis:** An ECG is performed to rule out ischemic heart disease in acute AR. The CXR will reveal cardiomegaly in chronic AR or pulmonary congestion with a normal-size heart in acute AR. TTE is performed to define the mechanism and severity of AR. TEE is useful, as TTE windows are limited; it defines the nature of perivalvular pathology and diagnoses an acute aortic dissection with high sensitivity and specificity. TEE is superior to magnetic resonance imaging and computed

FIGURE 87.2. Dilatation of aortic root and ascending aorta by transesophageal echocardiography in a patient with Marfan disease.

FIGURE 87.3. Aortic dissection intimal flap involving aortic root.

tomography scan to characterize the valve pathology in cases of acute dissection, and obviates the need for aortography (Fig. 87.3). Coronary angiography can rule out ischemic heart disease before surgery in chronic AR but is rarely indicated before emergency surgery in acute AR.

- **Therapeutic considerations:** Though medical therapy may allow mild acute AR to reach a chronic compensated state, emergency aortic valve replacement (AVR) is almost always indicated with severe acute AR after medical stabilization. The principle of therapy is to optimize CO and systemic perfusion, reduce pulmonary venous congestion, and initiate therapy for any underlying disorder. β -Blockers are avoided as tachycardia is beneficial in maintaining CO and decreases the regurgitant fraction by decreasing the duration of diastole. Hypertension and increased afterload are to be avoided. Inotropic therapy is advised only with depressed systolic function. An IABP is absolutely contraindicated, as it will increase the regurgitant fraction.
- In contrast to other causes of AR, inotropic therapy is avoided with aortic dissection. A result of long-standing, poorly controlled hypertension or trauma, LV contractility is preserved, and inotropes are not indicated. β -Adrenergic blockade may be initiated to reduce the velocity of LV ejection and aortic wall stress, therefore preventing extension of the aortic dissection or aortic rupture.
- In chronic AR with an acute decompensation, search for the precipitating cause, and pay particular attention to possible endocarditis. Most patients stabilize with medical therapy, and early elective surgery should be considered. Patients who do not improve with aggressive medical therapy should undergo emergency AVR.

Mitral Regurgitation

- The mitral valve apparatus is composed of the valve leaflets, mitral annulus, chorda tendineae, papillary muscles, and adjacent cardiac chambers, namely the LA and LV. Any disruption in the integrity of the mitral valve apparatus may

TABLE 87.3

FUNCTIONAL CLASSIFICATION OF MITRAL REGURGITATION

Type of MR	Pathology	Disease
Type I	Normal motion of leaflets	Endocarditis (leaflet perforation) or various etiologies causing left ventricular dysfunction (annular dilatation)
Type II	Increased leaflet motion with free edge of the leaflet traveling above the plane of the annulus; due to chordal elongation or rupture, papillary muscle rupture	Degenerative myxomatous valve disease
Type IIIA	Restricted leaflet motion during diastole and systole	Rheumatic heart disease
Type IIIB	Restricted leaflet motion during systole, papillary muscle displacement	Ischemic or dilated cardiomyopathy

result in regurgitation. One of the major breakthroughs in the management of mitral regurgitation (MR) was the functional classification by Carpentier in the early 1980s (Table 87.3).

- **Etiology:** Acute MR usually results from infective endocarditis, connective tissue or myxomatous disorders; or ischemic heart disease. Acute rheumatic mitral valvulitis is less common today.
- **Hemodynamics:** Chronic MR leads to adaptation of the LV by dilatation and eccentric hypertrophy. Over many years, systolic function may fail, resulting in decreased ejection fraction and PHT; LA dilatation leads to AF. In the absence of a precipitating event, patients with chronic MR are rarely critically ill on presentation. In acute MR, however, increased LA pressure is transmitted to the pulmonary venous system, resulting in pulmonary edema. Sudden volume overload causes LV failure; CO falls, and systemic vascular resistance rises, which further increases the regurgitant fraction.
- **Diagnosis:** Patients may present with acute onset of fatigue, dyspnea, and chest pain or have pulmonary edema and circulatory shock. The ECG may show AF, LVH, and RV strain or suggest ischemia; the CXR may show cardiomegaly, indicating pre-existing heart disease. Pulmonary venous congestion and/or edema with a normal-sized heart indicate acute MR. Echocardiography remains the standard; TTE is easy and safe and can be performed at the bedside. TEE has superior resolution, definition of the mitral valve apparatus, and assessment of the severity of MR (Fig. 87.4). The mechanism and type of MR should be defined. Qualitative and quantitative assessment of MR can be done by color and spectral Doppler methods.
- The suitability for repair and LV function is assessed. EF is unreliable as it is increased when contractility is normal. Normal EF indicates significant loss of myocardial function; with EF, $\leq 50\%$ advanced myocardial dysfunction is generally present.
- The American Heart Association/American College of Cardiology guidelines recommend medical treatment when EF is $<30\%$ and surgical treatment, even in asymptomatic patients, with EF $<60\%$ to prevent progression of disease.
- Urgent coronary angiography is indicated if myocardial ischemia or infarction is a real consideration and may delineate a culprit lesion amenable to catheter-based interventions. Severe triple-vessel disease should be referred for surgery. In

the case of chordal rupture or infective endocarditis without risk factors for CAD, angiography may be deferred.

- **Therapeutic considerations:** In acute, severe MR, medical therapy has a limited role and is aimed at stabilizing hemodynamics in preparation for surgery. Early valve surgery is life saving and should not be delayed. Often with a complication of myocardial infarction, therapy should maintain coronary perfusion pressure and reduce myocardial oxygen consumption. Use of a PAC and invasive arterial pressure monitoring is recommended. Sinus tachycardia maintains the forward flow and should not be suppressed. Hypertension and vasopressors should be avoided as increased afterload will increase the regurgitant fraction. Diuretics may be needed to reduce pulmonary venous congestion. If normotensive, vasodilators can increase forward flow and decrease the regurgitant fraction but should not be used except in combination with inotropes if hypotensive. With failure of medical management, IABP may be life saving.
- The surgical intervention is determined by the nature of the lesion. **Chordal rupture** or prolapse of the posterior leaflet can be repaired. Revascularization alone may improve

FIGURE 87.4. Transesophageal echocardiographic diagnosis of mitral regurgitation (MR) severity. Left atrial wall hugging eccentric regurgitant jet indicates severe MR.

transient papillary muscle ischemia without rupture. The standard of care for acute ischemic MR refractory to medical management and nonsurgical revascularization is a combination of revascularization with mitral valve repair or replacement with posterior chordal sparing. Mitral valve annuloplasty is the best approach for ischemic MR due to annular dilatation, diminished systolic contraction of the annulus, or papillary muscle malalignment; valve replacement should be considered if the repair is unsatisfactory. Papillary muscle rupture carries a high mortality without surgical intervention.

- **Infective endocarditis** should be treated with antibiotics. Indications for surgery include CHF refractory to medical treatment, uncontrolled infection despite antibiotics, recurrent systemic embolism, perivalvular or pericardial extension of infection, fungal endocarditis, and prosthetic valve endocarditis. Surgery should not be delayed for microbiologic clearance.
- **Mitral valve prolapse** deserves special mention because it is the most prevalent valvular heart disease and the most common cause of MR. Presentation includes severe MR, AF with transient ischemic attacks, long QT syndrome and tachyarrhythmias, PHT, cerebral embolism, infective endocarditis, or even sudden death. Medical stabilization and elective surgical repair of the mitral valve are recommended therapies.

Mitral Stenosis

- **Etiology:** Mitral stenosis (MS) is mostly related to rheumatic heart disease; degenerative calcific stenosis, congenital stenosis, and connective tissue disorders are other causes. Atrial myxomas and LA ball-valve thrombus can cause intermittent mitral obstruction and mimic MS.
- **Hemodynamics:** In rheumatic MS, inflammation of the connective tissue leaves patients with a funnel-shaped mitral apparatus. As the condition progresses, LA pressure and the transmitral gradient increase to maintain flow. The subsequent rise in pulmonary venous pressure leads to hydrostatic pulmonary edema, pulmonary vasoconstriction, and increased RV afterload. Persistently elevated pulmonary artery (PA) pressure leads to permanent structural changes, intimal hyperplasia, and medial hypertrophy, resulting in fixed PHT. RV dilatation and failure result in tricuspid insufficiency and systemic venous congestion.
- **The impact of MS on CO** is initially determined by the severity of the stenosis. As the disease progresses, severe **RV failure** may limit CO. Similarly, progression of rheumatic disease may impair LV function, important after surgical repair as increase in transmitral flow may expose the LV to a sudden increase in preload, causing failure.
- **Presentation:** MS often presents with acute cardiogenic pulmonary edema. Precipitating factors such as infective endocarditis, fever, anxiety, pain, AF, and pregnancy should be identified. Occlusion from an enlarging atrial myxoma should be ruled out. Right-sided heart failure with hepatic dysfunction, acute hemoptysis, systemic embolism, and hoarseness of voice may also be present.
- **Diagnosis:** The ECG may show LA enlargement, RV hypertrophy (RVH), and AF. CXR shows straightening of the left heart border, indicating LA and PA enlargement. **Kerley A and B lines** indicate pulmonary venous hypertension. TTE findings include doming of the anterior leaflet, decreased

FIGURE 87.5. Typical appearance of rheumatic mitral stenosis.

leaflet mobility, increased leaflet calcification and thickness, commissural fusion, calcification of the subvalvular apparatus, increased LA size, and the presence of an LA thrombus (Fig. 87.5). Color flow will show associated MR. Doppler echocardiography allows calculation of pressure gradients, mitral valve area, and estimation of PA systolic pressure. Cardiac magnetic resonance imaging is increasingly used in the evaluation of stenotic valvular lesions; it measures valve area by planimetry. Its advantage over echocardiography is the lack of dependence upon good echocardiographic windows.

- **Therapeutic considerations:** New-onset AF with hemodynamic instability should be treated with cardioversion. Cardioversion in AF of >48 hours or an unknown duration must be preceded by 3 weeks of anticoagulation or TEE to exclude LA thrombus. Anticoagulation should be continued for 4 weeks after cardioversion because the enlarged LA remains “stunned” and does not immediately recover a normal contractile state. Anticoagulants should also be used with a prior embolic event and LA diameter >55 mm by echocardiography. Antidysrhythmics may be used to maintain sinus rhythm but should not be expected to provide indefinite success.
- **Pulmonary edema** should be stabilized with oxygen, morphine, anxiolytics, diuretics, and digoxin; the latter is especially useful in atrial dysrhythmias and CHF. Sympathetic nervous system activity is increased with MS, and overactivity worsens the symptom complex; β -blockers are very useful in this situation.
- Intravenous nesiritide, a synthetic human natriuretic peptide, is used with acute decompensated cardiac failure and PHT; it does not appear to have proarrhythmic effects. Nesiritide also appears to be effective and well tolerated in patients receiving concomitant β -blocker therapy and those with renal insufficiency.
- Inotropes to improve LV function may cause tachycardia and pulmonary edema. Inodilators may be useful in improving RV dysfunction and reducing PHT. Systemic blood pressure may need support with vasopressors but may adversely impact pulmonary vascular resistance.
- Assessment of volume status is difficult as the pulmonary capillary wedge pressure does not correlate with LV end-diastolic pressure but does give useful information about the propensity to develop pulmonary edema.

- Emergency invasive intervention is rarely required. If the precipitating events are controlled, surgery or balloon valvotomy can be scheduled electively after medical optimization. Balloon valvotomy is indicated in patients with suitable anatomy: pliable leaflets, no commissural fusion, and minimal subvalvular calcification. LA thrombus and significant (3+ to 4+) MR should be excluded by echocardiography. Patients who are not candidates should be referred for surgery. Because of extensive calcifications and marked anatomic distortion, mitral valve repair often is not possible in rheumatic mitral disease, and replacement is necessary.

Tricuspid Stenosis

- **Etiology:** Tricuspid valve obstruction can be due to anatomic disease or functional, causes secondary to right atrial (RA) tumors and thrombus. Anatomic disease is usually related to rheumatic heart disease; other causes are carcinoid syndrome, infective endocarditis, congenital stenosis or atresia, and methysergide toxicity.
- **Hemodynamics:** Obstruction to RV inflow results in systemic venous congestion: elevated jugular venous pulse (JVP), congestive hepatomegaly, and peripheral edema. Diastole is shortened by increasing heart rate, thus causing dramatic increases in transvalvular gradients. Most patients are symptomatic from coexisting MS. The presence of systemic venous congestion out of proportion to pulmonary venous congestion should raise the suspicion for involvement of the tricuspid valve.
- **Clinical signs:** Physical exam will reveal an elevated JVP, a prominent a wave, and distention of veins of the upper arm and dorsum of extended hand. A diastolic thrill may be palpated at the lower left sternal border; the S_1 is increased, and an opening snap and diastolic murmur may be heard at the lower left sternal border. Assigning the murmur to the tricuspid valve is based on its location; the higher, shorter, and softer nature of tricuspid stenosis (TS) in comparison to MS; and the absence of crackles that commonly accompany the murmur of MS. Right-sided murmurs are increased during inspiration.
- **Diagnosis:** The ECG may show evidence of RA enlargement: a P wave exceeding 2.5 mm in lead II and 1.5 mm in V_1 . RA enlargement may cause first-degree heart block or AF in advanced disease. The CXR may show cardiomegaly, RA enlargement, and calcification of the valve. Echocardiography shows thickened leaflets, limited mobility, and a dome-shaped structure in diastole; RV function and the presence of tumor, thrombus, or vegetations can also be assessed. Spectral and color Doppler methods allow calculation of pressure gradients to grade the stenosis (mild <5 mm Hg, moderate 5 to 10 mm Hg, and severe >10 mm Hg) and valve area. Catheterization is unnecessary with good echocardiographic windows.
- **Therapeutic interventions:** Complete obstruction of the tricuspid valve by vegetations, thrombus, and/or tumors is an indication for emergency valve surgery (Fig. 87.6). Sodium restriction, careful diuresis, rate control, and anticoagulation are helpful, but surgical correction is required when the transvalvular gradient exceeds 5 mm Hg and the valve area falls below 2 cm². Percutaneous valvotomy or, more often, a bioprosthetic valve replacement is necessary. Mechanical valves are avoided because of the very high risk of thromboembolism in this position.

FIGURE 87.6. Complete obstruction of prosthetic tricuspid valve by vegetations, requiring emergency surgery.

Tricuspid Regurgitation

- **Etiology:** Tricuspid regurgitation (TR) can be classified as structural or functional. Most cases are chronic, but acute presentation may follow penetrating trauma, RV infarction, infective endocarditis, or repeated endomyocardial biopsies to diagnose allograft rejection.
- **Structural TR** is caused by rheumatic disease, infective endocarditis, carcinoid syndrome, radiation therapy, Marfan syndrome, congenital heart disease, or tricuspid valve prolapse.
- **Functional TR** is usually secondary to left-sided pathology, such as LV failure, mitral or aortic (less frequent) valve disease, primary PHT, pulmonic stenosis, RV infarction, and dilated cardiomyopathy; a small number are idiopathic.
- **Hemodynamics:** Elevated RA pressure from TR gives rise to the signs and symptoms of systemic venous congestion; RA dilatation may lead to AF and thrombus formation. An RA thrombus may lead to pulmonary or systemic (with patent foramen ovale [PFO]) emboli. RV volume overload leads to eccentric hypertrophy and dilatation. RV systolic dysfunction develops, leading to further decompensation and annular dilatation that increase the severity of TR. The left heart also suffers from low CO because the RV fails to deliver enough blood to the LV. Ventricular interdependence and paradoxical septal motion also decrease LV output with RV volume overload.
- **Clinical symptoms and signs:** Shock and hypotension may develop with acute TR after RV infarction or papillary muscle rupture. Signs of right-sided failure are present: distended neck veins with a prominent c-v wave, pulsatile hepatomegaly, a precordial bulge, and parasternal heave from RVH; soft S_1 , prominent P_2 , and right-sided S_3 from RV dilatation; pansystolic thrill; and a murmur heard at the left lower sternal border.
- **Isolated tricuspid valve endocarditis** may disseminate emboli to the lungs, resulting in multiple septic emboli and abscess formation. Peripheral stigmata of infective emboli are usually absent but may indicate paradoxical embolism or left-sided lesions.

- **Diagnosis:** The ECG may show AF, right axis deviation, RVH, and a right bundle branch block. Right-sided leads will show ST elevation in RV infarction and may be associated with LV inferior wall infarction. Enlarged RV and cardiomegaly are seen on CXR.
- **Echocardiography** can yield structural issues—prolapse, vegetations, annular diameter, and rheumatic disease—and rules out thrombus and PFO. With PFO, elevated RA pressure frequently exceeds LA pressure, causing right-to-left shunt and possible refractory hypoxemia.
- **Severity of TR** can be assessed by hepatic venous systolic flow reversal and estimation of regurgitant orifice area ($>40 \text{ mm}^2$ is severe). Also, pulmonary systolic pressure can be estimated by continuous wave Doppler signal of tricuspid regurgitation. Augmenting ultrasound signal with 10% air, 10% patient's blood, and 80% saline, and estimation of PA systolic pressures correlate well with PAC-measured PA systolic pressures. Right heart catheterization shows RV pressure $>60 \text{ mm Hg}$ in functional TR compared to $<40 \text{ mm Hg}$ in structural TR.
- **Therapeutic considerations:** In general, acute TR can be effectively managed with diuretics and inotropes; rare instances may require valvular surgery when refractory to medical therapy. Once stabilized, long-term prognosis depends on the etiology and severity. Mild and moderate degrees of chronic TR are tolerated in the presence of normal LV function; correction of left-sided heart lesions and treatment of left-sided failure and PHT take priority.
 - If functional TR is severe, ring annuloplasty can improve survival. Cardiac resynchronization therapy with biventricular pacemakers and the Dor procedure (endoventricular circular patch plasty) help patients with functional TR due to systolic heart failure.
 - Rheumatic TR may be treated with open valvotomy or valve replacement. Valves compromised by infective endocarditis can simply be removed after an aggressive course of antibiotics; valve replacement can be performed later if there is no recurrence of drug abuse. When acute TR is the result of RV infarction, the usual management of acute coronary insufficiency must be observed, including β -blockers, aspirin, fluids, thrombolysis, coronary angiography, angioplasty, and stenting and, in suitable patients, coronary artery bypass grafting.
- **Presentation:** Mild PS is often asymptomatic. Patients with more severe stenosis commonly develop fatigue, atypical chest pain, and syncope. When RV failure or TR occurs, systemic venous hypertension may be present. Elevated RA pressures in the presence of a PFO or atrial septal defect can result in a **right-to-left shunt**. Physical examination reveals a large venous a wave; in the absence of RV failure or TR, JVP remains normal. A left parasternal systolic lift is common with significant PS. The murmur is best heard at the left upper sternal border and radiates to the left clavicle; a thrill and ejection click may be present. Increasing duration, late systolic peaking, and wide splitting of the second sound (as P_2 is increasingly delayed) are indicators of significant stenosis; intensity of the murmur is not.
- **Diagnostic studies:** The ECG is normal in mild PS; with increasing severity, RVH and RA enlargement are common. The CXR may reveal poststenotic dilatation of the main and left PA. Echocardiography is particularly useful in assessing the valve morphology, calculating pressure gradients, grading the severity of stenosis, and evaluating RV function. The presence of other congenital abnormalities, TR, and RA enlargement can also be ruled out by echocardiography. Cardiac catheterization provides confirmation of pressure gradients, full hemodynamic assessment, and identification of associated PA branch stenosis. Pulmonary stenosis is graded based on the peak pressure gradient: **mild**, with a **gradient** of 25 to 49 mm Hg; **moderate**, 50 to 75 mm Hg; and **severe**, $>75 \text{ mm Hg}$.
- Currently, balloon valvuloplasty is recommended for symptomatic patients and those with a peak gradient $>50 \text{ mm Hg}$. Surgical valvuloplasty is reserved for severe calcification, dysplasia, endocarditis, and previous valvuloplasty failure. Medical management includes infective endocarditis prophylaxis, treatment of right heart failure and AF, and anticoagulation to prevent thromboembolic complications.

Pulmonic Insufficiency

- **Etiology:** Pulmonic insufficiency (PI) may be secondary to PHT or, rarely, leaflet damage caused by infectious endocarditis, rheumatic fever, or carcinoid syndrome. Occasionally, PI is congenital.
- **Pathophysiology:** In the absence of PHT, volume overload of the RV is well tolerated; RV failure can occur when PHT develops from other causes.
- **Presentation:** Generally an isolated abnormality with a benign course, the natural history is that of the associated lesions. PI is usually an incidental auscultatory finding: decrescendo diastolic murmur along the upper left sternal border. The intensity of the murmur does not correlate well with the severity of regurgitation.
- **Diagnostic studies:** The ECG is usually normal; RVH suggests PHT. The CXR is normal in mild insufficiency; the pulmonary trunk may be prominent when moderate to severe. Echocardiography can be useful for differentiating pulmonic from aortic insufficiency and establishing right heart chamber sizes and associated abnormalities.
- **Therapeutic considerations:** Specific treatment is rarely required, but PHT should be controlled when present. When the right heart fails, diuretics, sodium restriction, and possibly cardiac glycosides are helpful. Surgical treatment

Pulmonic Stenosis

- **Etiology:** Pulmonic stenosis (PS) is usually congenital. Though it does occur in isolation, subvalvular and supra-valvular stenosis usually comprise part of a larger syndrome. Severe forms, or those associated with other cardiac anomalies, are generally identified and treated in childhood. Acquired forms of PS include rheumatic, carcinoid disease; infundibular stenosis from PHT; extrinsic compression from aneurysm of the sinus of Valsalva; tumors; and scarring from previous surgery.
- **Pathophysiology:** PS causes obstruction to RV outflow resulting in RVH and subsequent RV failure or TR. The degree of stenosis, once established, tends to be stable; if decompensation does not occur in childhood, subsequent deterioration is unlikely. Occasionally, RV obstruction increases, possibly by secondary infundibular hypertrophy.

(bioprosthetic valve replacement) is reserved for advanced right heart failure. In patients with a remote repair of tetralogy of Fallot and chronic PI, RV dilatation has been linked to sudden death and may warrant valve replacement.

Mixed Valve Lesions

- **Mitral stenosis with regurgitation:** The combination of pressure and volume overload on LA favors early development of symptoms, AF, and CHF. Because transvalvular gradients may overestimate the degree of stenosis, Doppler measurement of valve area should be considered. Decision making is complex, and intervention is often required before either of the lesions reaches a severe degree. Moderate MR is a contraindication for balloon valvotomy.
- **AS and regurgitation:** This combination causes both pressure and volume overload on the LV. The predominant lesion is indicated by the size of the LV: a normal-sized but hypertrophied LV signifies predominant AS; a dilated LV suggests dominant AR. Transvalvular gradients may overestimate AS, so planimetry or the continuity equation method should be considered. The threshold for surgery is lowered as compared to single valve–defect patients. Surgery in patients with predominant AR can be delayed until symptoms develop or asymptomatic LV dysfunction becomes apparent on echocardiography.
- **MS and AS:** This combination causes serial obstructions resulting in reduced CO and early development of pulmonary venous congestion and hypertension. Low transvalvular gradients characterize this AS because of low CO. Mitral valvotomy is done first, followed by AVR as indicated.
- **MS and AR:** This combination creates a challenge for the physician attempting to make a diagnosis. MS decreases the volume overload of AR, and AR attenuates antegrade mitral valve flow by increasing LV diastolic pressure, thereby decreasing transmitral gradients. Balloon mitral valvotomy followed by AVR, as indicated, is a reasonable approach.
- **MR and AS:** AS aggravates MR by increasing the afterload. MR, by its pressure release effect, obscures even severe AS. Systolic function remains normal with low transaortic gradients. If both lesions are severe, AVR with mitral valve repair or replacement is necessary. Moderate or mild MR may improve after AVR for AS, especially if there is no anatomic lesion in the mitral valve. Intraoperative TEE plays an important role in this decision.
- **MR and AR:** These lesions create additive volume loads on the LV; the sequelae of dyspnea and LV dysfunction appear sooner.

Prosthetic Valve Dysfunction

- Prosthetic valves are broadly divided into mechanical, bioprosthetic, and homograft valves. St. Jude bileaflet valves are commonly used mechanical valves that need lifelong anticoagulation. Carpentier-Edwards and Hancock bioprosthetic valves are common tissue valves; they do not require long-term anticoagulation but have a short life span and are prone to degenerative changes and failure. Acute valvular complications may result from infective endocarditis, paravalvular leak, valve ring abscess, thrombosis, pannus formation,

degenerative calcification, lipid infiltration, dehiscence of the valve, and strut fracture.

- Progressive congestive cardiac failure is a common presentation with stenosis and regurgitation. Acute, complete valvular obstruction may lead to sudden death in the absence of surgical intervention. Embolic phenomenon, hemolytic anemia (indicating a paravalvular leak), and a new atrioventricular block (indicating a valve ring abscess) may be other presenting symptoms. Prosthetic valve thrombosis may present with nonspecific cardiac symptoms. Normally functioning prosthetic valves are associated with clicks and murmurs.
- Echocardiography is essential to make a diagnosis and has replaced cardiac catheterization. Fluoroscopy may be needed to identify the nature of the disease and assess the effects of thrombolysis. Excessive rocking motion of the valve ring or limited motion of the valve components due to thrombus or vegetation; calcification; thickening around the valve due to an abscess; and a pseudoaneurysm can be identified with two-dimensional echocardiography. The color Doppler technique may show a paravalvular leak, pseudoaneurysms, and/or fistula formation.
- Calculation of transvalvular gradients helps to diagnose prosthetic valve stenosis. Gradients depend on the valve type and size and dynamic conditions such as CO, blood volume, heart rate, and contractility. Measurements should be compared to values obtained immediately after valve replacement. It has also been suggested that it may be more appropriate to calculate the prosthetic valve area using the continuity equation:

$$\text{Area}_1 \times \text{velocity time integral}_1 = \text{Area}_2 \times \text{velocity time integral}_2$$

- Medical therapy is directed toward treatment of CHF: diuretics, vasodilators, and inotropes; initiation of antibiotics for infective endocarditis after obtaining blood cultures; and thrombolysis for certain cases of prosthetic valve thrombosis. Staphylococcal organisms predominate in early (<60 days after placement) prosthetic valve endocarditis, whereas in late (>60 days after placement) endocarditis, there are equal percentages of streptococcal and staphylococcal organisms. Empiric antibiotics are started until culture results and sensitivities are available. Fibrinolytic therapy is recommended for right-sided thrombosis with a large clot burden or New York Heart Association classes III to IV symptoms. Fibrinolysis for left-sided lesions is associated with a 12% to 15% risk of cerebral embolism and thus reserved for patients in whom emergency surgery is high risk or contraindicated. Ultimately, all prosthetic valve lesions require valve replacement surgery; reoperative mortality is high.

IMPORTANT CONSIDERATIONS IN THE TREATMENT OF RIGHT VENTRICULAR FAILURE SECONDARY TO VALVULAR HEART DISEASE

- Patients with chronic RV failure secondary to valvular heart disease (VHD) are usually debilitated, with low CO and pulmonary, hepatic, and renal dysfunction. Ascites, malnutrition, reduced systemic vascular resistance, jaundice, coagulopathy, and renal failure—the hepatorenal syndrome—are the manifestations of hepatic dysfunction. Hepatorenal

syndrome is challenging and often requires renal replacement therapy.

- Treatment of PHT in the critically ill patient with VHD decreases RV afterload and helps prevent or decrease RV failure. This approach, combined with maintenance of adequate coronary perfusion pressure, forms the mainstay of treatment of acute RV failure. Exacerbating factors of PHT, such as hypoxemia, hypercarbia, acidosis, hypothermia, hyperv-

olemia, and increased intrathoracic pressure, should be corrected aggressively.

- Recent advances in pharmacology provide intensivists with a wide variety of options for selective pulmonary vasodilation including inhaled prostaglandins and nitric oxide. Inhaled pulmonary vasodilators are preferred because they do not decrease systemic blood pressure or increase shunt fraction.

CHAPTER 88 ■ CARDIAC DYSRHYTHMIAS

BRADYARRHYTHMIAS

- Bradycardia is a common finding in hospitalized patients, especially during sleep. An increase in vagal tone may result in sinus bradycardia, sinus pauses, or atrioventricular (AV) nodal block—all physiologic findings that may have no clinical significance.

Sinoatrial Abnormalities

- Sinoatrial (SA) conduction block occurs when impulses generated by the sinus node are not conducted to the atrial myocardium.
 - **First-degree SA block** is not manifested on electrocardiogram (ECG), as it is merely the delay between the sinus impulse formation and atrial activation.
 - **Second-degree type I SA block (Wenckebach)** is manifested by group beating, with progressive shortening of PP intervals until a P wave is absent; this PP interval is usually less than twice the shortest cycle.
 - **Second-degree type II SA block** has fixed PP intervals, followed by a pause without a P wave that is twice the PP interval (Fig. 88.1).
 - **Third-degree SA block** is not visible on ECG, as no sinus impulse can escape the SA node. This disorder cannot be differentiated from sinus arrest.
- **Sinus arrest** is the failure of automaticity in which no impulses are generated by the sinus node (Fig. 88.2). Sick sinus syndrome is dysfunction of the sinus node or SA conduction in which no adequate escape mechanism is present, and the patient becomes symptomatic because of bradycardia. There are intrinsic and extrinsic causes of SA abnormalities.
 - The most prevalent intrinsic cause of sinus node dysfunction is aging, with replacement of the sinus node and the surrounding atrium by fibrotic degeneration.
 - Extrinsic causes of sinus node dysfunction include drugs (Table 88.1), electrolyte abnormalities (hyperkalemia), endocrine disorders (hypothyroidism), neurally mediated

conditions (vasovagal syncope), and intracranial hypertension.

- Diagnosis and treatment of SA abnormalities
 - Record a 12-lead ECG. Evaluate for myocardial infarction (MI), mechanism of bradycardia, P-wave regularity (sinus or an atrial rhythm). Abrupt pauses or group beating in the sinus rhythm suggests SA block. P waves without QRS complexes suggest AV block. Evaluate also for QRS axis and width for coexistent bundle branch block.
 - If hypotension, dizziness, and presyncope are absent, no immediate treatment is required. Symptoms dictate the treatment plan. Asymptomatic bradycardia due to sinus node dysfunction is not an emergency!
 - In sinus bradycardia, give intravenous (IV) atropine; 0.04 mg/kg, if hypotensive.
 - With SA block or sinus arrest, give no treatment unless hypotension is present or the rhythm is digitalis-induced (stop drug).
 - For sick sinus syndrome, treatment depends on symptoms such as dizziness, presyncope, and congestive heart failure.
 - Acute inferior-posterior MI with SA block, coronary reperfusion is indicated.

TABLE 88.1

DRUGS AFFECTING SINUS NODE FUNCTION

Drug types	
Antiarrhythmics	Class IA (quinidine, procainamide, disopyramide) Class IC (flecainide, propafenone) Class III (sotalol, amiodarone)
Beta-blocking agents	
Calcium channel blockers	Verapamil Diltiazem
Cardiac glycosides	
Miscellaneous	Lithium Cimetidine Diphenylhydantoin Clonidine and dexmedetomidine

FIGURE 88.1. Lead II rhythm strip. Second-degree type II sinoatrial block. The PP interval is initially 720 ms and appears to prolong to 1,440 ms.

Atrioventricular Conduction Abnormalities

- **Noninvasive methods for determining site of block**
 - In AV block, the conduction abnormality may be located within the AV node, the His bundle, or the bundle branches. Determining the location of block is important, as this will affect immediate and long-term treatment.
 - On ECG, baseline PR interval, QRS duration, and axis are important.
 - Bedside responses to noninvasive interventions, including IV atropine administration, exercise, or vagal maneuvers, may differentiate between AV nodal and infranodal block (Table 88.2). Specifically, interventions that slow AV nodal conduction, such as carotid sinus massage, will worsen AV nodal block but, because of sinus slowing, will seem to improve infranodal block. Conversely, interventions that improve AV nodal conduction, such as exercise and atropine, may worsen infranodal conduction because of acceleration of sinus rate.
- **First-degree AV block or prolonged PR interval:** The PR interval is a reflection of AV conduction time and is measured from the onset of the P wave to the beginning of the QRS complex. Conduction delay in the atrium, AV node, bundle of His, or bundle branches all may result in a prolonged PR interval; ≥ 280 ms usually indicates abnormal AV nodal conduction.
- **Second-degree type I AV block (AV Wenckebach):** There is progressive lengthening of the PR interval before there is a blocked P wave (Fig. 88.3). The QRS duration may be narrow or wide, depending on the presence of bundle branch block. When the QRS is narrow, it is most likely a block occurring at the level of the AV node; it is seen in young healthy individuals with increased vagal tone. Patients with an acute inferior MI can have AV nodal block ($\geq 20\%$), indicating a proximal right coronary occlusion.
- **Second-degree type II AV block (Mobitz II):** The PR intervals are normal or slightly prolonged and are exactly the same length before and after the nonconducted P waves (Fig. 88.4). Type II AV block is most likely infranodal in the His bundle if there is a narrow QRS duration (rare) or in the bundle branches if there is wide QRS duration (common). These patients are often symptomatic, with shortness of breath, fatigue, and syncope, and sudden progression to complete AV block.
- **Two-to-one AV block:** Every other P wave conducts to the ventricle and the conducted PR interval may be either normal or prolonged (Fig. 88.5). The level of block—AV nodal versus infranodal—cannot be determined with certainty without an electrophysiology study. A narrow QRS duration suggests that the block is in the AV node or the His bundle, whereas a wide QRS suggests block in the bundle branches.

FIGURE 88.2. Lead II rhythm strip. Sinus arrest with no ventricular escape.

TABLE 88.2**NONINVASIVE INTERVENTIONS TO DETERMINE SITE OF ATRIOVENTRICULAR (AV) BLOCK**

Intervention	AV nodal site of block	Infranodal site of block
Atropine	AV block improves	AV block worsens
Exercise	AV block improves	AV block worsens
Carotid sinus massage	AV block worsens	AV block improves

FIGURE 88.3. A 12-lead electrocardiogram. Sinus rhythm with type I second-degree atrioventricular conduction block.

FIGURE 88.4. A 12-lead electrocardiogram. Sinus rhythm with second-degree type II atrioventricular conduction block.

FIGURE 88.5. A 12-lead electrocardiogram. Sinus rhythm with 2:1 atrioventricular conduction block with left bundle branch block suggesting block below the His bundle.

- **Third-degree AV block or complete AV block:** There is no P wave-to-QRS relationship. Sinus rate (PP intervals) is usually faster than the escape rate. The escape rate is usually <50 beats per minute (bpm), with the exception of a congenital AV block (Fig. 88.6). If the escape rhythm has a narrow QRS complex, it originates in the AV junction and the site

of block is either AV nodal or, less likely, bundle of His. If the QRS is wide, the site of block is likely within the bundle branches.

- **Diagnosis and treatment of AV conduction abnormalities**
 - Record a 12-lead ECG and try to determine site of block by noninvasive methods.

FIGURE 88.6. A 12-lead electrocardiogram. Sinus bradycardia with third-degree AV conduction block.

- In the setting of an acute inferior MI, the site of block is usually the AV node and transient with successful reperfusion. Insert a temporary pacemaker if there is cardiogenic shock secondary to heart block. Use permanent pacing only if there is chronic, symptomatic second- or third-degree AV nodal block.
- Type II AV block: If there is no PR prolongation prior to block, it is most likely in the His–Purkinje system. Temporary pacemaker is required when associated with syncope; permanent pacemaker can be used in most cases.
- Two-to-one AV block: PR interval ≥ 160 ms suggests His bundle or below. Temporary pacemaker is indicated in patients with acute MI, wide QRS, and/or if symptomatic.
- Third-degree AV block: Temporary pacemaker required in acute anterior MI, wide QRS, and/or if symptomatic

NARROW QRS TACHYCARDIA

- *Narrow QRS tachycardia* is defined as an arrhythmia with a rate faster than 100 bpm and QRS duration of <120 ms. Patients are usually symptomatic, complaining of palpitations, lightheadedness, shortness of breath, or anxiety. 12-lead ECG features during tachycardia and sinus rhythm in the same leads and tachycardia response to carotid sinus massage will facilitate the correct diagnosis of the tachycardia. Pulsations in the neck may often reveal the mechanism of the tachycardia (Table 88.3) Sinus tachycardia can be differentiated from other narrow QRS tachycardias by the sinus

TABLE 88.3

JUGULAR PULSATION AND SUPRAVENTRICULAR TACHYCARDIA

Diagnosis of SVT	Jugular pulsation
Sinus tachycardia	Normal pulsation
Atrial tachycardia	Normal pulsation
Atrial flutter	Flutter waves
Atrial fibrillation	Irregular pulse
AV nodal re-entrant tachycardia	Large “A” waves
AV re-entry tachycardia	Large “A” waves
Junctional tachycardia	Large “A” waves

SVT, supraventricular tachycardia; AV, atrioventricular.

morphology of the P wave on a 12-lead ECG. The three most common causes of regular narrow QRS tachycardia are AV nodal re-entrant tachycardia (AVNRT), AV re-entrant tachycardia (AVRT), and atrial tachycardia, respectively.

Atrial Tachycardia

- An ectopic (nonsinus) P wave precedes the QRS complex and can often be localized using the ECG morphology of the P wave (Fig. 88.7). The atrial rate is regular, with PP intervals ranging between 120 and 250 bpm; AV block may be present. Atrial tachycardias may be paroxysmal or persistent (incessant).

FIGURE 88.7. A 12-lead electrocardiogram. Atrial tachycardia with a P wave preceding each QRS complex. The origin of the P wave is low atrial septal.

FIGURE 88.8. A 12-lead electrocardiogram. Atrial flutter with variable atrioventricular conduction.

sant). Paroxysmal tachycardias can originate from a focal area of the myocardium or may be due to re-entry within a macro-re-entrant circuit. Persistent or incessant atrial tachycardia is rare but important to recognize; patients who are in tachycardia >50% of the time may develop tachycardia-induced dilated cardiomyopathy.

Atrial Flutter

- Typical atrial flutter has a classic saw-tooth pattern of atrial activation in the inferior leads of the ECG (Fig. 88.8) with an atrial rate of 250 to 350 bpm; the ventricular response can

FIGURE 88.9. A 12-lead electrocardiogram. Atrial fibrillation with slow ventricular response. Note that there are no discernible P waves and that the rhythm is irregular.

be regular or irregular. The most common form of atrial flutter uses a right atrial macrore-entrant circuit, including the cavotricuspid isthmus. Flutter waves can be better appreciated during rapid tachycardia with slowing of the ventricular response by carotid sinus massage.

Atrial Fibrillation

- The atrial rhythm in atrial fibrillation (AF) is irregular, a rate of 350 to 500 bpm (Fig. 88.9), with variable AV conduction resulting in narrow QRS tachycardia and varying RR intervals. It is the most common supraventricular tachyarrhythmia (SVT) in the United States, and a major cause of cardiovascular morbidity and mortality, with an increased risk of death, congestive heart failure, and stroke.
- The incidence increases with age, with a lifetime risk of one in four men and women older than the age of 40. Similarly, the risk of embolic stroke from AF increases with age (>65 years) and other risk factors including hypertension, prior history of strokes, heart failure, left ventricular function of $\geq 35\%$, mitral stenosis, prosthetic heart valve, and diabetes.
- Stroke prevention is the key focus in the management of AF. Anticoagulation with warfarin, with an international normalized ratio (INR) between 2.0 and 3.0, is recommended in patients with AF and one or two of the aforementioned risk factors.
- AF can be divided into four categories: (a) new onset; (b) paroxysmal (spontaneous termination); (c) persistent (terminates only by pharmacologic or electrical conversion); and (d) permanent.

AV Nodal Re-entry Tachycardia

- AVNRT is the most common form of a regular SVT and is due to re-entry within AV nodal and perinodal tissue. The heart rhythm is regular, usually between 130 and 250 bpm. Different forms of AVNRT are classified based on the direction of the circuit and the electrophysiologic properties of the circuit. Typically, there is simultaneous activation of the atria and ventricles, with P waves either hidden or partially visible at the end of the QRS (Fig. 88.10A), producing a pseudo-r' in V1 and pseudo-s in inferior leads during tachycardia that is not present in sinus rhythm (Fig. 88.10B and C).

AV Re-entrant Tachycardia

- AVRT occurs due to re-entry involving an accessory pathway, an abnormal electrical connection between the atria and ventricle.
- If the accessory pathway conducts anterogradely, certain characteristics, such as a short PR interval, broad QRS, and a delta wave typical of Wolff-Parkinson-White syndrome, may be present on surface 12-lead ECG during sinus rhythm (Fig. 88.11A).
- Orthodromic AV re-entry (see Fig. 88.11B) is a narrow QRS tachycardia that conducts anterogradely down the AV node to activate the ventricles and then conducts retrogradely up the accessory pathway to activate the atria; both the atria

and ventricles are essential parts of the circuit. This is a regular paroxysmal tachycardia, usually with the RP interval less than the PR interval (see Fig. 88.11C).

- If AF occurs in a patient with an anterograde-conducting accessory pathway, the impulse can conduct rapidly down the accessory pathway anterogradely, resulting in variable QRS morphologies (see Fig. 88.11D). This rhythm can degenerate into ventricular fibrillation and sudden death. Treatment with IV ibutilide or procainamide should be first-line medical therapy as other drug therapies can cause hypotension and further hemodynamic compromise without affecting the properties of the accessory pathway or converting to sinus rhythm.

Treatment of Regular Narrow-complex Tachycardia

- Record a 12-lead ECG during tachycardia and in sinus rhythm; record the termination of the tachycardia. On physical examination, evaluate the jugular pulse.
- Vagal maneuver: If no success, then 6 mg of rapid IV adenosine and repeat with 12 mg of IV adenosine. If tachycardia continues, consider beta-blockers, calcium channel blockers (verapamil 5–10 mg IV, if normal left ventricular function), or digoxin.
- If tachycardia persists, use antiarrhythmic medications such as IV amiodarone, IV procainamide (10 mg/kg, no faster than 50 mg/minute), or sotalol.
- If tachycardia persists and/or patient is hemodynamically unstable, cardiovert.

Treatment of Atrial Fibrillation

- Recent onset (<48 hours) without significant heart disease and stable
 - Pharmacologic cardioversion with flecainide (300 mg PO once), propafenone (600 mg po), procainamide (5–10 mg/kg IV over 20 minutes), ibutilide (1 mg IV over 10 minutes, then repeat), or amiodarone (1,000 mg IV over first 24 hours).
 - Electrical cardioversion with sedation
- Recent onset (<48 hours) and unstable: Proceed with immediate cardioversion.
- More than 48 hours and stable:
 - Control ventricular rate with beta-blockers, calcium channel blockers, and/or digoxin.
 - Aspirin can be used in patients with lone AF (no risk factors of heart failure, history of thromboembolism, hypertension, or diabetes).
 - Patients with risk factors should be on oral anticoagulation with warfarin, with a goal of INR of 2.0 to 3.0.
 - If plan to cardiovert or treat with antiarrhythmic medications, either anticoagulate for ≥ 3 weeks prior to cardioversion with therapeutic INR or use transesophageal echocardiography with cardioversion if no thrombus is identified, followed by warfarin anticoagulation.
- More than 48 hours and difficulty in obtaining adequate rate control:
 - Proceed with transesophageal echocardiogram and, if no thrombus is present, cardiovert and anticoagulate.

WIDE QRS TACHYCARDIA

Ventricular Tachycardia

- Independent atrial and ventricular activity (AV dissociation) is an important ECG finding that is present in 60% of patients with ventricular tachycardia (Fig. 88.12). Physical examina-

tion findings of an irregular jugular pulse, known as cannon “A” waves, varying intensity of the first heart sound, and beat-to-beat changes in systolic blood pressure all are consistent with AV dissociation.

- Presence of supraventricular capture beats (sinus beats that are conducted to the ventricle with a narrow QRS during a wide-complex tachycardia) or fusion beats (sinus beats that fuse with the wide-complex beat, resulting in a QRS that is narrower than the tachycardia) would be consistent with a diagnosis of ventricular tachycardia (Fig. 88.13).
- The wide QRS of ventricular tachycardia does not usually mimic a true bundle branch block, as in ventricular

FIGURE 88.11. (Continued) C: A 12-lead electrocardiogram. Narrow-complex tachycardia in the same patient was found to be AVRT with anterograde conduction down the AV node and retrograde conduction up the accessory pathway. D: A 12-lead electrocardiogram. Atrial fibrillation in a patient with anterograde-conducting accessory pathway. There are various QRS widths as there is conduction simultaneously down both the AV node and the accessory pathway. This patient is at risk for ventricular fibrillation and sudden cardiac death.

FIGURE 88.12. A 12-lead electrocardiogram. Ventricular tachycardia with atrioventricular dissociation (arrows indicate P waves) and negative concordance. There is an atypical left bundle branch block pattern.

FIGURE 88.13. A 12-lead electrocardiogram. Ventricular tachycardia with AV dissociation and fusion beats (first and second arrows) and supraventricular capture beats (third arrow) confirming the diagnosis of ventricular tachycardia.

FIGURE 88.14. A: A 12-lead electrocardiogram. Atrial flutter with 1:1 conduction and typical left bundle branch block aberrancy. B: A 12-lead electrocardiogram. Atrial flutter with 2:1 conduction and typical left bundle branch block aberrancy in the same patient as in Figure 88.12A.

tachycardia, the impulse is generated in the ventricles; therefore, careful examination of the QRS morphology can usually differentiate ventricular tachycardia from right or left bundle branch block aberrancy.

- In addition, if all the QRS complexes in the precordial leads V1 to V6 are negative (negative concordance), this is con-

sistent with the diagnosis of ventricular tachycardia (see Fig. 88.12).

- The wider the QRS, the more likely that tachycardia is ventricular in origin.
- Hemodynamic stability, age of the patient, and ventricular rate or regularity should never be used to distinguish between

supraventricular or ventricular tachycardia, as they can be misleading.

Supraventricular Tachycardia with Aberrancy

- Supraventricular tachycardia with aberrancy still conducts down the AV node to the ventricle and can either present with a functional (intermittent) aberrancy or a fixed bundle branch block. The pattern of aberrancy is either typical left or right bundle branch block, and a baseline 12-lead ECG can determine the presence of underlying bundle branch block (Fig. 88.14A and B).

Pre-excited Tachycardia

- In patients with AV accessory pathways or Wolff-Parkinson-White syndrome, wide-complex (pre-excited) tachycardias can be seen. In the antidromic AV re-entrant variety, the atrial impulse activates the ventricle anterogradely via the accessory pathway, and retrograde conduction to the atrium is through either the AV node or another accessory pathway (Fig. 88.15). Atrial tachycardias or atrial flutter can conduct via the accessory pathway to produce pre-excited tachycardias.

Treatment of Wide QRS Tachycardia

- A correct and rapid diagnosis is essential, as incorrect treatment may result in hemodynamic decompensation and death.

FIGURE 88.15. Schematic of antidromic atrioventricular (AV) re-entry, a pre-excited tachycardia with anterograde conduction down the accessory pathway (AP) and retrograde conduction up the AV node.

- Monomorphic wide-complex tachycardia that is thought to be ventricular in origin in a stable patient can be treated with amiodarone (150 mg IV over 10 minutes; repeat as needed to a maximum dose of 2.2 g IV per 24 hours). If amiodarone is not successful or the patient develops hemodynamic instability or symptoms, electrical cardioversion is appropriate.
- If the wide-complex tachycardia is thought to be SVT with aberrancy, adenosine administration is recommended (6 mg rapid IV push; if no effect, 12 mg IV push can be tried). Adenosine may be therapeutic (terminating the tachycardia by blocking the AV node) if the patient has a re-entrant SVT or diagnostic (causing transient increase in AV block) if the patient has AF or flutter. In the latter case, if patient

FIGURE 88.16. A 12-lead electrocardiogram. Sinus rhythm with a long QT interval (arrows indicate QT measured at approximately 520 ms).

remains stable, rate-controlling IV drugs that have longer-lasting effects, such as beta-blockers or diltiazem, may be administered. Avoid the administration of IV verapamil if the patient has left ventricular dysfunction, heart failure, and/or if there is a possibility that the rhythm could be ventricular in origin, as verapamil has been shown to cause clinical deterioration and death. If the patient is hemodynamically unstable, synchronized cardioversion is appropriate.

- In a patient with Wolff–Parkinson–White and in AF with anterograde conduction down the accessory pathway, first-line medical therapy should be IV procainamide, 100 mg every 5 minutes (maximum 25–50 mg/minute or 17 mg/kg maximum if normal renal function) or IV ibutilide, 1 mg over 10 minutes (may be repeated). These drugs block the rapid conduction over the accessory pathway and may also terminate the AF. If there is no effect or the patient is unstable, immediate cardioversion is indicated.

DRUG-INDUCED ARRHYTHMIAS

- Many antiarrhythmic agents, noncardiac drugs, and nonprescription medications can cause QT prolongation (Fig. 88.16) and, subsequently, torsade de pointes.

Torsade de Pointes

- Polymorphic VT with beat-to-beat changes in the QRS axis (Fig. 88.17); there is QT prolongation, often with a pause or bradycardia-dependent initiation of the arrhythmia. The mechanism is thought to be related to reaching the threshold potential for the slow calcium channel, resulting in early afterdepolarizations and ectopic impulse formation, triggering re-entrant excitation. If a drug is responsible for prolonging the QT duration, it should be discontinued. The administration

FIGURE 88.17. Lead II rhythm strip. Long QT interval with torsade de pointes.

of IV magnesium is effective for treatment, even when serum magnesium is normal; hypokalemia should also be corrected. Close monitoring is essential, and if bradycardia persists, give atropine or institute temporary pacing. Isoproterenol infusion, between 1 and 4 $\mu\text{g}/\text{minute}$, can be used transiently to increase the heart rate.

Digitalis-induced Arrhythmias

- Digitalis, frequently used in heart failure and AF, is a positive inotrope. It slows the ventricular rate during AF, increases vagal tone, causes diuresis, and has vasodilatory effects. It has a narrow therapeutic window, with women requiring a lower dose than men, and unrecognized digitalis intoxication is a common problem. Often missed by clinicians, the symptoms are nonspecific (gastrointestinal symptoms, visual changes, neuropsychiatric problems, and weakness) and serum drug levels do not correlate well with toxicity. It is important for any health care professional caring for patients who take digitalis to be familiar with ECG findings consistent with digitalis toxicity.

- Diagnosis: Arrhythmias due to digitalis toxicity include atrial tachycardia, junctional tachycardia, ventricular tachycardia, and bradyarrhythmias, including AV block. Many other comorbidities and conditions can potentiate digitalis toxicity, including sympathetic stimulation, hypokalemia, hypercalcemia, hypomagnesemia, diuretics, ischemia and reperfusion, and heart failure.
- Digitalis toxicity can manifest as four ECG features: (a) bradycardia when the heart rate was previously normal or fast; (b) tachycardia when the heart rate was previously normal; (c) unexpected regular rhythm when the patient previously had an irregular rhythm; and (d) an irregular rhythm that regularly repeats itself.
- The treatment of digitalis toxicity depends on the clinical condition and not the drug level. The first step when suspecting digitalis toxicity is to discontinue the medication. Rest, continuous ECG monitoring, and correction of electrolyte abnormalities will often help. If the arrhythmia is life threatening, administering digitalis antibodies or phenytoin may be indicated. The patient's kidney function must be determined to estimate the severity of the suspected intoxication.

CHAPTER 89 ■ PERICARDIAL DISEASE

THE NORMAL PERICARDIUM

- The normal pericardium forms a sac around the heart and proximal large arteries and veins. It has a thin visceral mesothelial layer that closely adheres to the epicardial surface of the heart. The parietal layer consists of the same thin mesothelium and a thicker (up to 2 mm), fairly nonelastic fibrous layer on the outside. Physiologically, the space between both mesothelial layers contains 20 to 30 mL of fluid.
- The fibrous part of the pericardium is attached to the surrounding mediastinal structures and holds the heart in its position within the chest. It limits cardiac dilatation, contributes to the interventricular interaction, and primarily affects diastolic function. The smooth mesothelial surfaces and the pericardial fluid between them reduce friction and act as a barrier to inflammation from surrounding structures. The pericardium is well innervated, and pathologic processes can cause severe episodic or continuous pain.
- The intrapericardial pressure is usually negative; it is approximately equal to and varies with the pleural pressure at the same hydrostatic level. Pericardial pressure affects myocardial transmural pressure by the following relationship:

$$\text{Transmural pressure} = \text{cavitary pressure} - \text{adjacent intrapericardial pressure}$$

Because the intrapericardial pressure is normally negative, this usually adds to the normal transmural pressure gradient.

- The relationship between intrapericardial and pleural pressures causes a simultaneous fall of pressures in both spaces during inspiration and leads to an increased venous return into the right chambers (increased preload), with a subsequent increase in cardiac output. Inspiration influences filling and cardiac output of the left heart only indirectly and very little.

ACUTE PERICARDITIS

Etiology

- Inflammation of the pericardial sac is either an isolated problem or part of a systemic process. Depending on the frequency and time course, pericarditis can be acute, recurrent, or chronic. Common causes of acute pericarditis are shown in Table 89.1. Most often, clinically recognizable pericarditis in the adult is idiopathic, though various viruses are often suspected.
- The most commonly demonstrated virus is the Coxsackie B group, which causes myopericarditis in children and pleuropericarditis in adults (also called Bornholm disease). Enteric cytopathic human orphan (ECHO), influenza, Epstein-Barr, varicella, hepatitis, mumps, and human immunodeficiency viruses can also cause pericarditis.
- Up to one-third of patients with end-stage renal disease will develop uremic pericarditis, and the symptoms usually

disappear after beginning or increasing the frequency of dialysis. Increased toxin levels from declining renal function are suspected causes of the inflammatory process, but there is no direct association with serum blood urea nitrogen level or serum creatinine and the acute illness. Note that uremic patients are susceptible to infections that may cause pericarditis, and the underlying disease process leading to the renal insufficiency may also be the cause for the pericardial inflammation.

- Acute pericarditis after myocardial injury is thought to be due to direct irritation of the visceral mesothelium. Historically affecting up to 20% after transmural myocardial infarction; the frequency has decreased due to reperfusion therapy. Symptoms typically occur after 1 to 3 days and can mimic recurrent angina pectoris. If receiving anticoagulants, the inflammation can lead to hemorrhagic intrapericardial effusion and possibly cardiac tamponade.
- Acute pericardial inflammation is also found after open heart surgery, implantation of cardiac pacemakers, percutaneous coronary interventions, or external cardiac trauma. The **postpericardiotomy syndrome** was originally described as postmyocardial infarction pericarditis but later seen in children and adults after opening of the pericardium. The syndrome occurs in 10% to 30% after pericardiotomy and is thought

to be an immune complex reaction. In contrast to pericarditis caused by myocardial injury, chest pain and fever begin after several weeks to months.

- Neoplastic pericarditis is most often caused by cancer of the lung, breast, or esophagus and lymphoma and melanoma. The tumor directly invades the pericardial space or metastasizes through lymphatics or blood vessels; primary pericardial tumors such as mesothelioma are rare. The likelihood of finding previously undiagnosed cancer in a patient presenting with pericarditis is about 6% to 7%. In known malignancy, only 50% to 60% are neoplastic pericarditis; idiopathic and radiation-induced pericarditis are the most common benign causes. The prognosis of neoplastic pericarditis and effusion is poor.
- Pericarditis is also seen in patients with systemic lupus erythematosus, rheumatoid arthritis, and scleroderma. Inflammation of the pericardium is often the first manifestation of lupus in female patients; this diagnosis should be ruled out during the workup for a first episode of idiopathic pericarditis. Radiation pericarditis often follows a mediastinal dose of 4,000 rad or more and can lead to pericardial effusion and acute cardiac tamponade. The long-term effects of radiation also can lead to constrictive pericarditis.
- Pericarditis caused by infectious organisms other than viruses is less frequent now than it was in the preantibiotic era. Pneumonia is still the most common cause; others include sepsis or direct spread from mediastinitis or necrotizing fasciitis of the head or neck. Immunocompromised and elderly patients are more prone to infectious pericarditis than the general population. In adults, *Staphylococcus aureus* is still the most common organism, and there is an apparent decline in infections with *Streptococcus* spp., *Pneumococcus* spp., and *Haemophilus influenzae*.
- Tuberculous pericarditis was once a common cause of acute and constrictive pericarditis but, with the overall decline of tuberculosis, it has become a rare entity in the United States. States with a high percentage of immigrants have reported rising numbers, as 1% to 2% of patients with pulmonary tuberculosis will develop tuberculous pericarditis. Mycobacterial infection must be ruled out in any case of suspected purulent pericarditis.
- The most common fungal organism to cause pericarditis is *Histoplasma capsulatum*. Histoplasmosis in the United States is most common in the Mississippi and Ohio River valleys. Diagnosis is usually delayed and made by positive fungal culture of the pericardial fluid and/or a significant rise of serologic antibody titers (>1:32) against *Histoplasma capsulatum*.

Clinical Presentation

- The typical patient is young and was previously healthy. Symptoms of acute pericarditis include sharp and, usually, persistent chest pain that is generally increased with respiration and motion. It is worse in the supine position and usually improves sitting up and/or with shallow breathing. The pain can radiate to the neck, and dyspnea may also be present. Other common findings preceding or accompanying pericarditis are fever, myalgia, malaise, and tachycardia.
- The characteristic and pathognomonic three-component friction rub is best heard at the left sternal border or the

FIGURE 89.1. Electrocardiogram of a patient with acute pericarditis. Note the PR-segment depressions (arrows) and convex ST-segment elevations in the inferolateral leads and PR-segment elevation (arrow-head) and ST-segment depression in lead aVR, consistent with stage I of electrocardiogram findings in acute pericarditis.

cardiac apex and described as coarse, leathery, superficial—like “pulling Velcro.” The rub is only intermittently heard; auscultate frequently in a quiet setting with an upright position leaning forward.

- An electrocardiogram (ECG) should be obtained in every patient presenting with chest pain. Four ECG stages, evolving over hours to days and weeks, have been described:
 - Stage I includes classic and diffuse ST elevations with a concave ST segment and significant PR-segment depression (Fig. 89.1).
 - Stage II is normalization of the ECG.
 - Stage III is development of diffuse T-wave inversion that may persist or normalize.
 - Stage IV is final normalization of the ECG.
- The ECG may show all, several, or none of the stages during an episode of acute pericarditis. The key to the ECG diagnosis is the diffuse nature of the changes, the absence of localization to a particular ECG anatomic area, PR-segment depression, and the absence of ST depression except in lead aVR. Variant angina, hypertrophic cardiomyopathy, and the benign finding of early repolarization can mimic the ECG changes described.
- Atrial arrhythmias are rare but do occur and can be the first manifestation of acute pericarditis. Sustained atrial or ventricular arrhythmias are suggestive of concomitant myocarditis.
- A chest radiograph will be normal in most cases of pericarditis; an enlarged cardiac silhouette is suggestive of a pericardial effusion (>200 mL) and should be further evaluated.
- The laboratory may report positive acute-phase reactants (especially the erythrocyte sedimentation rate) and an elevated white blood cell count; however, these are nonspecific findings. Cardiac troponin T or I and CK-MB isoenzymes are often minimally elevated. Viral studies may confirm the cause of the pericarditis but are low yield and do not change management. In cases of suspected infectious etiology, cultures from blood and pericardial fluid, if available, should be examined for bacterial and mycobacterial pathogens.
- Echocardiography should be performed in every patient with the suspected diagnosis of pericarditis to evaluate for and follow pericardial effusion (Fig. 89.2) and to help diagnose cardiac tamponade.
- The triad of typical chest pain, pericardial friction rub, and the aforementioned ECG changes confirms the diagnosis of

FIGURE 89.2. Subcostal echocardiogram showing a giant pericardial effusion (asterisk) in a patient with neoplastic pericarditis.

TABLE 89.2

LIFE-THREATENING DIFFERENTIAL DIAGNOSIS OF ACUTE PERICARDITIS

Acute coronary syndrome

acute pericarditis. However, this diagnosis should be made only after life-threatening conditions with similar presentation have been ruled out (Table 89.2). Computed tomography (CT) of the chest may be necessary to rule out pulmonary embolism or aortic dissection (Fig. 89.3); with newer scanners, a *triple rule-out* scan can evaluate the pulmonary artery tree, thoracic aorta, and coronary arteries on a single breath-hold, contrasted, ECG-gated exam.

Treatment

- Acute pericarditis has a high likelihood of uncomplicated recovery; however, several factors are described as being associated with a complicated course and should prompt hospitalization for their initial treatment (Table 89.3).
- Acute idiopathic or viral pericarditis usually responds to nonsteroidal anti-inflammatory drugs (NSAIDs). The drug regimen consists of high-dose aspirin (325–975 mg three to four times daily for 4 weeks), with a proton pump inhibitor to lessen gastrointestinal effects.
 - Alternatively, indomethacin (25–50 mg four times daily) or ibuprofen (400–600 mg four times daily) can be given.
 - Colchicine has been shown to be effective as a second-line treatment for patients who do not respond to NSAIDs or who have recurrence of their acute pericarditis. Routine initial use of colchicine (1–2 mg on day 1 followed by

TABLE 89.3

PRESENTING FACTORS PREDICTING COMPLICATED COURSE

Large effusion (>20 mm) or tamponade
Failure to respond to nonsteroidal anti-inflammatory drugs

0.5–1 mg/day for 3 months) in addition to aspirin may significantly reduce symptoms at 72 hours and recurrence at 18 months compared to aspirin alone. Diarrhea is a known side effect of colchicine and may cause discontinuation of drug therapy in about 5% of patients.

- Symptoms of acute pericarditis respond rapidly to systemic steroids, but there seems to be an increase in relapse after tapering. Corticosteroid therapy should be reserved for recurrent pericarditis not responding to NSAIDs and colchicine. The recommended regimen is 1 to 1.5 mg/kg of prednisone for at least 1 month before slowly tapering the dose by 5 mg/week until the drug is withdrawn. The possible side effects include peptic ulcer disease, sodium retention, hypokalemia, hyperglycemia, Cushing syndrome, and suppression of the adrenal axis. Treatment with corticosteroids also requires the exclusion of infection or an appropriate antibiotic regimen before initiation of therapy.
- The treatment of choice for uremic pericarditis consists of intensive, initially daily dialysis therapy. Heparin should be used sparingly during dialysis to reduce the risk of intrapericardial hemorrhage and possible tamponade.
- The presence of acute pericarditis in acute myocardial infarction also requires caution with the use of intravenous anticoagulants. These drugs are not, however, absolutely contraindicated. Thrombolytic agents have been reported to lead to cardiac tamponade and should be used with caution in the patient with acute myocardial infarction and acute pericarditis.
- The postpericardiotomy syndrome is usually self-limited if left untreated; however, it may increase the risk of early coronary artery bypass graft closure so aggressive treatment with NSAIDs has been recommended. Refractory cases may occur but usually respond rapidly to systemic corticosteroids. Advocates of corticosteroid therapy claim that this treatment reduces the incidence of late constrictive pericarditis.
- Nonviral infectious etiology of pericarditis requires prompt evacuation of pus from the pericardium, usually by operative intervention, because of the need to establish a definitive diagnosis, eradicate the infection, and prevent constrictive pericarditis.
- Recurrence of acute pericarditis is quite common and often requires long-term drug therapy as noted earlier. In a few selected cases refractory to medical therapy, radical pericardiectomy may need to be considered.
- In general, acute pericarditis symptoms subside within several days to weeks. The major immediate complication is cardiac tamponade, which occurs in fewer than 5% of patients. For diagnostic and treatment approach in patients with

FIGURE 89.3. Computed tomography (CT) of the chest with large pericardial effusion (asterisk) and small right-sided pleural effusion (plus sign). The dark rim between the pericardial effusion and the right heart represents epicardial fat.

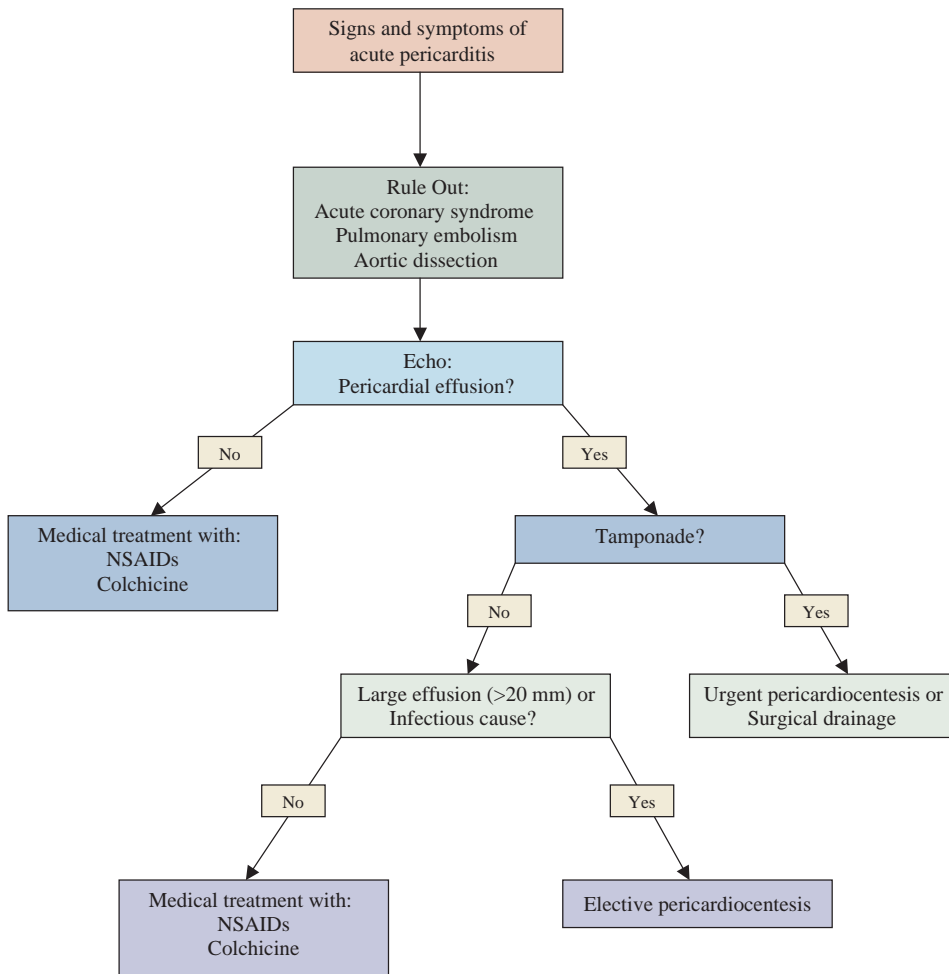

FIGURE 89.4. Diagnostic and treatment algorithm for patients presenting with signs and symptoms of acute pericarditis.

suspected acute uncomplicated or complicated pericarditis, see Figure 89.4.

PERICARDIAL EFFUSION AND CARDIAC TAMPONADE

Etiology

- With acute pericarditis, exudation of fluid and occlusion of the normal drainage through epicardial venous and lymphatic systems by the inflammatory process result in pericardial effusion. The most common causes of tamponade include idiopathic pericarditis, cancer of the lung and breast, lymphoma, renal failure, and tuberculosis.
- Pericardial effusion may also occur in the absence of pericardial inflammation as in hemorrhagic effusion from internal sources such as a pacemaker, angioplasty, coronary artery bypass grafting surgery, aortic dissection, ventricular rupture, or external cardiac trauma.
- Regardless of their size, pericardial effusions can either be clinically silent or cause hemodynamic compromise; the latter situation is called **cardiac tamponade**. The pericardium resists sudden stretching but can gradually expand in response to a chronic distending force. The factor most important to the

development of cardiac tamponade is not the total amount of pericardial fluid but the rate at which it accumulates. A small (<200 mL) but rapidly developing effusion can cause tamponade, whereas a very large pericardial effusion (1,000 mL) developing over weeks or months may be completely asymptomatic.

- The pericardial pressure–volume curve is generally flat until the limits of distention are reached. The pressure–volume curve then becomes curvilinear, and very small volumes of additional fluid raise the intrapericardial pressure significantly. Once the intrapericardial pressure exceeds the filling pressures of the right atrium and/or the right ventricle, central venous pressure rises, cardiac output drops, and cardiac tamponade—and consequently cardiogenic shock—occur.
- Physiologically, the total cardiac volume is limited, and volume in one chamber can increase only if volume in another chamber decreases. This physiologic interdependence of the ventricles is accentuated in cardiac tamponade when right ventricular filling during inspiration causes a significant decrease in left ventricular filling and a significant decrease in stroke volume.
- Cardiac tamponade, if not treated aggressively and rapidly, may be fatal. If diagnosed in a timely fashion, treatment may be successful so cardiac tamponade needs be included in the initial differential diagnosis of cardiogenic shock or pulseless electrical activity.

Clinical Presentation

- The patient with early pericardial tamponade is often confused, agitated, pale, and diaphoretic and complains of chest pain and dyspnea. Initially, compensatory catecholamine release, caused by a decreased cardiac output, leads to sinus tachycardia and often to peripheral vasoconstriction. Later, bradycardia occurs, indicating imminent pulseless electrical activity and cardiorespiratory arrest unless the effusion is immediately decompressed.
- Classic clinical signs include jugular venous distension, demonstrating a rapid x-descent but no y-descent because of right atrial and ventricular compression throughout the entire diastolic cycle. In this situation, the central venous pressure is usually >15 mm Hg, but jugular venous distention may be missing in trauma patients with rapidly developing hemorrhagic tamponade or in patients with uremic pericarditis due to volume depletion from blood loss or dialysis, respectively (*low-pressure tamponade*).
- A drop in systolic blood pressure of >10 mm Hg with inspiration, termed **pulsus paradoxus**, is very suggestive of cardiac tamponade in a patient with hypotension and tachycardia. It can be ascertained through invasive arterial pressure tracing, by palpation or with a sphygmomanometer. Paradoxical pulse is absent in patients with severe aortic insufficiency or atrial septal defect and is difficult to assess in acute cardiac tamponade with hypotension, as the pulse may be unobtainable or disappear completely with inspiration. It is not specific and can also present in other conditions such as chronic obstructive pulmonary disease, pulmonary embolism, pneumothorax, acute asthma, and hypovolemic shock. Patients with tamponade physiology often drop their systolic blood pressure more than 20 mm Hg with inspiration.
- Other clinical signs of cardiac tamponade are distant and muffled heart sounds and clear lungs. The patient with chronic tamponade may present with a low-output state, right-upper quadrant pain caused by swelling of the hepatic capsule, or even ascites and lower-extremity edema. The two main differential diagnoses for cardiac tamponade are tension pneumothorax and pulmonary edema; both conditions can present with tachycardia, hypotension, and jugular venous distension.
- The ECG usually shows signs of acute pericarditis, including sinus tachycardia, PR depression, and abnormal T-wave changes. Electrical alternans of the ECG is almost pathognomonic of pericardial tamponade; it represents a change of direction and amplitude of the P, QRS, and T vectors with every other heart beat and probably results from the “swinging” movement of the heart in a large volume of fluid. A change of the electrical QRS alternans alone is the most common finding. Its absence does not rule out large effusion or tamponade, particularly if they develop rapidly.
- The chest radiograph may show a globular heart hanging down in the mediastinum—the *water bottle heart* (Fig. 89.5). It is also helpful to rule out diagnoses presenting similarly to tamponade, such as tension pneumothorax and pulmonary edema.
- **Echocardiography** is a very useful tool to assess pericardial effusion and determine its hemodynamic significance. It can detect very small pericardial effusions (<20 mL), helps estimate amount and distribution, and visualizes clot or tumor

FIGURE 89.5. Anteroposterior chest radiograph in patient with a very large pericardial effusion. The extensive widening of the cardiac silhouette resembles a water bottle.

in the fluid if present. Small effusions (<1 cm) are seen only inferolaterally and around the right atrium (Fig. 89.6). Pericardial effusion tracks between the inferolateral wall and the descending thoracic aorta in the parasternal long-axis view and separates both structures (Fig. 89.7), whereas pleural effusion is found only posterior to the aorta in this view. Effusions causing tamponade are mostly large (>2 cm) and circumferential; in acute tamponade, they are usually smaller.

- Once a pericardial effusion begins to compromise the hemodynamics, there are several characteristic echocardiographic findings. There is diastolic collapse, first of the right atrium,

FIGURE 89.6. Apical four-chamber view echocardiogram in patient presenting with acute pericarditis. The very small pericardial effusion is seen only around the right atrial wall (asterisk). The right atrium is not compressed by the effusion. This location may be the only one in which an early or small pericardial effusion can be seen in a patient with poor subcostal windows.

FIGURE 89.7. Parasternal long-axis echocardiographic view in a patient presenting with clinical symptoms of acute pericarditis. There is a small to moderate-sized concentric effusion (*asterisk*). It tracks between the inferolateral wall and the descending thoracic aorta (*arrow*) and thereby confirms the diagnosis of pericardial effusion. A pleural effusion may be seen in the same inferolateral location but would not separate the heart from the aorta.

and then right ventricle, both of which worsen during expiration when right-sided filling is reduced. Diastolic collapse lasting more than one-third of diastole is considered indicative for tamponade (Fig. 89.8). Reciprocal respiratory variation of $>20\%$ to 25% of the peak transmitral and transtricuspid Doppler velocities is another very specific indicator (Fig. 89.9). Lifesaving treatments for an unstable or deteriorating patient suffering from cardiac tamponade should not be delayed by waiting for an echocardiogram to be performed.

- The invasive hemodynamic profile of acute cardiac tamponade is characteristic and can be assessed by a pulmonary artery catheter. The right-sided cardiac pressures are elevated, and the diastolic pressures equilibrate. The mean right atrial pressure, right ventricular diastolic pressure, pulmonary artery diastolic pressure, and the pulmonary capillary wedge pressure are elevated and are measured within 2 to 3 mm Hg of one another. The pressure contour does not show a dip and plateau sign as seen in constrictive pericarditis. The pressures in chronic congestive heart failure are elevated but do not equilibrate in diastole.

Treatment

- Patients with newly diagnosed pericardial effusion, without tamponade physiology, should be monitored in the hospital for 24 to 48 hours, with at least one repeat echocardiogram prior to discharge. A follow-up echocardiogram should be performed for large pericardial effusions 4 to 6 weeks after the initial presentation or with change in symptoms suggestive of early hemodynamic significance.
- Hemodynamically significant cardiac tamponade, defined as systolic blood pressure <110 mm Hg or pulsus paradoxus >10 mm Hg, should receive immediate aggressive fluid resuscitation with normal saline to increase right-sided filling pressures to at least temporarily stabilize hemodynamics. Inotropic support with dobutamine, dopamine, isoproterenol, or norepinephrine may be needed to further stabilize the blood pressure. More definitive treatment with percutaneous pericardiocentesis or surgically created pericardial window should follow promptly. Any patient presenting with traumatic hemopericardium should be treated surgically.
- Pericardiocentesis should be performed in any patient with acute tamponade and hemodynamic compromise or when an infectious or malignant cause of the pericardial effusion is

FIGURE 89.8. Subcostal echocardiogram in a patient with cardiogenic shock. Compared to early systole (A), there is significant collapse of the right ventricular free wall until very late into the diastolic filling phase (B), consistent with pericardial tamponade. The treatment of choice is immediate decompression of the effusion (*) by percutaneous or surgical drainage.

FIGURE 89.9. Transmitral pulse-wave Doppler tracing with significant (>20%) decrease of E-wave velocity during inspiration (x) when compared to velocity during expiration (+). This finding indicates hemodynamic significance if found in conjunction with a pericardial effusion, and immediate drainage of the effusion via percutaneous or surgical route should be considered.

suspected. The procedure is usually performed in the cardiac catheterization laboratory but, in an emergency, may be done at the bedside if clinically necessary.

- Position the patient supine at a 45-degree angle. The area between the xiphoid and the left costal arch should be sterilely prepped using a chlorhexidine–alcohol solution and draped, then anesthetized with a 1% or 2% lidocaine solution. A 7.6-cm (3-inch) aspiratory needle (16–18 gauge) with a short bevel, attached to a three-way stopcock and a 50-mL syringe, is advanced with negative pressure at an angle of 30 to 45 degrees to the abdominal wall and oriented in a posterocephalad direction toward the left shoulder. Once in the pericardial space, fluid can be easily removed. Removal of a small amount of fluid may provide significant clinical improvement. A temporary catheter is then placed into the pericardial space via the Seldinger technique and connected to a bag draining to gravity for several days. This approach provides more complete drainage and reduces the risk for reaccumulation of the effusion. The first sample of fluid retrieved should be sent for microbiologic studies and several other diagnostic tests (Table 89.4).
- Echocardiography can be used to locate the ideal spot for percutaneous puncture, determine distance from the surface to the effusion, demonstrate liver or lung tissue in the projected path, and confirm position within the pericardial effusion. Alternatively, the needle is connected to a V lead of the ECG via an alligator clamp to detect needle contact with the epicardium by sudden demonstration of ST-segment elevation. Complications of this procedure include pneumothorax, myocardial and coronary artery laceration, dysrhythmias, and death.

TABLE 89.4

DIAGNOSTIC TESTS ON PERICARDIAL FLUID

- Complete blood count (CBC) and differential
- Microbiology (Gram stain, culture, acid-fast bacillus smear)
- Chemistry (glucose, protein, albumin, LDH, amylase)
- Cytology

LDH, lactate dehydrogenase.

- If the patient with acute cardiac tamponade can be stabilized by volume expansion and vasopressor support, a safer and equally effective drainage of pericardial fluid can be accomplished by surgical subxiphoid pericardial resection and drainage. Subxiphoid resection can be performed in a sterile environment under local anesthesia; pericardial fluid can be removed and pericardial tissue obtained for biopsy and culture.
- Malignant recurrent pericardial effusions often require a pericardial window to allow fluid to drain into the adjacent pleural space. More recently, percutaneous balloon pericardiectomy has been developed as a nonsurgical approach to create such a window and to drain large pericardial effusions.

CONSTRICTIVE PERICARDITIS

Etiology

- Constrictive pericarditis occurs when chronic inflammation leads to scarring and, in some cases, calcification of the pericardium. Tuberculosis is the most common cause worldwide; the leading causes in the United States are idiopathic pericarditis, previous mediastinal radiation, or cardiac surgery. The thickened (>2 to 3 mm) and shrunken pericardium leads to compromise of diastolic filling and elevation and equalization of end-diastolic pressures in all four cardiac chambers. Up to 20% of patients with surgically proven constriction may present without any pericardial thickening (Fig. 89.10).
- Contrary to pericardial tamponade, the initial diastolic ventricular filling is very rapid; filling abruptly ceases once ventricular volume has reached the limits allowed by the constricted pericardium. Together, these two findings compose the dip and plateau or square root sign of constrictive pericarditis seen during pulmonary artery catheterization (Fig. 89.11).
- The signs and symptoms of constrictive pericarditis generally develop over a prolonged period and are similar to those of biventricular congestive heart failure, restrictive cardiomyopathy, cor pulmonale, cirrhosis, and pericardial tamponade.

FIGURE 89.10. Axial slice of chest computed tomography in a patient with clinical findings of severe right heart failure. The pericardium is well seen (arrowheads) due to the separation from the myocardium by a very small pericardial effusion (arrow). Of note is that the pericardium is neither thickened (maximally 3 mm in thickness) nor calcified; however, preoperative cardiac catheterization results and the intraoperative findings during surgical pericardial stripping confirmed the diagnosis of constrictive pericarditis.

Features of cardiac tamponade and constrictive pericarditis can occur simultaneously, referred to as *effusive-constrictive pericarditis*. This likely represents a transitional state from effusive to constrictive pericarditis and is commonly seen with malignant pericardial effusion from thoracic neoplasm and constrictive pericarditis after radiation to the chest.

FIGURE 89.11. Right (RV) and left ventricular (LV) pressure tracings in a patient with clinical findings consistent with constrictive pericarditis. The early diastolic dip is followed by plateau, with elevation and equalization of right and left ventricular pressures. Note that contrary to ventricular discordance, the dip and plateau sign is classic but not specific for constrictive pericarditis and can be found in several other medical conditions (see text for details). The electrocardiographic tracing shows atrial fibrillation seen often in constrictive pericarditis.

Clinical Presentation

- Patients often complain of fatigue, increasing dyspnea on exertion, abdominal discomfort, and abdominal and lower-extremity swelling. Physical findings include increased jugular venous pressure with a prominent x- and y-descent. A loud early diastolic sound, a “pericardial knock,” caused by the sudden cessation of ventricular filling is heard in up to 50% of patients and pathognomonic for pericardial constriction. The lungs remain clear initially and later develop left-sided or bilateral pleural effusions. The liver is enlarged secondary to congestion; ascites, splenomegaly, and significant lower-extremity edema are also present.
- Unlike in cardiac tamponade, blood pressure is maintained, and fewer than 20% of patients have a significant pulsus paradoxus. A lateral chest radiograph may show pericardial calcium in up to 50% (Fig. 89.12).
- The ECG findings are nonspecific and include T-wave inversions, low voltage, and atrial fibrillation. Echocardiography is helpful to distinguish right heart failure from pericardial constriction; however, echocardiographic findings are not specific for the diagnosis. They include paradoxical septal motion, rapid deceleration of the early diastolic mitral inflow velocity (E wave), significant respiratory variation of mitral inflow velocity (>25%), and normal mitral valve annular tissue Doppler velocity. In the absence of a pericardial effusion, a thickened pericardium is often hard to distinguish from the myocardium.
- Cardiac CT and cardiac magnetic resonance imaging (MRI) are very useful to precisely determine the pericardial

FIGURE 89.12. Lateral chest radiograph showing calcifications of the anterior and inferolateral pericardium in a patient with constrictive pericarditis (arrowheads).

FIGURE 89.13. Four-chamber view of electrocardiogram-gated cardiac magnetic resonance imaging (MRI) in a patient with suspected pericardial constriction. The normal-appearing pericardium (arrowheads) is very precisely visualized in areas with pericardial effusion (arrows) and with pericardial fat (asterisk) only. The outstanding soft-tissue imaging capabilities of MRI make it preferable over cardiac computed tomography (CT) to evaluate the pericardium in patients with no or very little pericardial effusion. ECG, electrocardiogram.

thickness. Cardiac MRI is better suited to image soft tissues and can, in contrast to CT, show normal pericardium, even in the absence of pericardial effusion (Fig. 89.13). Furthermore, tagged cine MRI is able to demonstrate adhesions between the pericardium and myocardium.

- Cardiac catheterization pressure tracings are still the gold standard to diagnose constrictive pericarditis and to differentiate it from restrictive cardiomyopathy. The hemodynamic findings of elevated and equalized diastolic pressures in all four chambers and the dip and plateau sign are classic, although not very specific for constriction. In contrast, respiratory variation of ventricular pressures (right ventricular pressure rises and left ventricular pressure falls during inspiration and vice versa during expiration, causing ventricular discordance) has been shown to be highly sensitive and specific for the diagnosis of constrictive pericarditis (Fig. 89.14). Hemodynamically silent constrictive pericarditis can be evaluated by performing volume loading during catheterization; the initially normal right and left heart pressures may elevate and equilibrate in diastole.

Treatment

- Patients with acute onset of constrictive symptoms may improve significantly with medical treatment that includes NSAIDs, colchicine, and steroids. Chronic constrictive pericarditis can be treated initially with diuretics and with sodium and fluid restriction, if symptoms are mild.
- Moderate to severe disease requires definitive treatment with complete removal of the pericardium by surgical stripping. This major procedure is associated with a perioperative mortality of >6%; it can be life-saving and improves symptoms drastically in most patients; however, poor outcome is likely if the constriction is radiation induced.

FIGURE 89.14. Simultaneous invasive left (LV) and right ventricular (RV) pressure tracings. Note the ventricular discordance with respiration: RV pressure rises and LV pressure falls during inspiration and vice versa during expiration. This finding is highly sensitive and specific for the diagnosis of constrictive pericarditis; its presence rules out the differential diagnosis of restrictive cardiomyopathy.

CHAPTER 90 ■ ACUTE HYPERTENSION MANAGEMENT IN THE ICU

DEFINITIONS

- Acute hypertension is a common issue in the intensive care unit (ICU). The settings in which blood pressure (BP) elevation occur are highly variable, and optimal care must be tailored to the pathophysiology of the specific circumstances in which it is encountered.
- The terminology used in the literature to classify this heterogeneous group of disorders has been somewhat inconsistent and confusing (Table 90.1).
 - The terms *hypertensive emergency* or *hypertensive crisis* are commonly defined as a marked increase in BP associated with target-organ damage. We define a hypertensive emergency broadly—as any condition in which BP should be lowered immediately. Although the term *malignant hypertension* has been discouraged, it is still widely used to describe the syndrome where organ dysfunction is a direct consequence of the elevated BP rather than an epiphenomenon. The presence of papilledema is not necessarily required for this diagnosis to be made.
 - In contrast, a hypertensive urgency is a condition with severe BP elevation and no target-organ damage, such that the BP can be decreased more gradually over the course of several hours, often with oral medications.
- It is the presence or absence of organ dysfunction, rather than the absolute degree of BP elevation, that determines whether a patient is classified as having a hypertensive emergency or urgency.
- It is not always clear how clinicians distinguish between hypertensive urgencies and severe, poorly controlled, chronic hypertension.
- The most recent Joint National Committee Guidelines classify patients with hypertension into stage 1 (systolic blood

TABLE 90.1

DEFINITIONS

1. *Hypertensive emergency*: Any condition in which hypertension is causing or potentially exacerbating organ dysfunction and should be lowered emergently
2. *Hypertensive urgency*: Severe hypertension that is not associated with acute organ dysfunction and requires gradual reduction in blood pressure over several hours
3. *Malignant hypertension*: A syndrome in which uncontrolled hypertension directly causes organ dysfunction (note that this is a subtype of 1). Although previous definitions have sometimes mandated the presence of retinopathy with papilledema, this is only one of several possible clinical manifestations and should not necessarily be required.

pressure [SBP] 140–159 mm Hg or diastolic blood pressure [DBP] 90–99 mm Hg) and stage 2 (SBP \geq 160 mm Hg or DBP \geq 100 mm Hg). The previously used category of “stage 3 hypertension” (SBP \geq 180 mm Hg or DBP \geq 110 mm Hg) has been combined with stage 2.

EPIDEMIOLOGY AND ETIOLOGY

- Hypertension is extraordinarily common, with only a minority having adequate BP control. The incidence of hypertensive emergencies and urgencies has not been assessed in population-based studies but $<1\%$ with chronic hypertension ever present in this fashion. Nevertheless, because hypertension is so common and a wide variety of conditions other than malignant hypertension can be categorized as hypertensive emergencies, acutely elevated BP is still a factor in a substantial number of medical visits to emergency departments and a frequent problem in the ICU (Table 90.2).

TABLE 90.2

TYPES OF HYPERTENSIVE EMERGENCIES

Malignant hypertension

- Hypertensive encephalopathy/RPLS
- Retinopathy and papilledema
- Acute heart failure
- Myocardial ischemia
- Malignant nephrosclerosis and acute renal failure
- Microangiopathy

Neurocritical care emergencies

- Acute ischemic stroke requiring thrombolysis
- Acute intracerebral hemorrhage
- Subarachnoid hemorrhage
- Severe hypertension following craniotomy
- Cerebral hyperperfusion syndrome (postendarterectomy or stenting)
- Normal perfusion pressure breakthrough (after AVM resection)

Cardiovascular emergencies

- Acute myocardial infarction
- Acute heart failure
- Aortic dissection
- Severe hypertension following cardiovascular surgery

Preeclampsia/eclampsia

RPLS, reversible posterior leukoencephalopathy syndrome; AVM, arteriovenous malformation.

Malignant Hypertension

- Peak incidence occurs between the ages of 40 and 50; risk factors include poor long-term BP control, lack of a primary care physician, noncompliance with antihypertensive medications, male gender, African American ethnicity, illicit drug use, and lower socioeconomic class. Prior to effective antihypertensive therapy, the mortality very high, with approximately 80% of patients dying within a year (hence, the term *malignant*).
- At least 90% to 95% of patients with chronically elevated BP can be classified as having “essential” hypertension, meaning that the underlying cause is multifactorial and not specifically known.
- A small proportion have “secondary” hypertension, where there is an identifiable and sometimes treatable condition. Among patients who present with malignant hypertension, as many as 50% to 80% may have a secondary etiology. Other clues are a history of BP resistant to medical therapy, sudden worsening in a previously well-controlled patient, and the onset of hypertension at an unusually young or old age. A careful history, physical examination, and appropriate diagnostic testing to exclude causes of secondary hypertension are indicated during the hypertensive emergency and after it has resolved (Table 90.3).
- **Renovascular** disease, the most common cause, may be present in up to 45% with severe or malignant hypertension, although the proportion is higher in Caucasians than African Americans. Features that suggest renovascular hypertension include atherosclerotic vascular disease in other organ systems, systolic-diastolic abdominal bruits, a history of deterioration in renal function with exposure to angiotensin-converting enzyme (ACE) inhibitors, or angiotensin II receptor blockers, recurrent flash pulmonary edema, and small kidneys (determined by ultrasound or other imaging).

TABLE 90.3

ETIOLOGIES OF MALIGNANT HYPERTENSION

Essential hypertension
Secondary hypertension
Renovascular disease
Atherosclerosis, thrombosis
Fibromuscular dysplasia
Medium- and large-vessel vasculitis
Glomerular disease
Glomerulonephritis
Small-vessel vasculitis
Microangiopathies
Scleroderma
Renal parenchymal disease
Polycystic kidney disease (and others)
Renin-producing tumors
Endocrine causes
Pheochromocytoma
Primary hyperaldosteronism
Cushing syndrome
Hypercalcemia
Aortic coarctation
Medications (e.g., cyclosporine, tacrolimus, erythropoietin)
Sympathomimetic drugs (e.g., cocaine, amphetamines)

- Hypertension is almost universally present in patients with acute or chronic kidney disease, especially when the etiology is a glomerulonephropathy. A common manifestation of obstructive sleep apnea, hypertension can be improved by use of noninvasive positive airway pressure.
- Various rare **endocrine** causes, including primary aldosteronism, Cushing syndrome, hypercalcemia, hypothyroidism, and pheochromocytoma, are responsible for a small proportion of cases.
- Several **illicit drugs** can cause malignant hypertension in addition to other hypertensive emergencies. Sympathomimetics, such as cocaine and methamphetamine, have been implicated in causing intracerebral hemorrhage (ICH) and subarachnoid hemorrhage (SAH), ischemic stroke, and aortic dissection.
- Various drugs used in clinical practice can cause severe hypertension, or even hypertensive emergencies. The most commonly implicated are **erythropoietin** and various **immunosuppressants**, most notably cyclosporine, tacrolimus, interferon, and high-dose corticosteroids, although it is sometimes difficult to separate the hypertension-inducing effects of these drugs from the complications of the diseases they are intended to treat.

Neurologic Hypertensive Emergencies

- **Acute stroke** is one of the most common indications for which emergent BP control may be necessary and often the most frequent form of end-organ damage. Stroke is the second leading cause of death worldwide and is also a major reason for long-term disability. Cerebral ischemia is responsible for 70% to 80% of strokes, whereas ICH and SAH account for 5% to 20% and 1% to 7%, respectively.
- Overall, >80% of patients with ischemic or hemorrhagic strokes are initially hypertensive to some degree. Even without treatment, the BP usually declines gradually over the first several hours or days in hospital. An even larger proportion of patients with ICH develop, and are treated for, acute hypertension. The incidence of hypertension with SAH is somewhat lower, but aggressive treatment is sometimes advocated to minimize the initial risk of rebleeding from the aneurysm.

Perioperative Hypertension

- Depending on the patient population, type of surgery (especially neurosurgical and cardiovascular), and how hypertension is defined, 3% to 34% of operations are complicated by postoperative hypertension in the recovery room or ICU, with the most important risk factors being inadequately controlled pain and a history of hypertension, especially if antihypertensives were withdrawn preoperatively.
- Elevations in BP occur most often during the initial 30 to 60 minutes after surgery, may last for several hours, and have been associated with higher rates of postoperative hemorrhage and myocardial ischemia in certain patient populations.
- Preoperative hypertension is predictive of intra- and postoperative BP fluctuations, and has been associated with the occurrence of complications and worse outcomes. The American Heart Association recommends that nonemergent surgery be deferred if the BP exceeds 180/110 mm Hg; it remains

controversial whether delaying surgery ultimately modifies perioperative risks.

Pregnancy-induced Hypertension

- Hypertension complicates approximately 12% of pregnancies and is responsible for 18% of maternal deaths in the United States. When BP elevation occurs prior to 20 weeks' gestation, it is considered chronic hypertension. If it occurs without complication after 20 weeks, it is referred to as gestational hypertension.
- **Preeclampsia** is a form of pregnancy-induced hypertension that is associated with vasoconstriction, endothelial dysfunction, platelet aggregation, and increased coagulation.
 - Usually defined by the concomitant presence of hypertension and proteinuria (>300 mg of protein per 24 hours), some develop severe symptoms without proteinuria.
 - Preeclampsia occurs in 2% to 10% of pregnancies, with important risk factors including nulliparity, antiphospholipid antibodies, diabetes mellitus, obesity, family history, multiple (twin) pregnancies, maternal age beyond 40, and a previous history during other pregnancies.
 - Maternal complications can include progression to eclampsia, pulmonary edema, microangiopathy, and renal failure. The most common neonatal complications are prematurity and growth restriction. **Eclampsia** is defined as the development of severe neurologic manifestations, including seizures and a depressed level of consciousness, in women with preeclampsia.

Cardiovascular Hypertensive Emergencies

- Acute heart failure is responsible for 5% to 10% of hospital admissions. Hospital mortality is about 4% but increases to >50% by 1 year. In patients presenting with flash pulmonary edema, acute hypertension is particularly common and is likely to be both a consequence and contributing cause.
- A history of chronic hypertension exists in about 40% to 70% of patients with acute coronary syndromes, and about 30%

have an elevated BP when initially assessed. Severe uncontrolled hypertension at admission (>180/110 mm Hg) is a relative contraindication to thrombolysis for ST elevation myocardial infarction (STEMI).

- **Aortic dissection** is a relatively rare condition; mortality has decreased from as high as 90% to about 20% to 35% with modern medical and surgical therapy. More than 70% have chronic hypertension, but BP can be highly variable at presentation. Most type B dissections (descending aorta) have an admission systolic pressure of >150 mm Hg compared with just more than a third of type A dissections (ascending aorta).

PATHOPHYSIOLOGY OF HYPERTENSION-INDUCED END-ORGAN DYSFUNCTION

- Autoregulation keeps blood flow to organs relatively constant despite variations in BP; its limits are usually between mean arterial pressure of 60 and 150 mm Hg. Extreme hypertension exceeding the upper range of autoregulation causes edema, hemorrhage, and organ dysfunction, whereas reductions in BP beyond the lower limits of autoregulation result in tissue hypoperfusion and ischemia (Fig. 90.1).
- In addition to the systemic myogenic response, there are also organ-specific vascular regulatory mechanisms to protect against the effects of acute hypertension. The likelihood of end-organ damage increases not only with the absolute degree of BP elevation but also with the rate at which this occurs.
- With chronic hypertension, the walls of small arteries and arterioles hypertrophy, shifting the autoregulation curve toward the right to maintain blood flow even at unusually high BPs. Conversely, ischemia may occur when BP falls to levels that would otherwise be well tolerated. In the setting of neurologic injury, autoregulation is often impaired, and cerebral blood flow becomes directly dependent on BP (see Fig. 90.1).
- Normal endothelial function is necessary for the regulation of vascular tone, BP, and regional blood flow. The endothelium

FIGURE 90.1. Cerebral blood flow autoregulation: effect of changes in cerebral perfusion pressure on cerebral blood flow and vascular caliber in normal and hypertensive patients (*dashed line*).

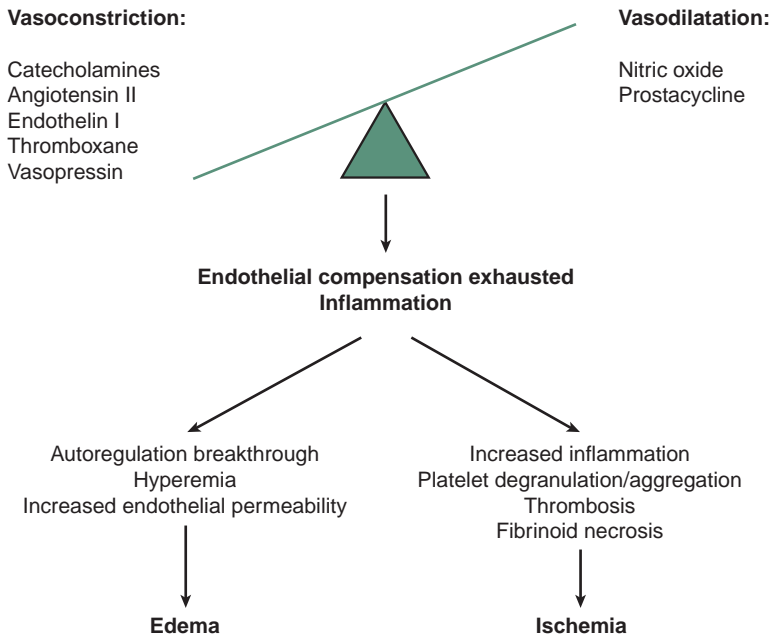

FIGURE 90.2. Simplified pathophysiology of acute hypertension-induced organ dysfunction. (Adapted from Vaughan CJ, Delanty N. Hypertensive emergencies. *Lancet*. 2000;356:411–417.)

is involved in maintaining a delicate balance between vasodilating substances (e.g., nitric oxide, bradykinin, prostacyclin) and vasoconstrictors (e.g., endothelin), as well as between coagulation and fibrinolysis.

- When BP is elevated, **natriuretic peptides** are released from the endothelium, which in turn induce sodium and water loss, with decreased intravascular volume.
- Excessive activation of the **renin-angiotensin** system causes vasoconstriction and inflammation, leading to hypertensive emergencies, an effect that can be blocked by ACE inhibitors.
- **Angiotensin II** levels are elevated in most cases of malignant hypertension, particularly when the etiology is a renal condition. Increased wall stress and prolonged vasoconstriction in the face of severe hypertension eventually causes endothelial compensatory mechanisms to fail, such that a vicious cycle ensues, with consequent hyperemia, increased permeability, inflammation (endarteritis), platelet aggregation, coagulation, and thrombosis.
- Transmural necrosis and the entry of blood components into the vessel wall lead to obliteration of the lumen and replacement of smooth muscle with fibrous tissue, a process called **fibrinoid necrosis**. Patients with malignant hypertension may therefore paradoxically develop both hyperemia (due to endothelial dysfunction and loss of autoregulation) and ischemia (due to thrombosis and fibrinoid necrosis) (Fig. 90.2).

MANIFESTATIONS

Hypertensive Encephalopathy and Reversible Posterior Leukoencephalopathy Syndrome

- Severe elevations in BP eventually cause a breakdown of the blood–brain barrier, with subsequent development of vaso-

genic cerebral edema. White matter is less tightly packed than the overlying cerebral cortex, making it more vulnerable to the spread of edema.

- Swelling occurs predominantly, but not exclusively, in the **posterior regions of the brain**. Possibly it is due to a larger concentration of sympathetic fibers around arterioles in the anterior brain, resulting in a greater degree of vasoconstriction and relative protection against the effects of severe hypertension.
- Characteristic clinical features and magnetic resonance imaging (MRI) findings of vasogenic edema in posterior white matter led to the description of a clinical radiologic syndrome, now most commonly termed *reversible posterior leukoencephalopathy syndrome* (RPLS) or posterior reversible encephalopathy syndrome.
- Although occurring most commonly in association with severe hypertension, other conditions may at least predispose to, if not directly cause, the development of RPLS, perhaps by inducing endothelial toxicity. RPLS has been described in association with certain medications and immunosuppressive agents (most notably cyclosporine), and in the setting of microangiopathies, connective tissue diseases, vasculitis, and preeclampsia.
- RPLS is best visualized using T₂ and fluid-attenuated inversion recovery MRI sequences. Diffusion-weighted MRI has confirmed that vasogenic edema is much more prominent than cytotoxic edema and, although RPLS is usually “reversible,” some patients do develop ischemic strokes.
- Many patients do not adhere perfectly to the typical patterns of RPLS: gray-matter involvement of the cerebral cortex and basal ganglia and edema occurring in the frontal lobes, posterior fossa, and brainstem have all been described. It is rare for only one vascular territory to be involved (Fig. 90.3).
- The clinical manifestations of RPLS in the setting of acute BP elevation are collectively described by the term *hypertensive encephalopathy*, which is characterized by the subacute development of neurologic signs and symptoms and may

FIGURE 90.3. Fluid-attenuated inversion recovery magnetic resonance imaging sequences of a 15-year-old patient with a history of Wegener granulomatosis presenting with seizures and altered mental status. The findings are consistent with reversible posterior leukoencephalopathy syndrome (RPLS). Although vasogenic edema is seen predominantly posteriorly, anterior changes are also present.

include headache, altered mental status, seizures, and visual disturbances.

- **Headaches** are usually generalized, severe, and poorly responsive to analgesics and improve rapidly with treatment of hypertension.
- **Altered mental status** can range from lethargy and confusion to stupor and coma, although the latter is unusual.
- The posterior predominance of RPLS is reflected by the frequent occurrence of unilateral or bilateral visual disturbances, including hemianopsia, visual neglect, cortical blindness, Anton syndrome (patient is not aware of blindness), and visual hallucinations.
- **Focal seizures** originating in the occipital regions have also been described, although they most often generalize, and may be recurrent.

Retinopathy

- Endothelial damage and leakage of plasma proteins into the retina lead to edema and the formation of hard exudates (Fig. 90.4). Focal areas of ischemia and infarction within the nerve fiber layer cause white areas, called cotton-wool spots, to appear. Breakdown of the blood–retinal barrier results in flame-shaped hemorrhages within the retina.
- The development of papilledema has historically been used to differentiate “accelerated” from “malignant” hypertension. However, the presence or absence of papilledema has little impact on the natural history and prognosis of hypertensive emergencies, nor should it significantly alter management. The mechanism of papilledema may include raised intracranial pressure (ICP), present in some patients with hypertensive encephalopathy and ischemia of the optic nerve head.

Nephropathy and Microangiopathy

- Certain conditions causing acute renal failure may cause hypertensive emergencies, but severely elevated BP can also cause renal dysfunction, a condition called malignant nephrosclerosis. Renal biopsies reveal fibrinoid necrosis,

hyperplastic arteriolitis, neutrophilic infiltration, and thrombosis of glomerular capillaries. The histologic appearance can be difficult to distinguish from other microangiopathies, such as hemolytic uremic syndrome and thrombotic thrombocytopenic purpura.

- More than a fourth of patients with malignant hypertension, especially those with acute renal failure, have typical clinical features of microangiopathy, including thrombocytopenia, elevated lactate dehydrogenase, and schistocytes on blood smear.
- Impaired renal perfusion leads to greater activation of the renin-angiotensin system, which further augments vasoconstriction, fluid retention, and BP elevation. The earliest evidence of renal involvement is the presence of abnormal urine sediment, with proteinuria, hematuria, and the appearance of red and white blood cell casts.
- Acute renal failure follows, which is sometimes severe enough to require dialysis and occasionally results in end-stage renal disease. This is more common when the etiology is secondary

FIGURE 90.4. Severe hypertensive retinopathy with evidence of disc swelling (DS, papilledema), cotton wool spots (CWS), and flame-shaped hemorrhage (FH). (From Wong T, Mitchell P. The eye in hypertension. *Lancet*. 2007;369:425–435, used with permission.)

rather than essential hypertension, particularly with renal causes. The degree of renal dysfunction is an important prognostic variable.

Cardiovascular Complications

- Approximately 20% of patients with malignant hypertension present with cardiac complications, which may include myocardial ischemia or pulmonary edema. Many have chronic hypertension, left ventricular hypertrophy, and diastolic dysfunction; a smaller subset also have impaired systolic function. Left ventricular hypertrophy increases myocardial oxygen requirements while also outstripping vascular supply and compressing coronary arterioles.
- The increased afterload associated with severe hypertension further increases myocardial wall stress and oxygen demand, such that ischemia occurs, especially with concomitant coronary artery disease.
- Increased wall thickness and changes to the extramyocardial collagen network impair myocardial relaxation and compliance. As a result, even small increases in intravascular volume and afterload can produce pulmonary edema.

TREATMENT: PHARMACOLOGIC AGENTS

- An ideal pharmacologic agent (Table 90.4) for treatment of hypertensive emergencies should have a rapid onset but also be short-acting and easy to titrate to avoid excessively lowering the BP for long periods of time.
- Sodium nitroprusside (NTP) is considered first-line therapy, largely because of its rapid onset, short duration of action, affordability, familiarity, and efficacy. NTP is a parenterally administered, potent arterial and venous vasodilator, which has an onset within <30 seconds and a duration of action of only 2 to 3 minutes, such that cessation of the infusion allows BP to rise back to previous levels within 1 to 10 minutes.
- Cardiac output is either preserved or increased, and cardiac filling pressures decrease. The mechanism of action involves the release of nitric oxide into the bloodstream, activation of

guanylate cyclase, and subsequent conversion of guanosine triphosphate to cyclic guanosine monophosphate in vascular smooth muscle, which in turn inhibits the intracellular movement of calcium.

- The usual starting dose of NTP is 0.25 to 0.5 $\mu\text{g/kg/minute}$, and it is increased in increments of 0.5 $\mu\text{g/kg/minute}$ every 5 to 10 minutes until the goal BP is achieved.
- NTP has the potential for several serious, life-threatening complications.
 - Despite lowering preload and afterload, NTP may induce **coronary steal**, whereby excessive vasodilatation of coronary arterioles shunts blood away from ischemic regions.
 - Vasodilation of cerebral vasculature increases **cerebral blood volume** and ICP. This phenomenon is not entirely consistent and may be avoided with a somewhat slower administration.
- Each NTP molecule has five **cyanide** moieties, such that cyanide makes up 44% of its molecular weight. Cyanide is metabolized by transsulfuration in the liver to thiocyanate, which is 100 times less toxic than cyanide, and is cleared in the urine and stool. When this pathway is overwhelmed, cyanide accumulates and causes toxicity. Patients are particularly vulnerable when treated with prolonged, high-dose infusions, especially if hepatic and renal function are impaired or if sulfur stores are depleted because of malnutrition.
- Cyanide blocks oxidative phosphorylation and essentially causes tissue anoxia and lactic acidosis despite adequate oxygen delivery and high venous oxygen saturation levels. Manifestations of cyanide poisoning include depressed mental status, seizures and, eventually, bradycardia and hemodynamic collapse. Cyanide levels are not easily monitored, and the development of lactic acidosis is a late finding. The development of tachyphylaxis to nitroprusside, with consequent increasing dose requirements, may be a harbinger of toxicity.
- Treatment of cyanide poisoning consists of discontinuation of nitroprusside, supportive care with the delivery of 100% oxygen, and the administration of **sodium nitrite** (300 mg IV), followed by **sodium thiosulfate** (12.5 g IV). The use of sodium nitrite is controversial, as it actually causes the production of methemoglobin, which, although

TABLE 90.4

INTRAVENOUS PHARMACOLOGIC AGENTS FOR MANAGEMENT OF HYPERTENSIVE EMERGENCIES

Drug	Dose	Onset	Duration	Precautions
Nitroprusside	0.25–10 $\mu\text{g/kg/min}$ (ideally <2 $\mu\text{g/kg/min}$)	Immediate	1–10 min	Cyanide toxicity with prolonged infusions; coronary steal; \uparrow ICP
Nitroglycerin	10–200 $\mu\text{g/min}$	Immediate	3–10 min	Severe hypotension in hypovolemic patients; \uparrow ICP; contraindicated if on PDE-5 inhibitors
Labetalol	10–40-mg boluses 1–4 mg/min infusion	5–15 min	2–4 h	Bradycardia, heart block; LV dysfunction; asthma
Esmolol	0.5 mg/kg load, 50–200 $\mu\text{g/kg/min}$	5 min	10–30 min	Bradycardia, heart block; LV dysfunction; asthma
Nicardipine	3–15 mg/min	5–15 min	30–60 min	Rebound tachycardia; ICP effects require more study
Fenoldopam	0.1–1.6 $\mu\text{g/kg/min}$	5–15 min	20–60 min	Glaucoma
Enalaprilat	0.625–2.5-mg bolus every 6 h	15 min	4–6 h	Renal failure; hyperkalemia
Hydralazine	10–20 mg every 4–6 h	5–20 min	2–6 h	Reflex tachycardia; ischemic heart disease

ICP, intracranial pressure; PDE-5, phosphodiesterase-5; LV, left ventricular.

also potentially toxic, binds avidly to cyanide. Sodium thiosulfate acts as a sulfur donor to promote the formation of thiocyanate and has been used effectively as monotherapy. Hydroxycobalamin combines with cyanide to form cyanocobalamin and may provide synergy with sodium thiosulfate. Accumulation of thiocyanate, although far less toxic than cyanide, may also cause complications.

- Despite these concerns, NTP has an extensive track record, and many prospective studies have not found evidence of clinical toxicity even after using it for several days. Still, NTP should be administered at as low a dose as possible and for as short a duration as possible.
- Nitroglycerin: Because nitroglycerin produces more venous than arterial vasodilatation, it is usually not used as first-line therapy for hypertensive emergencies unless there is concurrent pulmonary edema or myocardial ischemia. Usually started at 5 to 10 $\mu\text{g}/\text{minute}$, it can be titrated up every 5 to 10 minutes to doses as high as 200 to 300 $\mu\text{g}/\text{minute}$.
- Particular caution must be exercised in the setting of hypovolemia.
- Patients using drugs for erectile dysfunction should not be given nitroglycerin or nitroprusside, as this may induce profound hypotension.
- It may increase ICP and should be used with caution in brain-injured patients.
- β -Blockers: Labetalol is the most commonly used IV β -blocker for the management of hypertensive emergencies. One of its unique properties is that it blocks both α and β receptors, although the β -blocking effect is more prominent. Usually administered as 10- to 20-mg boluses, it can be repeated every 15 minutes until the desired effect is achieved. BP lowering begins within 2 to 5 minutes, with maximal effect after about 10 to 15 minutes. It can also be delivered as an infusion, beginning at a dose of 1 to 2 mg/minute.
- Labetalol has been demonstrated to be safe and effective in the management of severe hypertension, with advantages including that it does not cause reflex tachycardia, and has little effect on cerebral blood flow or ICP.
- Labetalol does not cross the placenta well, and there is extensive experience using it in pregnancy, making it one of the preferred agents in preeclampsia and eclampsia.
- Esmolol is an extremely short-acting, relatively cardioselective β -blocker, has an onset within less than a minute, and is uniquely metabolized by red blood cell esterases, such that its duration of action is only 10 to 20 minutes. A loading dose of 0.5 mg/kg is administered over 1 minute, followed by an infusion of 50 $\mu\text{g}/\text{kg}/\text{minute}$, which can be adjusted as often as every 5 minutes to a maximum dose of 200 $\mu\text{g}/\text{kg}/\text{minute}$. It is a useful agent when BP is elevated and cardiac output is preserved, especially when there are concerns about myocardial ischemia.
- Nicardipine is a dihydropyridine calcium channel blocker that inhibits calcium influx through L-type channels, thereby preventing smooth-muscle contraction, particularly in vascular smooth muscle, rather than cardiac myocytes. This causes arterial vasodilatation, with minimal venodilatation or change in cardiac output. It is most often administered as an IV infusion, beginning at 3 to 5 mg/hour, to a maximum of 15 mg/hour, but can also be given as 0.5- to 3-mg boluses. Because of a distribution half-life of <3 minutes and an intermediate elimination half-life of <45 minutes, nicardipine has a relatively rapid onset and offset.

- It has compared favorably with NTP, as therapeutic targets are achieved in a similar amount of time but with fewer episodes of severe hypotension and less frequent dose adjustment.
- Nicardipine has been used in a variety of settings, including malignant hypertension, perioperative hypertension, preeclampsia, and acute heart failure. It is generally well tolerated, with few adverse effects when used with caution.
- Given that nicardipine increases cerebral blood flow, one might expect that it would raise ICP, but this does not appear to be a major concern.
- Fenoldopam is a selective dopamine-1 (DA-1)-receptor agonist, which produces peripheral, renal, splanchnic and, to a lesser degree, coronary vasodilatation. Stimulation of DA-1 receptors also promotes natriuresis. It is typically administered in doses of 0.025 to 1 $\mu\text{g}/\text{kg}/\text{minute}$ and begins to lower BP after as little as 2 minutes, although the maximal effect is not seen for at least 20 to 30 minutes or more. With discontinuation of an infusion, the elimination half-life is <10 minutes. Reflex tachycardia, thought to be related to activation of the baroreflex, may occur and can be attenuated with concomitant use of a β -blocker.
- Unlike dopamine, fenoldopam does not have any effect on DA-2 receptors, nor does it act at the α - or β -adrenergic receptor level. It does not cross the blood-brain barrier, and therefore has little effect on cerebral blood flow and ICP.
- A theoretical advantage of fenoldopam is improved renal blood flow but, despite a slight increase in creatinine clearance, it remains unclear that this will translate into clinically important prevention of renal failure.
- Fenoldopam has been demonstrated to be effective at controlling BP in hypertensive emergencies, with similar efficacy to NTP, but has shown no clear improvement in outcomes and is considerably more expensive.
- Overall, fenoldopam seems to have few adverse effects. It **does raise intraocular pressure** and should therefore probably be avoided in patients with a known history of glaucoma.

TREATMENT FOR SPECIFIC HYPERTENSIVE EMERGENCIES

Malignant Hypertension

- Because of the shift in the autoregulatory curve that occurs with prolonged hypertension, rapid reductions in BP may cause organ ischemia.
- With hypertensive urgencies, the BP should be reduced carefully and gradually with oral medications over the course of several days. It is not certain how long it takes for the autoregulatory curve to recover and shift back toward the left; the initial goal should never be a normal BP.
- With hypertensive emergencies, the BP must be reduced immediately, with an initial goal of no more than a **15% reduction**. Specific treatment goals should be individualized to ensure that the pressure is reduced sufficiently for organ failure to resolve without compromising perfusion. To facilitate keeping BP within a narrow range, placement of an arterial catheter and careful observation in the ICU are recommended.

Neurologic Hypertensive Emergencies

- **Acute ischemic stroke:** Although acute hypertension is common, optimal treatment remains uncertain. The greatest priority is to preserve as much of the ischemic penumbra as possible. Because autoregulation is usually impaired within the penumbra, pressure reductions may cause blood flow to fall, which in turn may increase infarct size.
- **Transcranial Doppler middle cerebral artery flow velocities, cerebral perfusion as determined by MRI, and neurologic examination may improve with supranormal augmentation of BP using a vasopressor.**
- **The best outcomes occur in patients with a presenting systolic BP of about 150 mm Hg. The American Stroke Association guidelines currently recommend not treating hypertension unless the systolic pressure exceeds 220 mm Hg or the diastolic pressure exceeds 120 mm Hg.**
- **The exception to this rule is if the patient is a candidate for IV, or possibly intra-arterial, thrombolysis. Of patients who receive IV rt-PA, approximately 5% to 6% will develop ICH; whether lowering BP helps to limit this risk is not certain.**
- **Intracerebral hemorrhage:** Good neurologic recovery is very uncommon if the volume of ICH exceeds 30 to 60 mL. Hematoma growth is a dynamic process that occurs over several hours, with a significant proportion having detectable expansion even within the first few hours after presentation to the emergency department or ICU. Patients with early hematoma enlargement have substantially worse outcomes, and it is likely that therapy that can limit this early growth will improve outcomes.
- **Patients with higher BP at presentation are more likely to develop hematoma expansion and have a higher mortality, though a randomized controlled trial of lowering BP for acute ICH has not yet been performed.**
- **The American Heart Association guidelines are conservative and recommend the following goals: mean arterial pressure <130 mm Hg, SBP <180 mm Hg, and DBP <105 mm Hg. The main reason for concern has been the observation that there is reduced blood flow around areas of ICH and the belief that this represents an ischemic penumbra that could be compromised with lower BP.**
- **Positron emission tomography and MRI have suggested that decreased flow surrounding ICH is appropriate for the corresponding reduction in cerebral metabolic rate, and CBF autoregulation in this region appears to be preserved.**
- **SAH: Nontraumatic SAH results from a ruptured intracranial aneurysm in >80% of cases. The risk of recurrent hemorrhage from the aneurysm is about 4% on the first day, followed by 1% to 2% per day for the next 2 to 3 weeks. Although the risk of rebleeding has decreased with early surgical clipping or endovascular coil embolization, the incidence of this devastating complication remains approximately 7%, with a mortality of >50%. Many centers attempt to decrease the risk of recurrent hemorrhage by reducing BP prior to the aneurysm being secured, with a goal SBP <140 to 180 mm Hg.**
- **The efficacy of this practice remains uncertain, with conflicting results from observational studies. Particular caution should be exercised when treating patients with high-grade SAH who are stuporous or comatose, because these patients may have a raised ICP, and excessive reduc-**

tion in BP may compromise cerebral perfusion and promote ischemia.

- **After the aneurysm has been treated, the most concerning complication is cerebral vasospasm and delayed ischemic neurologic deficits, which occur in 20% to 30% of patients, with maximum risk between days 4 and 12 after the event. Hypertension should not routinely be treated during this time, even at relatively high levels, as this increases the risk of delayed infarction. If clinical vasospasm develops, first-line therapy actually involves hemodynamic augmentation, using vasopressors to raise BP to increase CBF and improve cerebral perfusion.**
- **Perioperative neurosurgery:** Hypertension occurs in the setting of craniotomy more often than any other type of surgery. Neurosurgery results in the release of large amounts of vasoactive substances that raise BP, including catecholamines, endothelin, and renin. Important is that severe hypertension occurring intraoperatively or during the first 12 postoperative hours has been associated with a higher risk of ICH.
- **In certain procedures, tight postoperative BP control is particularly important. With carotid stenting or endarterectomy, the sudden resolution of carotid stenosis results in a sudden, asymptomatic, 20% to 40% increase in ipsilateral CBF.**
- **In some patients, the increase can be much more profound, to the degree that it overcomes the autoregulatory capacity of the corresponding, previously hypoperfused territory. The resulting cerebral hyperperfusion syndrome is characterized by the presence of vasogenic edema, which resembles RPLS in that there is a posterior predilection.**
- **Patients who are most vulnerable are those with relatively severe carotid stenosis and poor collateral circulation, but postoperative hypertension is also an important risk factor. Cerebral hyperperfusion syndrome is treated with tight BP control, but agents that cause cerebral vasodilatation, including nitroprusside and perhaps calcium channel blockers, ideally should be avoided.**
- **Mild intraoperative hypotension is sometimes used for vascular neurosurgical procedures, such as microsurgical excision or endovascular obliteration of arteriovenous malformations to reduce the risk of hemorrhage. With arteriovenous malformations, the sudden "repressurization" of previously hypotensive arterioles may contribute to the development of regional hyperemia, edema, and bleeding, a condition sometimes referred to as "normal perfusion pressure breakthrough." Consequently, hypertension should be avoided in the immediate postoperative period. Conversely, the sacrifice of vascular branches during the procedure, or vasospasm from surgical manipulation and retraction, may also create areas of relative underperfusion, such that hypotension would also be deleterious.**

Cardiovascular Hypertensive Emergencies

- **Aortic dissection:** The purpose of emergently lowering BP in aortic dissection is to decrease shear stress in the aorta and limit propagation of the intimal tear and false lumen. To concomitantly reduce both BP and the force of left ventricular contraction, first-line therapy consists of a β -blocker or, if contraindicated, a calcium channel blocker with

negative inotropic and chronotropic properties (e.g., diltiazem or verapamil).

- If the BP remains elevated despite adequate β -blockade, a vasodilator can be added. Pure vasodilators should not be used in isolation.
- If possible, the heart rate should be <60 beats/minute, and the BP reduced as much as can be tolerated, ideally below a SBP 120 mm Hg.
- Use of opiates for the substantial chest discomfort may greatly reduce antihypertensive requirements.
- Acute pulmonary edema: Acute hypertension exists in the majority of patients presenting with flash pulmonary edema and is likely to be both a consequence and contributing cause. The venodilating properties of **nitroglycerin** make it an excellent initial choice as an antihypertensive in both normotensive and hypertensive patients, especially if there is failure to improve after administration of a loop diuretic.
- In titrating the dose of IV nitroglycerin, clinicians should be aware that relatively large doses, often in excess of 100 $\mu\text{g}/\text{minute}$, may be required to significantly lower cardiac filling pressures and improve symptoms.
- Patients who benefit from aggressive **afterload reduction**, such as those with acute aortic or mitral regurgitation (if not hypotensive), may require a more potent arterial vasodilator than nitroglycerin, such as NTP or nicardipine.
- Although ACE inhibitors are standard care for chronic heart failure, there is little evidence of benefit for acute decompensated heart failure. The only IV preparation, enalaprilat, was potentially harmful when routinely administered to patients within the first 24 hours following STEMI and is therefore not recommended.
- Considerable caution must be exercised when intubating hypertensive patients with acute pulmonary edema, as it is very common for BP to drop precipitously with sedation and positive pressure ventilation.
- **Nesiritide** (recombinant human brain natriuretic peptide) has been proposed for use in acute heart failure. However, it has not demonstrated improved clinically important outcomes when compared with standard therapy, may worsen renal function, and has been linked to a possible increased risk of short-term death.
- Acute coronary syndrome (ACS): Although definitive therapy for ACS involves revascularization, tachycardia and hypertension increase myocardial oxygen requirements and can potentially worsen ischemia and increase infarct size. β -Blockers are recommended for all ACS patients without a contraindication.
- An IV β -blocker is therefore a good initial choice as an antihypertensive but must be used with caution with reduced

left ventricular systolic function and in those in whom there is concern about impaired cardiac conduction (e.g. inferior myocardial infarction).

- Early β -blockade in patients with STEMI has an increased risk of cardiogenic shock. If the BP remains significantly elevated, especially with ongoing chest pain or pulmonary edema, nitroglycerin should be used. In addition to reducing preload and afterload, nitrates also vasodilate coronary arteries, especially at the site of plaque disruption. If three sublingual tablets (0.4 mg over 5 minutes) are ineffective, an IV infusion should be started and adjusted to alleviate chest pain and reduce BP (10% reduction in normotensive patients, 30% reduction in hypertensive patients).

Preeclampsia and Eclampsia

- Although hypertensive encephalopathy and eclampsia have largely been considered separate entities, they have a similar pathophysiology and essentially the same MRI findings (RPLS). Definitive treatment for severe preeclampsia and eclampsia is delivery, but careful IV BP control is frequently also necessary.
- Treatment of hypertension in severe preeclampsia has not been shown to improve perinatal outcomes and may actually contribute to a decrease in neonatal birth weight. Pharmacologic therapy is not recommended unless the degree of BP elevation is severe (defined as SBP exceeding 160 mm Hg or DBP exceeding 105 to 110 mm Hg) or there are end-organ complications.
- Oral medications, with a goal pressure of 140 to 155/90 to 105 mm Hg, may be sufficient in the absence of organ dysfunction, but more rapid and tighter control is necessary for severe preeclampsia and eclampsia.
- Although there has been extensive experience with IV hydralazine (5–10 mg every 15–20 minutes to a maximum dose of 30 mg), this agent has a relatively slow onset, has not commonly been used as an infusion, may overshoot BP goals, and has recently been linked to worse outcomes, including more placental abruption, adverse effects on fetal heart rate, lower Apgar scores, and a greater need for cesarean section.
- Other IV agents that have been successfully and safely used include labetalol and nicardipine.
- In addition to the foregoing, magnesium sulfate should be given to prevent the development of seizures in patients with severe preeclampsia, and should be used to treat acute seizures when eclampsia occurs.

SECTION XIII ■ RESPIRATORY DISORDERS

CHAPTER 91 ■ NONINVASIVE VENTILATORY SUPPORT MODES

- Noninvasive ventilation (NIV) refers to the provision of ventilatory assistance using techniques that do not bypass the upper airway. The theoretical advantages of NIV include avoiding the complications associated with endotracheal intubation, improving patient comfort, and preserving airway defense mechanisms. NIV may be delivered through various devices including negative and positive-pressure ventilators.
- The following sections deal with the history and epidemiology of NIV and currently available equipment and techniques, practical applications, appropriate indications, and possible adverse effects. In this chapter, continuous positive airway pressure delivered noninvasively is referred to as *CPAP*, and NIV using intermittent positive-pressure ventilation with or without positive end-expiratory pressure (PEEP) is referred to as noninvasive positive-pressure ventilation (NPPV). The term *NIV* is considered to include either CPAP or NPPV.

EQUIPMENT AND TECHNIQUES

- The following paragraphs discuss various interfaces and ventilatory modes available for administration of NIV. Cough-enhancing techniques are also described.

Interfaces

- Interfaces are devices that connect ventilator tubing to the face, allowing the delivery of pressurized gas into the airway during NIV. Currently available interfaces include nasal and oronasal masks, helmets, and mouthpieces. Selection of a comfortable interface that fits properly is a key issue for the success of NIV.

Nasal Masks

- The standard nasal mask is a triangular or cone-shaped clear plastic device that fits over the nose and uses a soft cushion or flange to seal over the skin. Because of the pressure exerted over the bridge of the nose, the mask may cause skin irritation and redness and occasionally ulceration. For occasional patients who cannot tolerate commercially available masks, custom-molded, individualized masks that conform to facial contours of the patient can be constructed. Several types of strap systems have been used to hold the mask in place.

Nasal Pillows

- Nasal pillows or seals consist of soft rubber or silicone plugs that are inserted directly into the nostrils. As they exert no pressure over the bridge of the nose, nasal pillows may be useful in patients who develop irritation or ulceration on the nasal bridge while using nasal or oronasal masks.

Oronasal Masks

- Oronasal or face masks cover both the nose and the mouth. The oronasal mask is largely used in patients with copious air leaking through the mouth during nasal mask ventilation. Interference with speech, eating, and expectoration and the likelihood of claustrophobic reactions are greater with oronasal than with nasal masks. In the acute setting, however, oronasal masks are preferable to nasal masks because dyspneic patients are mouth breathers, predisposing to greater air leakage during nasal mask ventilation.
- A type of oronasal mask is the “total” face mask, which is made of clear plastic and uses a soft silicone flange that seals around the perimeter of the face like a hockey goalie’s mask, avoiding direct pressure on facial structures.

Helmet

- The helmet is made of transparent latex-free polyvinyl chloride and is secured by two armpit braces at two hooks (one anterior and the other posterior) of the plastic ring that joins the helmet with a seal connection soft collar adherent to the neck. The pressure increase during ventilation makes the soft collar sealing comfortable to the neck and shoulders, avoiding air leakage.
- The entire apparatus is connected to an intensive care unit (ICU) ventilator by a standard respiratory circuit. The two ports of the helmet act as inlet and outlet for inspiratory and expiratory gas flows. The inspiratory and expiratory valves are those of the mechanical ventilator. The main advantages of the helmet include a good tolerability in both adult and pediatric populations, with a satisfactory interaction of the patients with the environment; a lower risk of dermal lesions; and, compared with the mask, easier applicability to any patient regardless of the face contour.

Mouthpieces

- Mouthpieces are simple and inexpensive devices used to provide NPPV for as long as 24 hours a day to patients with chronic respiratory failure. If nasal air leaking reduces efficacy; ventilator tidal volume may be increased; or cotton plugs or nose clips may be used for occluding the nostrils. NPPV via mouthpieces has proved to be a valid alternative to tracheostomy in some patients with chronic respiratory muscle insufficiency.

Noninvasive Ventilatory Modes

Continuous Positive Airway Pressure

- CPAP delivers a constant pressure throughout spontaneous inspiration and exhalation *without* assisting inspiration.

Because spontaneous breathing is not assisted, this technique requires an intact respiratory drive and adequate alveolar ventilation. CPAP increases functional residual capacity and opens underventilated alveoli, thus decreasing right-to-left intrapulmonary shunt and improving oxygenation and lung mechanics. Moreover, CPAP may reduce the work of breathing and dyspnea in COPD patients by counterbalancing the inspiratory threshold load imposed by intrinsic PEEP.

- Effects on hemodynamics during CPAP have been widely described. By lowering left ventricular transmural pressure in patients with left congestive heart failure, CPAP may reduce left ventricular afterload without compromising cardiac index. CPAP can be applied by various devices including low-flow generators with an inspiratory reservoir, high-flow jet venturi circuits (both of them with an expiratory mechanical or water valve), and bilevel and critical care ventilators.
- Continuous positive pressure may be administered using the demand flow (DF) or the gold standard continuous flow (CF) system. With DF CPAP, the patient has to trigger a preset pressure to open the demand valve, whereas with CF CPAP, no valves are present. The work of breathing is significantly greater with the DF system than with the CF one. It is crucial to provide an adequate air flow rate for maintaining a continuous positive pressure, especially in dyspneic patients who breathe at high flow rates.

Pressure Support Ventilation

- Pressure support ventilation (PSV) is a pressure-triggered, pressure-targeted, flow-cycled mode of ventilation. It delivers a preset inspiratory pressure to assist spontaneous breathing, augmenting spontaneous breaths and offsetting the work imposed by the breathing apparatus. A sensitive patient-initiated trigger causes the delivery of inspiratory pressure support that is maintained throughout inspiration, and a reduction in inspiratory flow drives the ventilator to cycle into expiration. Therefore, the patient can control either inspiratory duration or breathing rate. Typical starting pressures are a PEEP of 3 to 5 cm H₂O and an inspiratory airway pressure of 8 to 12 cm H₂O

Bilevel Positive Airway Ventilation

- In bilevel positive airway pressure, a valve sets two pressure levels, the expiratory positive airway pressure (EPAP) level and the inspiratory positive airway pressure (IPAP) level, even in the presence of rapidly changing flows. With this technique, ventilation is produced by the cyclic delta pressure between IPAP and EPAP. EPAP also recruits underventilated lung and offsets eventual intrinsic PEEP.

Controlled Mechanical Ventilation

- In the mandatory controlled mechanical ventilation mode, no patient effort is required, as full ventilatory support is provided. In this mode, ventilator settings include inflation pressure or tidal volume, frequency, and the timing of each breath. Controlled mechanical ventilation can be delivered noninvasively as a volume control or pressure control mode.

Proportional Assist Ventilation

- Proportional assist ventilation is an alternative technique in which both flow and volume are independently adjusted. In

this technique, the ventilator generates volume and pressure in proportion to the patient's effort, increasing comfort and so improving success and compliance with NPPV. Despite the promising concept, there is a substantial lack of large clinical studies.

Ventilatory Mode Selection

- All ventilatory modes of NPPV have been used to achieve physiologic or clinical benefit, with theoretical advantages and limitations. Spontaneously breathing patients with respiratory failure of various causes may benefit from CPAP to correct hypoxemia. In acute cardiogenic pulmonary edema (CPE), mask CPAP can result in early physiologic improvement and reduce the need for intubation
- Pressure-targeted modes maintain delivered tidal volume in patients with air leaking better than volume-targeted modes. Therefore, pressure-targeted ventilators are preferred over volume-targeted ventilators to deliver NPPV in the presence of substantial leaks. To best compensate for air leaks, pressure-targeted ventilators should have high and sustained maximal inspiratory flow capabilities (>3 L/sec); adjustable I:E ratios and other mechanisms to limit inspiratory duration so that inversion of the I:E ratio is avoided; and adjustable trigger sensitivities or algorithms to prevent autocycling. Ventilatory systems for air leak detection, calculation, and compensation are now largely available.
- When PSV is used as a noninvasive ventilatory assistance mode, some forms of patient-ventilator asynchrony might be intensified, causing breathing discomfort. In acute hypercapnic exacerbations of chronic obstructive pulmonary disease (COPD), NPPV performed by different ventilatory modes including PSV, assist control ventilation (ACV), and proportional assist ventilation is able to provide respiratory muscle rest and improve respiratory physiologic parameters. As in the intubated mechanically ventilated COPD patients, application of external PEEP is effective in counterbalancing the effects of auto-PEEP and dynamic hyperinflation. The use of noninvasive ventilatory modes in patients with hypoxemic acute respiratory failure (ARF) of various causes can improve arterial blood gases, respiratory rate, and dyspnea, and unload the accessory muscles of respiration.
- Triggering systems are critical to the success of NPPV in both assist and control modes. During assisted ventilation, flow triggering reduces breathing effort more effectively as compared with pressure triggering, obtaining a better patient-ventilator interaction.

PRACTICAL APPLICATION OF NONINVASIVE VENTILATION

- NIV should be considered early when patients first develop signs of incipient respiratory failure needing ventilatory assistance. It is crucial that caregivers can identify patients who are likely to benefit from NIV and exclude those for whom NIV would be unsafe. Once the decision to institute NIV has been taken, an interface and ventilatory mode must be chosen, and a close monitoring in an appropriate hospital location must be provided. The initial approach should consist in fitting the interface and familiarizing the patient with the apparatus,

TABLE 91.1**CRITERIA FOR NONINVASIVE VENTILATION DISCONTINUATION AND ENDOTRACHEAL INTUBATION**

Technique intolerance (pain, discomfort, or claustrophobia)
 Inability to improve gas exchanges and/or dyspnea
 Hemodynamic instability or evidence of shock, cardiac ischemia, or ventricular dysrhythmia
 Inability to improve mental status within 30 min after the application of NIV in hypercapnic, lethargic COPD patients or agitated hypoxemic patients

NIV, noninvasive ventilation; COPD, chronic obstructive pulmonary disease.

explaining the purpose of each piece of equipment. Patients should be motivated and reassured by the clinician, instructed to coordinate their breathing with the ventilator, and encouraged to communicate any discomfort or fears. Collaboration among medical practitioners including physicians, respiratory therapists, and nurses is critical to the success of NIV during the early phase of milder respiratory failure and after an initial period to 20 minutes' interruption. For patients with more severe failure, NIV application has to be continuous for at least 12 to 24 hours, and discontinuation is allowed for short periods only when the clinical situation improves. Aggressive physiotherapy is crucial during the periods of NIV discontinuation. Endotracheal intubation must be rapidly accessible, when indicated (Table 91.1).

Patient Selection

- The criteria for selecting appropriate patients to receive NIV for ARF include clinical indicators of acute respiratory distress, such as moderate-to-severe dyspnea, tachypnea, accessory muscle use and paradoxical abdominal breathing, and gas exchange deterioration. Blood gas parameters aid in identifying patients with acute or acute superimposed on chronic CO₂ retention. A conscious and cooperative patient is crucial for initiating NIV (Table 91.2), although hypercapnic patients with narcosis who are otherwise good candidates for NIV may represent an exception.
- NIV should be avoided in patients with hemodynamic instability and in those who are unable to protect the airways (coma, impaired swallowing, and so on) (see Table 91.2). Patients with severe hypoxemia (PaO₂/FiO₂ <100) or morbid obesity (>200% of ideal body weight) should be closely managed only by experienced personnel and with a low threshold for intubation. In the presence of a pneumothorax, NIV can be initiated provided an intercostal drain is inserted. Criteria for NIV discontinuation and endotracheal intubation must be thoroughly considered to avoid dangerous delays (see Table 91.1).
- Identification of predictors of success or failure may help in recognizing patients who are appropriate candidates for NIV and those in whom NIV is not likely to be effective, thereby avoiding its application and unnecessary delays before invasive ventilation is given. The severity of acidosis at baseline

TABLE 91.2**CONTRAINDICATIONS TO NONINVASIVE VENTILATION**

Unconsciousness or mental obtundation (chronic obstructive pulmonary disease [COPD] patient may be an exception)
 Inability to protect the airway
 Inability to clear respiratory secretions
 Severe upper gastrointestinal bleeding
 Life-threatening hypoxemia
 Unstable hemodynamic conditions (blood pressure or rhythm instability)
 Recent gastroesophageal surgery
 Fixed obstruction of the upper airway
 Vomiting
 Recent facial surgery, trauma, burns, or deformity
 Undrained pneumothorax

is a logical starting point for identifying patients who might benefit from NPPV. Patients affected by acute respiratory distress syndrome with a Simplified Acute Physiology Score II >34, and whose PaO₂/FiO₂ does not improve over 175 after 1 hour of NPPV should be carefully treated under strict monitoring within the ICU where endotracheal intubation and invasive ventilation are promptly available. It is still unclear whether the higher mortality observed in patients who failed NPPV and are eventually intubated might be due to a delayed intubation.

Machine Settings

- Pressures commonly used to administer CPAP in patients with ARF range from 5 to 12 cm H₂O. For pressure-cycled ventilation, it is suggested to start at low pressures to facilitate patient tolerance (appropriate initial pressures are a CPAP of 3 to 5 cm H₂O and an inspiratory pressure of 8 to 12 cm H₂O) and, if necessary, gradually increase pressure settings as tolerated to obtain alleviation of dyspnea, decreased respiratory rate, adequate exhaled tidal volume, and good patient-ventilator interaction (Table 91.3). In the presence of air leaks, adequate inspiratory flows and durations should be set, triggering sensitivity should be adjusted to prevent auto-cycling, and a mechanism to limit inspiratory time and avoid I:E ratio inversion should be considered when available. A backup rate should be applied in patients with inadequate triggering.

Monitoring

- In the acute setting, patients can initiate NIV anywhere; at the onset of the acute respiratory distress, but after initiation, they should be transferred to an ICU or a step-down unit for continuous monitoring until they are sufficiently stable to be moved to a medical ward. During transfers, NIV and monitoring should not be discontinued. The early use of NIV for less acutely ill patients with COPD on a medical ward seems to be effective, but if pH is <7.30, admission to an

TABLE 91.3**PROPOSED VENTILATOR SETTINGS FOR PRESSURE SUPPORT VENTILATION MODE**

	Initial setting	Treatment setting
PEEP	3–5 cm H ₂ O	Slowly increased to up to 8–12 cm H ₂ O in hypoxemic patients
PSV	8–12 cm H ₂ O	Increased as tolerated to 20 cm H ₂ O to obtain an exhaled tidal volume of about 7 mL/kg and respiratory rate <25 breaths/min
FiO ₂	Titrated to achieve an arterial saturation >90% or 85%–90% in patients at risk of worsening hypercapnia	Titrated to achieve an arterial saturation >90% or 85%–90% in patients at risk of worsening hypercapnia

PEEP, positive end-expiratory pressure; PSV, pressure support ventilation.

environment with intensive care monitoring is highly recommended (Table 91.4).

- If a poor response to NIV occurs and the specific measures used to correct the situation fail to address an adequate improvement within a few hours, NIV should be considered a failure, and invasive ventilation should be promptly considered.

CLINICAL APPLICATION OF NONINVASIVE VENTILATION

- The following sections review the available evidence on the efficacy of NIV for various applications in the acute care setting.

Acute Exacerbations of Chronic Obstructive Pulmonary Disease

- In patients with ARF resulting from acute exacerbations of COPD, the use of NPPV has been proven to be effective

in ameliorating dyspnea, improving vital signs and gas exchange, preventing endotracheal intubation, and improving hospital survival. Consequently, there is a general agreement concerning the early use of NPPV in such patients.

- During NPPV, the combination of external PEEP and PSV offsets the auto-PEEP level and reduces the work of breathing that the inspiratory muscles must generate to produce the tidal volume.
- In general, NPPV should be considered the first-line therapeutic option to prevent endotracheal intubation and improve outcome in patients with exacerbations of COPD who have no contraindication to NPPV (see Table 91.2).

Asthma

- NPPV is considered an option in asthmatic patients at risk for endotracheal intubation. However, to date, guidelines for NPPV in severe asthma are not supported by strong data.

Hypoxemic Respiratory Failure

- Trials of NPPV in patients with hypoxemic respiratory failure, defined as those with ARF not related to COPD, have yielded conflicting results.
- NPPV can be initially used to treat hypoxemic patients without hypercapnia as long as there are no clear contraindications. However, an extremely prudent approach is needed, limiting the application of NPPV to hemodynamically stable patients who can be closely monitored in the ICU where endotracheal intubation is promptly available. A decisional flow chart may be adopted in applying NPPV to patients with acute respiratory distress syndrome (Fig. 91.1).

Cardiogenic Pulmonary Edema

- Applying positive air pressure has been shown to decrease the work of breathing and left ventricular afterload while maintaining cardiac index, thereby benefiting patients with cardiac dysfunction and ARF.
- In the comparison of NIV modalities, bilevel positive airway pressure has the potential advantage over CPAP of assisting the respiratory muscles during inspiration, which would result in faster alleviation of dyspnea and exhaustion.

TABLE 91.4**MONITORING OF PATIENTS RECEIVING NONINVASIVE VENTILATION IN THE ACUTE CARE SETTING****Bedside observation**

- Conscious level
- Comfort
- Chest wall motion
- Accessory muscle recruitment

Vital signs

- Respiratory rate
- Exhaled tidal volume (and flow, volume, and pressure waveform for poor synchrony problems)
- Heart rate
- Blood pressure
- Continuous electrocardiography

Gas exchange

- Continuous oximetry
- Arterial blood gas at baseline, after 1–2 h, and as clinically indicated

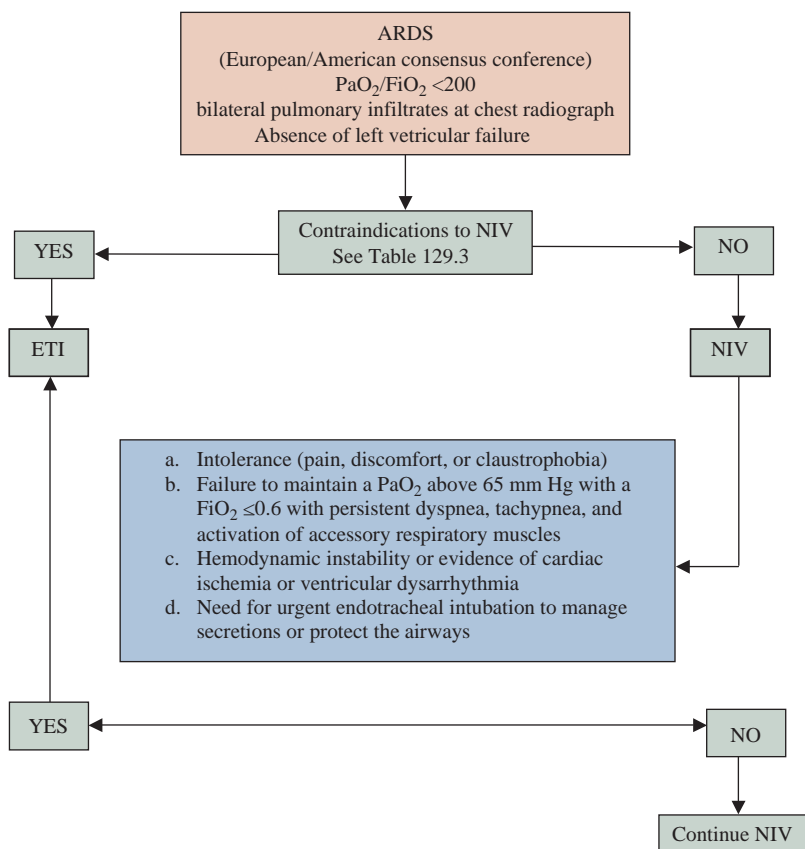

FIGURE 91.1. Decisional flow chart for the application of noninvasive ventilation to acute respiratory distress syndrome (ARDS). ETI, endotracheal intubation; NIV, noninvasive ventilation.

Pneumonia

- The application of NIV to treat pneumonia has yielded no definitive conclusions. NPPV's best application here is in COPD patients with community-acquired pneumonia, but caution should be applied in pneumonia patients without COPD, as the benefit of NPPV in such patients is currently unclear.

Immunocompromised Patients

- Immunocompromised patients in whom respiratory failure develops often require mechanical ventilatory assistance. Endotracheal intubation is associated with numerous complications and, in immunosuppressed patients, invasive mechanical ventilation is associated with a significant risk of death. A decreased mortality by the application of NPPV in selected cases of immunosuppressed patients has been reported in several studies.

Facilitation of Weaning and Extubation

- NPPV has been used to permit early extubation in patients who fail to meet standard extubation criteria, thus reducing the complications related to endotracheal tube.
- Besides weaning facilitation, another potential application of NIV in the weaning process is to avert the need for reintubation in patients with extubation failure, thereby avoiding

the risk of increased morbidity and mortality associated with failed extubation.

Do-Not-Intubate Orders

- Applying NPPV has been described in patients with ARF who are poor candidates for endotracheal intubation or who are reluctant to undergo invasive ventilation. NPPV offered an effective, comfortable, and dignified method for these patients in providing symptomatic relief of dyspnea and maintaining continuous verbal communication with loved ones, allowing a more aggressive pain and discomfort control therapeutic plan.

Postoperative Patients

- Thoracic and upper-abdominal surgery are associated with a prolonged postoperative gas exchange deterioration and reduction in functional residual capacity, PaO_2 , and forced vital capacity. Applying mask CPAP or NPPV can improve oxygenation and pulmonary function. Furthermore, accumulating evidence supports the use of NIV to improve gas exchange and avoid reintubation.

Obstructive Sleep Apnea

- CPAP is recognized to be effective in correcting the respiratory and arousal abnormalities and improving sleep quality in obstructive sleep apnea syndrome. CPAP is believed to act by pneumatically "splinting" the pharyngeal airway, thus preventing its collapse during sleep. Also, nasal NPPV has been used in patients with ARF after obstructive sleep apnea syndrome, with improvements in clinical status and arterial blood gas values.

FIGURE 91.2. Skin lesions caused by a mask. Please note that the point at major risk to develop skin necrosis is the bridge of the nose. (Photograph printed with the permission of the patient.)

Trauma

- ARF in trauma patients is generally associated with reduced pulmonary compliance and functional residual capacity and with subsequent restrictive defects. NIV in association with aggressive use of regional and neuraxial anesthetic block can be used in patients with respiratory insufficiency secondary to chest trauma, but caution should be used to avoid unnecessary delay of intubation in patients with flail chest. Despite the favorable results obtained, large randomized studies are

needed before definitive recommendations on the use of NIV in posttraumatic ARF can be made.

Restrictive Diseases

- NPPV has a role in the treatment of respiratory failure caused by some types of restrictive thoracic diseases. Aggressive respiratory physiotherapy is also crucial in all patients with thoracic restriction.

Bronchoscopy

- In nonintubated patients, severe hypoxemia is an accepted contraindication to fiberoptic bronchoscopy. Specific seal connectors have been applied with success to maintain adequate O_2 saturation while performing a fiberoptic bronchoscopy, with or without alveolar lavage.

ADVERSE EFFECTS AND COMPLICATIONS OF NONINVASIVE VENTILATION

- Major adverse effects of NIV seldom occur in appropriately selected patients and are minimized when the technique is applied by experienced caregivers. The most frequently encountered complications are related to the interface, ventilator airflow or pressure, or patient–ventilator interaction (Fig. 91.2).

CHAPTER 92 ■ INVASIVE VENTILATORY SUPPORT MODES

PHYSICS OF VENTILATION: THE EQUATION OF MOTION

- During spontaneous breathing, air flows into the lungs as the result of the pressure generated by the respiratory muscles. Exhalation normally occurs passively due to the elastic recoil pressure of the respiratory system.
- The pressure generated by the respiratory muscles during inspiration is opposed by the elastic forces of the lungs and chest wall, and by the resistance to gas flow that occurs in the airways:

$$P_{MUS} = P_E + P_R,$$

where P_{MUS} is the pressure generated by the respiratory muscles, P_E is the pressure required to overcome the elastic properties of the respiratory system, and P_R is the pressure required to overcome the resistive properties of the respiratory system.

- During positive pressure ventilation, the driving pressure for air to flow is applied by the ventilator and, depending on the mode, the respiratory muscles. Hence:

$$P_{APPL} = P_{MUS} + P_{VENT} = P_E + P_R,$$

where P_{APPL} is the pressure applied across the respiratory system to inflate the lungs, and is the combination of contributions from the respiratory muscles (P_{MUS}) and the ventilator (P_{VENT}).

- P_E is the result of elastance (E) and tidal volume (V_T):

$$P_E = \text{elastance} \times V_T.$$

Because elastance is the reciprocal of compliance (C), a more familiar version is

$$P_E = V_T/C.$$

P_R is determined by the resistance of the airways:

$$P_R = \dot{V} \times R,$$

where \dot{V} is gas flow and R is resistance.

- These physiologic relationships are described by the equation of motion of the respiratory system for both spontaneous breathing and mechanical ventilation:

$$P_{APPL} = P_{MUS} + P_{VENT} = V_T/C + \dot{V} \times R$$

- This states that a pressure applied to the respiratory system—whether it is from the respiratory muscles, the ventilator, or both—generates gas flow through the airways and volume change in the lungs that is opposed by the airway's resistance and respiratory system elastance. From the equation of motion, we can derive three important principles to guide the delivery of positive pressure ventilation:
 - The result of any ventilator setting depends not only on what is set on the ventilator but on the physiologic characteristics of the patient—compliance and resistance—and any active inspiratory effort of the respiratory muscles. Hence, for the appropriate application of mechanical ventilation, we must understand the ventilator operation and the patient's respiratory mechanics and the interaction between the ventilator and any active breathing efforts of the patient.
 - For any independent variable set on the ventilator (e.g., P_{VENT}), physiologic variables (compliance and resistance) in the patient, and respiratory muscle pressure generated by the patient (P_{MUS}), there is only one possible result for the dependent variables (e.g., flow and tidal volume). The ventilator typically controls the independent variables of flow (volume-controlled ventilation [VCV]) or pressure (pressure-controlled [PCV] or pressure support ventilation [PSV]). The ventilator cannot regulate both pressure and volume (i.e., flow) during mechanical ventilation.
 - If we know the volume and flow during VCV, we can calculate resistance and compliance from the pressures required. Similarly, if we know the resistance and compliance during PCV, we can calculate the flow and tidal volume. This is relatively straightforward if the patient is being passively ven-

tilated ($P_{MUS} = 0$) but becomes more difficult if the patient is actively breathing. Hence, it is difficult to predict respiratory mechanics in the actively breathing patient receiving PCV or PSV.

NOMENCLATURE: DESCRIPTION OF A VENTILATOR BREATH

The Trigger

- The trigger starts inspiration. Breaths are triggered either by the patient or by the ventilator. If the ventilator initiates the breath, the trigger is time (i.e., the operator sets a respiratory rate), and the ventilator will deliver the breath at time intervals to achieve that rate. If the breath is initiated by the patient, inspiration starts when the ventilator detects a pressure or flow change at the airway (pressure trigger and flow trigger).
- With a pressure trigger (Fig. 92.1), a decrease of pressure at the airway relative to positive end-expiratory pressure (PEEP; adjustable sensitivity, but generally set at 0.5–2 cm H₂O) results in closure of the expiratory valve, opening of the inspiratory valve, and delivery of gas to the airway. With a flow trigger (see Fig. 92.1), a flow increase at the airway (adjustable sensitivity but generally set at 1–3 L/min) results in initiation of the inspiratory phase. In modern ventilators, both flow triggers and pressure triggers are very sensitive. If the trigger sensitivity is set correctly, either flow triggering or pressure triggering is acceptable

The Limit

- The limit determines the size of a breath. When volume is the preset variable (VCV), flow and volume delivery by the ventilator are limited, but the pressure applied to the airway can vary. When pressure is the preset limit variable (PCV or PSV), the pressure applied at the airway is limited, but the flow and tidal volume are variable.

FIGURE 92.1. Pressure triggering and flow triggering. With pressure triggering, the ventilator responds to a decrease in airway pressure. With flow triggering, the ventilator responds to a change in flow.

The Cycle

- The cycle is what ends the breath. This can be volume, time, flow, or pressure. In modern ventilators, time is the cycle criteria with VCV or PCV. Note that for VCV, the ventilator actually controls the flow during inspiration, and inspiration is time-cycled. With PSV, the cycle is usually flow; inspiration ends when the flow rate reaches a fraction of the peak flow (adjustable on some ventilators) or a fixed flow. During VCV or PCV, pressure cycle is an alarm condition that avoids application of unsafe high pressure to the airway.

VENTILATOR MODES

- Modern ventilators are equipped to provide various modes. For all modes, the ventilator delivers one of two types of breath: mandatory or spontaneous (Fig. 92.2). A mandatory breath is triggered by the ventilator or the patient and cycled by the ventilator. A set volume (VCV) or pressure (PCV) is delivered regardless of the contribution from the patient and regardless of whether the breath is triggered by the patient or the ventilator. A spontaneous breath is triggered and cycled by the patient.
- A ventilator mode describes the pattern of breath delivery from the ventilator. With continuous mandatory ventilation (CMV), also called assist/control ventilation, every breath is a mandatory breath type. With continuous spontaneous ventilation, every breath is a spontaneous breath type. With synchronized intermittent mandatory ventilation (SIMV), the ventilator delivers a mix of mandatory and spontaneous breaths. With CMV or SIMV, a minimum backup rate is set on the ventilator, but the patient can trigger at a more rapid rate. With continuous spontaneous ventilation, there is no backup

rate other than the alarm parameter set on the ventilator. The taxonomy of ventilator modes is shown in Figure 92.2.

Continuous Mandatory Ventilation

- The main feature of CMV (or assist/control ventilation) is that it supplies full support of the patient's respiratory muscles, provided that the level of support is set appropriately.

Volume-controlled Ventilation

- With VCV, the ventilator controls the flow and the inspiratory time to deliver the resultant tidal volume. In some cases (e.g., Draeger ventilators), tidal volume, flow, and inspiratory time are each set. In this case, an inspiratory breath hold occurs if the inspiratory time setting is greater than that required to deliver the tidal volume at the flow selected. For example, for a tidal volume of 0.5 L, flow 60 L/minute, and inspiratory time 1 second, a 0.5-second inspiratory breath hold will result.
- On other ventilators (e.g., Puritan-Bennett 840), an inspiratory hold (pause) is set separately, which prolongs the inspiratory time. For VCV, tidal volume, flow, and inspiratory time are the independent variables. The dependent variable is the inflating pressure applied to the lungs, which is affected by the ventilator settings, the patient's lung mechanics, and the inspiratory effort of the patient, as explained by the *equation of motion* (see earlier). Hence, during VCV, the pressure applied by the ventilator will increase with a higher tidal volume, higher flow, lower compliance, and higher resistance.
- Also, the pressure applied by the ventilator will decrease if the patient generates a vigorous inspiratory effort (i.e., a higher P_{MUS}). This explains the deformation of the airway pressure waveform during VCV in patients who are generating vigorous inspiratory efforts and are dyssynchronous with the

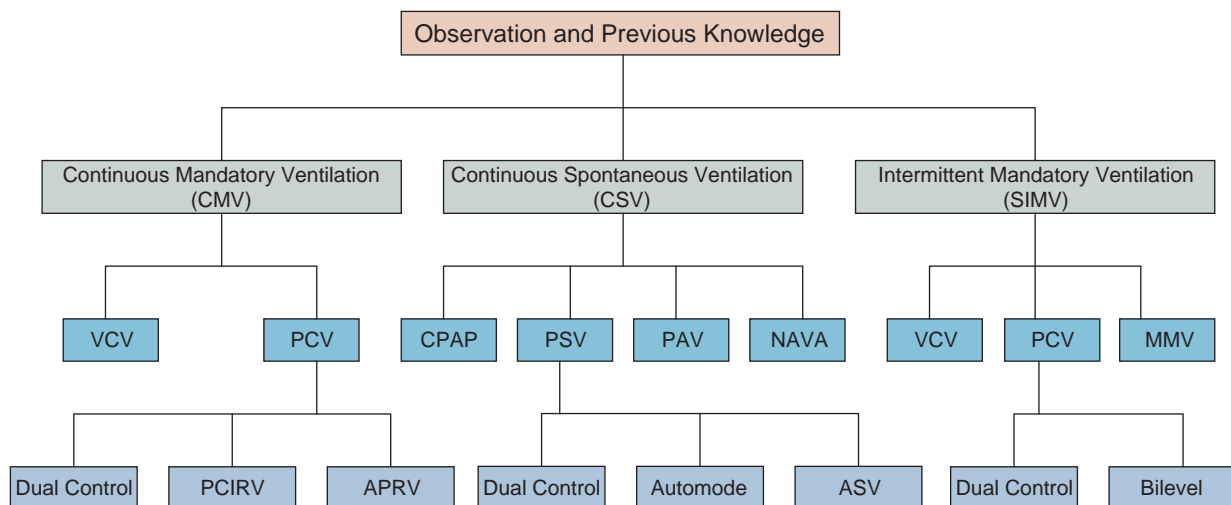

FIGURE 92.2. The taxonomy of ventilator modes. APRV, airway pressure release ventilation; ASV, adaptive support ventilation; CPAP, continuous positive airway pressure; MMV, mandatory minute ventilation; NAVA, neurally adjusted ventilatory assist; PAV, proportional assist ventilation; PCIRV, pressure-controlled inverse ratio ventilation; PCV, pressure-controlled ventilation; PSV, pressure support ventilation; VCV, volume-controlled ventilation.

ventilator. Inspiratory flow should be set to meet the demand of patients in respiratory failure.

- The main advantage of VCV is the ability to control the tidal volume. This may be important when the PaCO_2 must be closely controlled, such as in patients with head trauma or when a low tidal volume is used in patients with acute lung injury/acute respiratory distress syndrome as part of a lung-protective ventilation strategy. Limitations of VCV are related to the fixed tidal volume and flow pattern. This can result in patient–ventilator dyssynchrony in actively breathing patients if efforts are not made to set the inspiratory flow appropriately or to provide adequate sedation. With VCV, a high peak inspiratory pressure may occur with changes in lung mechanics. However, this increases the risk of lung injury only if the high peak inspiratory pressure is associated with an increase in plateau pressure. Accordingly, it is important to monitor plateau pressure on a regular basis when VCV is used.

Pressure-controlled Ventilation

- With PCV, airway pressure and inspiratory time are set on the ventilator. In some cases (e.g., Draeger ventilators), the inspiratory pressure setting is the peak pressure but, more commonly, the pressure control setting is the pressure applied above PEEP. For PCV, pressure and inspiratory time are the independent variables. The dependent variables are flow and volume, which are affected by the ventilator settings, the patient's lung mechanics, and the inspiratory effort of the patient as described by the *equation of motion* (see earlier). Hence, during PCV, the flow and tidal volume will increase with a higher pressure control setting, higher compliance, and lower airways resistance.
- Also, the flow and tidal volume will increase if the patient generates a vigorous inspiratory effort (i.e., an increase in P_{MUS}). In other words, during PCV, the distending pressure ($P_{\text{VENT}} + P_{\text{MUS}}$) and tidal volume increase if the patient makes an active inspiratory effort. Compared to VCV, this may improve patient–ventilator synchrony but with an increased risk of overdistention lung injury. An understanding of the equation of motion as it applies to PCV prevents errors when assessing lung mechanics or risk of overdistention when PCV is used.
- A potential advantage of PCV is that it limits the pressure applied to the alveoli and the risk of ventilator-induced lung injury. However, it is important to note that this benefit occurs only if the patient is making no inspiratory effort, because any inspiratory efforts of the patient will increase the transpulmonary distending pressure during PCV. The variable inspiratory flow pattern may improve patient–ventilator synchrony during active breathing efforts, although this has not been tested in the setting of a low lung volume, lung-protective ventilation strategy.
- The pressure waveform with PCV produces a higher mean airway (and alveolar) pressure than the pressure waveform associated with constant flow volume ventilation.

Dual-controlled Ventilation

- Dual-controlled modes allow the ventilator to control pressure or volume based on a feedback loop. At any given time, the ventilator controls either pressure or volume but cannot

do both at the same time. Pressure-regulated volume control (PRVC) provides PCV and in addition ensures a minimum tidal volume. PRVC (Servo, Viasys), AutoFlow (Draeger), and VC+ (Puritan-Bennett) are trade names that function in a similar manner. The proposed advantage of dual control is the ability of the ventilator to meet patient demand (an advantage of PCV) while maintaining a minute ventilation constant (an advantage of VCV). However, the tidal volume and transpulmonary distending pressure during PRVC can potentially exceed safe limits, as illustrated by the example in Figure 92.3.

- Moreover, if patient effort increases, the level of support decreases, which could result in dyssynchrony and discomfort. Additionally, as the pressure level is reduced, mean airway pressure will fall, potentially resulting in a fall in PaO_2 . Because this mode depends on the measured tidal volume, any errors in tidal volume measurement will result in decision errors.

Pressure-controlled Inverse Ratio Ventilation

- With pressure-controlled Inverse ratio ventilation PCIRV, the inspiratory time is set longer than the expiratory time (Fig. 92.4). The result is a higher mean airway pressure and enhanced lung recruitment but also a higher potential for air trapping and hemodynamic compromise. The likelihood of an improvement in oxygenation using PCIRV is small, and the risk of auto-PEEP and hemodynamic compromise is great. Moreover, the prolonged inspiratory time may not be well tolerated and may require high levels of sedation and, in some cases, paralysis.

Airway Pressure Release Ventilation

- Current-generation ventilators use an active exhalation valve whereby the ventilator controls the inspiratory pressure by allowing the exhalation valve to open if pressure increases and by adding additional flow if the pressure decreases below the pressure control setting. Such a design can also allow spontaneous breathing during the inspiratory phase of the ventilator, which is what happens in airway pressure release ventilation (APRV). The ventilator allows spontaneous breathing at two levels of pressure (Fig. 92.5). Because the low pressure is applied for a short period, generally all of the spontaneous breathing occurs at the high level. In the absence of spontaneous breathing, APRV is exactly the same as PCIRV.
- The potential advantage of APRV is to provide lung recruitment at lower airway pressures than with traditional positive pressure ventilation by taking advantage of the spontaneous breathing efforts.

Continuous Positive Airway Pressure

- For the intubated patient, CPAP is usually applied with a ventilator (Fig. 92.6). Modern ventilators provide efficient CPAP by virtue of having very-low-resistance exhalation valves and minimal time delay for triggering and cycling. CPAP is used to treat hypoxemia by maintaining alveolar recruitment to treat acute cardiogenic pulmonary edema by raising intrathoracic pressure and to counterbalance auto-PEEP in patients with obstructive lung disease.

FIGURE 92.3. Airway pressure (P_{aw}), flow, and volume waveforms demonstrating the response of a dual-control algorithm over a 2-minute period with varying patient effort. The tidal volume varies above and below the target (500 mL) by as much as 150 mL. (From Branson RD, Johannigman JA. The role of ventilator graphics when setting dual-control modes. *Respir Care*. 2005;50:187, with permission.)

- Despite an apparent contradiction in terms, CPAP can be set to 0 cm H₂O (although in reality the ventilator often applies a small level of inspiratory pressure support) and is commonly used as a spontaneous breathing trial to test extubation readiness.

Pressure Support Ventilation

- With PSV, the ventilator applies a set inspiratory pressure to support each patient-initiated breath (Fig. 92.7). Tidal volume is determined by the level of inspiratory pressure support,

FIGURE 92.4. Flow, pressure, and volume waveforms during pressure-controlled inverse ratio ventilation.

FIGURE 92.5. Pressure waveform during airway pressure release ventilation (APRV).

respiratory mechanics, and the patient's inspiratory effort. The initial part of the breath is delivered in a manner similar to PCV. During inspiration, the flow is delivered at a variable rate. In addition, rise time can be adjusted in a manner similar to that during PCV. When the set pressure is reached, the flow decreases at a rate determined by lung mechanics and the patient's inspiratory effort.

- With PSV, inspiration continues until the inspiratory flow falls to a ventilator preset value—commonly 25% of the peak flow or a fixed flow such as 5 L/minute. In newer-generation ventilators, the flow cycle criteria can be adjusted (expiratory sensitivity, Fig. 92.8).

Dual Control

- Dual-controlled ventilation can also be applied during a PSV breath. Volume-assured pressure support combines the high

initial flow of PSV with the constant flow delivery of a volume-controlled breath (Fig. 92.9). After inspiration is triggered, the ventilator reaches the set airway pressure as occurs with PSV. The ventilator's microprocessor determines the volume that has been delivered and compares this to the set tidal volume. If the set tidal volume is not reached, the ventilator prolongs the inspiratory phase until the set tidal volume is delivered. Volume-assured pressure support is designed to reduce the work of breathing (pressure support) while maintaining a minimum tidal volume (volume control).

- A concern with this mode is that the ventilator takes away support if the patient's respiratory demand increases and tidal volume exceeds the set tidal volume. This results in increased work of breathing for the patient.

AutoMode

- AutoMode is a dual-controlled mode available on the Servo 300 and Servo 300A ventilators. It provides automated weaning from PCV to PSV and automated escalation of support if patient effort diminishes. The ventilator provides PRVC if the patient is making no breathing efforts.

Adaptive Support Ventilation

- Adaptive support ventilation is based on the minimal work-of-breathing concept, which suggests that a patient will breathe at a tidal volume and respiratory frequency that minimize the elastic and resistive loads while maintaining oxygenation and acid-base balance.
- If a patient breathes spontaneously, the ventilator will support breaths. Spontaneous and mandatory breaths can be combined to meet the minute ventilation target. The pressure limit of both the mandatory and spontaneous breaths is

FIGURE 92.6. Flow, pressure, and volume waveforms during continuous positive airway pressure (CPAP). Note that the airway pressure fluctuates above and below the set CPAP level of 5 cm H₂O. There is a pressure decrease below CPAP to trigger the breath, a low level of pressure support is applied during inhalation, and there is a small increase in pressure to cycle the end of inhalation.

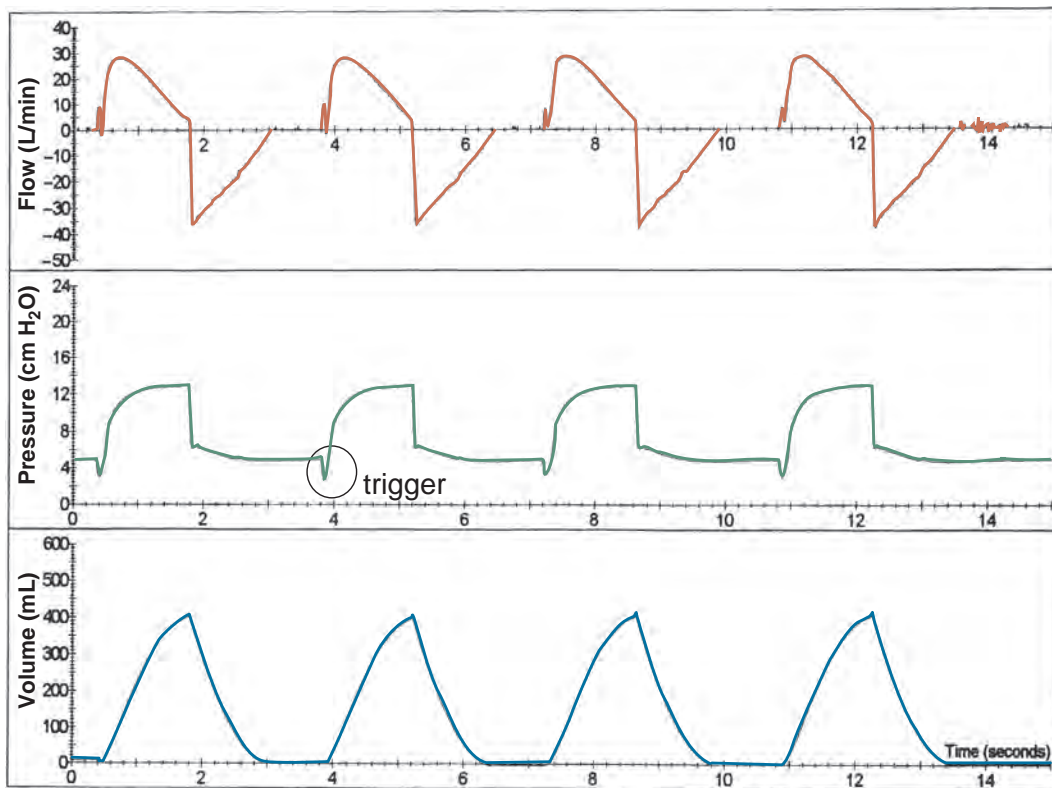

FIGURE 92.7. Flow, pressure, and volume waveforms during pressure support ventilation. (From Gibbons FK, Hess DR. Mechanical ventilation. In: Bigatello LM, ed. *Critical Care Handbook of the Massachusetts General Hospital*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006, with permission.)

FIGURE 92.8. Examples of flow termination criteria of 10%, 25%, and 50% using a Puritan-Bennett 840 ventilator with pressure support of 15 cm H₂O and PEEP 5 cm H₂O. (From Gibbons FK, Hess DR. Mechanical ventilation. In: Bigatello LM, ed. *Critical Care Handbook of the Massachusetts General Hospital*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006, with permission.)

FIGURE 92.9. The possible breath types during volume-assured pressure support ventilation. In breath A, the set tidal volume (V_T) and delivered V_T are equal. This is a pressure support breath (patient triggered, pressure limited, and flow cycled). Breath B represents a reduction in patient effort. As flow decreases, the ventilator determines that delivered V_T will be less than the minimum set volume. At the shaded portion of the waveform, the breath changes from a pressure-limited to a volume-limited (constant flow) breath. Breath C demonstrates a worsening of compliance and the possibility of extending inspiratory time to ensure the minimum V_T delivery. Breath D represents a pressure support breath in which the V_T is greater than the set V_T . (From Branson RD, Johannigman JA. The role of ventilator graphics when setting dual-control modes. *Respir Care*. 2005;50:187, with permission.)

adjusted continuously. This means that adaptive support ventilation is continuously using dual-control breath-to-breath of mandatory and spontaneous breaths.

Tube Compensation

- Tube compensation (TC) is designed to overcome the flow-resistive work of breathing imposed by the endotracheal or tracheostomy tube. TC uses the known resistive coefficients of the artificial airway (tracheostomy or endotracheal tube) and measurement of instantaneous flow to apply a pressure proportional to resistance throughout the total respiratory cycle. With TC, the ventilator targets the tracheal pressure rather than proximal airway pressure, increasing the proximal airway pressure necessary to overcome the flow-resistive properties of the artificial airway (Fig. 92.10).

Proportional Assist Ventilation

- With proportional assist ventilation (PAV), the ventilator delivers gas as a positive feedback controller, where respiratory elastance and resistance are the feedback signal gains, defined as K_1 (cm H_2O/L) and K_2 (cm $H_2O/L/s$), respectively.
- A potential advantage of PAV is that it should provide optimal patient-ventilator synchrony. By following and amplifying the patient's inspiratory flow and volume on a breath-by-breath basis, the ventilator provides support in proportion to patient demand. This differs from PSV, in which the level of support is constant regardless of demand, and VCV, in which the level of support decreases when demand increases. It is important to note that, like other continuous spontaneous breathing modes, PAV requires the presence of an intact ventilatory drive. A concern with PAV is its dependence on measures of resistance and compliance, often under- or overestimated.

Neurally Adjusted Ventilatory Assist

- Control of the ventilator through direct measurement of the output of the respiratory center is presently not possible. However, it is possible to transform neural drive into ven-

tilatory output (neuroventilatory coupling) by measuring the electrical activation of the diaphragm. This neurally adjusted ventilatory assist will vary on a moment-by-moment basis according to diaphragmatic electrical activity and the gain factor selected on the ventilator. This allows a patient's respiratory center to be in direct control of the mechanical support provided throughout the course of each breath, provided there is a functioning phrenic nerve and neuromuscular junction and also that the diaphragm is the primary inspiratory muscle. Although neurally adjusted ventilatory assist is clinically attractive, it is not yet commercially available.

FIGURE 92.10. Tube compensation. Pressure waveforms from the trachea (heavy lines) and the proximal airway (light lines) during pressure support ventilation and automatic tube compensation. Note that the tracheal pressure fluctuates very little during automatic tube compensation. (From Fabry B, Haberthur C, Zappe D, et al. Breathing pattern and additional work of breathing in spontaneously breathing patients with different ventilatory demands during inspiratory pressure support and automatic tube compensation. *Intensive Care Med*. 1997;23:545, with permission.)

FIGURE 92.11. Using a sigh breath in conjunction with pressure support ventilation. The patient is ventilated with a Draeger Evita 4 (PCV+ mode). P_{aw} , airway pressure. (From Patronati N, Foti G, Cortinovis B, et al. Sigh improves gas exchange and lung volume in patients with acute respiratory distress syndrome undergoing pressure support ventilation. *Anesthesiology*. 2002;96:788, with permission.)

Synchronized Intermittent Mandatory Ventilation

- With synchronized intermittent mandatory ventilation (SIMV), the ventilator provides a mandatory breath rate. If the patient breathes at a more rapid rate, the additional breaths are unsupported. If the patient does not breathe at a rate more rapid than that set on the ventilator, SIMV and CMV are synonymous.

Mandatory Minute Ventilation

- Mandatory minute ventilation is intended to guarantee the minute ventilation that the patient receives. If the patient's spontaneous ventilation does not match the target minute

ventilation set by the clinician, the ventilator supplies the difference between the patient's minute ventilation and the set minute ventilation.

Bilevel and PCV+

- This mode is available on the Puritan-Bennett 840 (Bilevel) and the Draeger Evita 4 (PCV+). It is essentially a modification of SIMV that uses PCV for the mandatory breaths and PSV for the spontaneous breaths. This mode can be thought of as PSV with a sigh. The mandatory breath rate is set at 1 to 4 breaths/minute, with the pressure during the sigh set at 25 to 30 cm H₂O and a sigh duration of 2 to 4 seconds (Fig. 92.11). This mode may be more comfortable than the sighs traditionally incorporated into ventilators because it is a pressure-controlled breath using an active exhalation valve.

CHAPTER 93 ■ HIGH-FREQUENCY VENTILATION

- High-frequency ventilation (HFV) has been recognized as a modality that can provide optimal lung protection from iatrogenic complication in patient with acute lung injury (ALI) and acute respiratory distress syndrome (ARDS).

SUBTYPES OF HIGH-FREQUENCY VENTILATION

- HFV is a collection of ventilatory modes grouped together by their common property of employing high respiratory rates, all >60 breaths/minute. In addition to high-frequency oscillation (HFO), other modes in this group include high-frequency jet ventilation (HFJV) and high-frequency percussive ventilation (HFPV).

High-frequency Jet Ventilation

- HFJV is a mode of ventilation in which gas is delivered through a small-bore catheter into the lungs at rates of 100 to 150 breaths/minute. Delivered tidal volume is still small but higher than just the volume exiting the jet, as the jets entrain an additional flow of gas by the *Venturi effect*. Exhalation is passive during HFJV, and gas trapping or dynamic hyperinflation can be an issue. In practice, a conventional ventilator is set up as a “slave” to the jet to provide positive end-expiratory pressure along with basic monitoring and alarms.
- HFJV is a very efficient mode for removing CO₂. Additionally, because of HFJV’s very high flow rates and the differing pulmonary time constants in the clinical setting of bronchopleural fistulae, this mode of ventilation is purported to have beneficial effects in the presence of this disorder; however, these benefits have not been verified during objective testing. Concerns with HFJV relate to the delivery of high pressures (10–50 pounds per square inch), unpredictable tidal volumes, and the development of dynamic hyperinflation, all of which may worsen ventilator-induced lung injury (VILI) rather than minimize it. In addition, problems with adequate humidification of inspired gas and the subsequent risks of tracheobronchitis have been noted and documented.

High-frequency Percussive Ventilation

- HFPV is the newest and least well studied of the HFV modes. It combines a high-frequency rate of 200 to 900 breaths/minute superimposed on a conventional pressure mode of ventilation. HFPV is reported to enhance the clearance of respiratory secretions and has been successfully used in this regard in patients with burns and inhalational injury.

High-frequency Oscillation

- High-frequency oscillation (HFO) is a mode of mechanical ventilation that delivers very small tidal volumes around a set mean airway pressure at high respiratory rates of 3 to 15 Hz (equivalent to 180–900 breaths/minute, as 1 Hz = 60 breaths/minute). HFO has been widely and effectively used in neonates and children for close to 20 years but only recently has become available in the adult intensive care unit; previous versions of this ventilator were capable of generating only sufficient flow so as to provide adequate CO₂ elimination in patients <35 kg. In contrast to other HFV modes, humidification is less of an issue during HFO, as a continuous bias flow of humidified gas is passed in front of an oscillating membrane (Fig. 93.1). This oscillating membrane pushes the humidified gas into the patient and also provides active expiration, a factor that likely accounts for the lack of important gas trapping that is observed when HFO is employed at adequate airway pressures. The elegance of HFO is that it allows for “decoupling” of oxygenation and ventilation. Alveolar ventilation, and thus carbon dioxide elimination, are dependent on the frequency and tidal volume but are relatively independent of lung volume. In contrast, oxygenation is proportional to mean airway pressure and lung volume.

RATIONALE FOR THE USE OF HIGH-FREQUENCY VENTILATION IN ACUTE LUNG INJURY TO LIMIT VENTILATOR-INDUCED LUNG INJURY WITH CONVENTIONAL VENTILATION

- VILI is histologically indistinguishable from ARDS; three decades of experimental research have shown it to occur through a number of mechanisms, including (a) overdistention injury (*volutrauma*), (b) collapse-reopening injury (*atelectrauma*), and (c) oxygen toxicity. Each of these can lead, in turn, to further injury—termed *biotrauma*—the release of inflammatory mediators that may worsen pulmonary injury and propagate systemically to harm distant organs.
- Numerous studies, performed using both small and large animals, consistently show that ventilatory high end-inspiratory stretch can cause a clinical and histologic picture similar to ARDS even in the absence of any other noxious stimulus. Patients with ARDS are at increased risk of regional lung overdistention because of the patchy nature of ARDS; the small areas of relatively normal lung (the so-called “baby lung”) receive the bulk of the tidal volume and are at particular risk of *volutrauma*. Repeated opening and closing of alveolar units can also cause VILI. In the injured lung, alveolar

FIGURE 93.1. Schematic overview of the high-frequency oscillation (HFO) circuit. (Reused with permission from Ferguson ND, Stewart TE. New therapies for adults with acute lung injury: high-frequency oscillatory ventilation. *Crit Care Clin.* 2002;18:91–106.)

damage and absolute, or qualitative, deficiencies in alveolar surfactant lead to alveolar instability and localized lung unit collapse. Through each respiratory cycle, these unstable alveoli undergo collapse and reopening, a process that generates injurious mechanical forces and causes further lung injury. There is a substantive body of animal evidence showing that efforts to limit lung unit closing on expiration by maintaining an adequate positive end-expiratory pressure (PEEP) are relatively protective against atelectrauma. Here, the paradigm is one of “opening the lung and keeping it open,” thereby avoiding cyclic collapse and recruitment/derecruitment.

- The goals of mechanical ventilation in a patient at risk of VILI, therefore, should be to ventilate and oxygenate the patient while staying within a “safe window,” avoiding both overdistention and derecruitment—collapse—as illustrated in the volume–pressure curve of the lung shown in Figure 93.2.

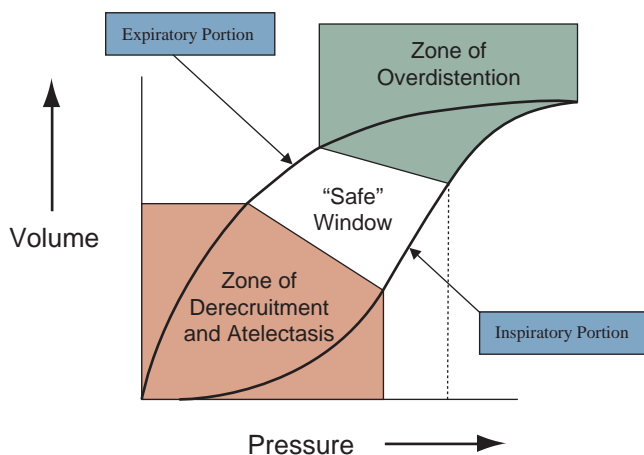

FIGURE 93.2. Volume–pressure curve of the injured lung. (Reused with permission from Froese AB. High-frequency oscillatory ventilation for adult respiratory distress syndrome: let’s get it right this time. *Crit Care Med.* 1997;25[6]:906–908.)

- A large, methodologically rigorous, and adequately powered trial conducted by the National Institutes of Health ARDS Network did show important differences in mortality. A low-stretch strategy with a targeted tidal volume of 6 mL/kg predicted body weight (PBW) and a plateau pressure limit of 30 cm H₂O was compared to a higher-stretch strategy using a targeted tidal volume of 12 mL/kg PBW and a plateau pressure limit of up to 50 cm H₂O. The low-stretch strategy was associated with a mortality reduction from 40% in the control group to 31% in the experimental group (relative risk [RR] 0.78; 95% confidence interval [CI] 0.65–0.93). This trial clearly indicates that avoiding volutrauma saves lives in patients with acute lung injury. The trial has subsequently generated significant discussion regarding its mechanisms of benefit and its choice of control strategy but, nevertheless, 6 mL/kg PBW has emerged as a standard for tidal volume limitation against which other strategies are compared.
- Another early randomized controlled trial published in the late 1990s demonstrated dramatic reductions in mortality using a lung-protective strategy whose goal was to limit both volutrauma and atelectrauma using low tidal volumes and higher PEEP compared with traditional ventilation. Though no single trial has definitively shown an incremental mortality benefit with higher PEEP and attempts to limit atelectrauma while already avoiding overdistention injury, when viewed together, these trials suggest that this benefit may well exist. These studies clearly demonstrated that ventilatory strategy is important in patients with ARDS and that lung-protective strategies can minimize VILI and decrease mortality in humans with ARDS. As such, and given the proposed mechanisms of lung protection (see Fig. 93.2), a strategy that minimizes overdistention and allows the use of high PEEP should be the ideal mode in patients with ARDS. This is where HFO may have great clinical benefit.
- The very small delivered tidal volumes are the key to the lung-protective potential of HFO. Because cyclic alveolar stretch is minimal, clinicians are able to set the mean airway pressure

FIGURE 93.3. Pressure–time curve contrasts tidal variations in airway pressure associated with conventional ventilation (*dashed line*) and high-frequency oscillation (*solid line*). HFOV, high-frequency oscillation ventilation; CMV, conventional mechanical ventilation. (Reused with permission from Ferguson ND, Stewart TE. New therapies for adults with acute lung injury: high-frequency oscillatory ventilation. *Crit Care Clin.* 2002;18:91–106.)

(mP_{AW}) on HFO significantly higher than they are able to set PEEP on conventional ventilation, thereby avoiding cyclic collapse and atelectrauma—and yet they are still able to avoid very high peak inspiratory pressures and subsequent volutrauma (Fig. 93.3).

IMPLEMENTING AND OPTIMIZING HIGH-FREQUENCY OSCILLATION IN ADULTS

- Several key messages for HFO can be gleaned from animal studies on the use of HFO in ALI and ARDS models.
 - At adequate mP_{AW} , gas trapping is not an issue despite very high respiratory rates.
 - Increasing mP_{AW} leads to improved oxygenation through lung recruitment.
 - Tidal pressure swings measured in the trachea can be increased with either underrecruitment or overdistention of the lung.
- Recruitment maneuvers (sustained inflations) may be required to adequately recruit severely injured lungs.
- Taken together, and in keeping with the current understanding of VILI mechanisms, these studies suggest that HFO in adults should be employed using an open-lung strategy, facilitated by higher mean airway pressures and lung recruitment maneuvers.
- Most of the clinical information available on HFO is based on its use as rescue therapy for patients with extremely severe disease who were “failing” conventional ventilation. Despite being limited by their uncontrolled nature and by selection bias, consistent messages that arise from these rescue series include the following:
 - HFO is usually effective in improving oxygenation.
 - HFO appears safe, with no obvious increased rates of complications.
 - Both baseline oxygenation index and duration of CMV prior to HFO are associated with increased mortality.
- Despite the very strong physiologic rationale and the encouraging clinical data to date, there are potential detrimental consequences of HFO.
 - First, the physiologic benefit of HFO is likely derived from recruitment of the lung with higher mean airway pressures, though still not overdistending alveoli because of the very small tidal volumes. Hence, patients with mild disease and minimal collapsed or consolidated lung may not be good candidates for HFO.
 - Second, the high mean airway pressures may negatively impact hemodynamics.
 - Third, because the bias flow rate is insufficient to meet the inspiratory flow demands of adults in respiratory distress, all adults on HFO must have their respiratory efforts suppressed with intravenous sedation.
- This means that the majority of adults will be heavily sedated, and many may need transient neuromuscular blockade. Due to these concerns and to target a population in need of recruitment, we believe that future studies should enroll patients with severe ARDS who are likely to have significant lung collapse and who frequently require significant amounts of sedation, with or without paralysis, on conventional ventilators.

CHAPTER 94 ■ EXTRACORPOREAL CIRCULATION FOR RESPIRATORY OR CARDIAC FAILURE

- Extracorporeal life support (ECLS) is the use of an artificial heart (pump) and lung (membrane oxygenator) to replace organ function for days or weeks, to allow time for diagnosis, treatment, and organ recovery or replacement. The indications for ECLS are acute, severe heart or lung failure not improving on conventional management. This review is limited to the adult population.

EXTRACORPOREAL LIFE SUPPORT TECHNIQUE AND PHYSIOLOGY

- ECLS is simply the use of a modified heart/lung machine to provide gas exchange (and systemic perfusion if necessary) to prolong the life of a patient when native heart and lung

functions are not adequate to sustain life. The heart–lung machine used for cardiac surgery is modified, both in devices and technology, to be used for days or weeks in the intensive care unit, but the purpose is the same: to keep the body alive during heart or lung failure. The technique is invasive and complex.

- A large catheter (No. 23–30 French) is inserted into the inferior vena cava or right atrium; venous blood is drained, passed through an artificial lung, and pumped back into the patient, either into the aorta (venoarterial [VA] bypass) or into the right atrium (venovenous [VV] bypass). VA bypass puts the artificial lung in parallel with the native lungs and substitutes for both heart and lung function. In VV bypass, the artificial lung is in series with the native lungs, and the patient is reliant on his or her own hemodynamics for pulmonary and systemic perfusion. ECLS allows decreasing the ventilator to nondamaging “rest” settings (typically FiO_2 0.3, pressure 20/10, rate 4), decreasing vasoactive drugs, and optimizing other aspects of treatment.
- Because the surfaces of the extracorporeal devices are plastic, it is necessary to anticoagulate the blood with a continuous infusion of heparin, titrated to a low but constant level of anticoagulation. This level of anticoagulation is measured by whole blood-activated clotting time (ACT). The normal is 120 seconds, and during ECLS, ACT is maintained at approximately 180 seconds. Although this level of heparinization prevents thrombosis in the extracorporeal circuit, circulating platelets still adhere to the plastic surfaces, become activated (which attracts more platelets), grow into platelet aggregates, and eventually break off and recirculate as effete platelets, which are removed by the reticuloendothelial system in the liver and spleen.
- Because heparinization and thrombocytopenia are necessary components of ECLS, the major risk of the procedure is bleeding. As currently practiced, significant bleeding is rarely a serious problem, but this requires the continuous bedside attendance of a specialist whose primary job is to measure the ACT and platelet count at very frequent intervals and titrate heparin dose and platelet infusions accordingly. Properly managed, ECLS can be used for weeks without hemolysis, device failure, clotting, or bleeding, but it is invasive and expensive. The technology not only must be learned and practiced by the intensive care unit team but must be endorsed by the entire hospital. Management of the patient during ECLS includes management of perfusion and gas exchange as earlier but also attention to fluid balance, oxygen consumption and delivery, nutrition, position, and the monitoring and sustaining of function of other organs.
- In *respiratory failure*, VV access is preferred. Gas exchange across the native lungs is usually minimal during the first several days of ECLS; therefore, the patient is totally dependent on the extracorporeal system. As native lung function returns, systemic blood oxygenation and CO_2 clearance improve, improved gas exchange can be measured at the airway, and the extracorporeal blood flow rate is gradually decreased, allowing the native lungs to assume a larger percentage of gas exchange. When the native lungs have improved, the patient is tried off ECLS at nondamaging ventilator settings. When this trial is successful, the cannulas are removed, and recovery continues. Patients who are successfully weaned off ECLS have a 90% likelihood of complete recovery.
- In *cardiac failure*, VA access is required (usually via the femoral vessels). Inotropes and pressors are weaned off,

and systemic perfusion is maintained by extracorporeal flow. Lung function usually returns to normal in a day or two, and the patient can be awakened and extubated. When the patient is stable and the function of other organs can be determined (especially the brain), a decision can be made regarding bridge to recovery or bridge to ventricular assist device (VAD) and transplantation. When ECLS is used for cardiac support, the pulmonary and left ventricular blood flow is decreased in proportion to the extracorporeal flow. This can lead to two problems. First, if the heart stops altogether, the left atrium and the left ventricle will gradually distend with bronchial venous blood, leading to high left atrial pressure and pulmonary edema. This condition is diagnosed by the lack of pulsatility in the systemic arterial system. If left ventricular function is inadequate to maintain emptying of the left heart, the left side of the heart must be drained into the venous line, either by direct catheterization of the left atrium or by creation of an atrial septal defect. The second problem with VA bypass in the totally failing heart is thrombosis in the left atrium or left ventricle. This will occur even in the presence of systemic heparinization. Thrombosis is diagnosed by echocardiography. If a patient has left atrial or left ventricle thrombus, it is important to avoid spontaneous left ventricular function. Usually such patients are candidates for VAD or cardiac replacement, and the clot is removed before embolism could occur.

CLINICAL RESULTS

- The most recent data from the Extracorporeal Life Support Organization registry are shown in Table 94.1. Participation in the Extracorporeal Life Support Organization is voluntary, but almost all cases treated with ECLS in established centers are included in the registry. There are currently more than 30,000 patients who have been managed with ECLS. Although there are extensive data on gas exchange, perfusion, coagulation, and so on, the only important statistic is hospital discharge survival because the technique is a life-support technique, and it is applied only to patients who are not expected to survive otherwise, with a high (80%–100%) risk of dying with continuing conventional treatment. The mortality risk is measured differently in different age groups.

Extracorporeal Life Support for Acute Respiratory Distress Syndrome

- The University of Michigan has reported the largest experience with ECLS for ARDS. In that series, the overall survival rate was 52% and rose to 65% in 2002. The series is large enough to characterize the patient population and identify the likelihood of recovery based on age and days on mechanical ventilation.
- As technology for adult respiratory failure has evolved, ECLS is now practiced using primarily venovenous access, with high blood flow adequate to sustain oxygenation and CO_2 removal, lung rest, diuresis, and prone positioning. This approach leads to 50% to 60% survival. Though the majority of adult patient were treated with ECLS for severe ARDS, this technology can be utilized for severe status asthmaticus, refractory to all conventional therapy.

TABLE 94.1

OVERALL PATIENT OUTCOMES WITH EXTRACORPOREAL LIFE SUPPORT FOR CARDIAC AND RESPIRATORY FAILURE

	Total	Surv	ECLS	Surv to	DC
Neonatal

Extracorporeal Life Support Organization registry data, December 2006. The data for 2006 are incomplete.

Extracorporeal Life Support for Cardiac Failure

- The experience with ECLS for cardiac failure in adults is shown in Table 94.1. The most common indication for ECLS for cardiac support in adults is acute myocardial failure after myocardial infarction or heart failure after cardiac operation. Most of the patients treated with ECLS have failed balloon pumping and full inotropic support. If a balloon pump is in place through one of the femoral arteries, it is best left in place because of the risk of bleeding once the pump has been removed. The opposite femoral artery is used for arterial access.
- Adult patients in acute cardiac failure are candidates for left ventricular assist device placement as a bridge to recovery or a bridge to transplantation. However, in the acute failure situation, it is best to institute ECLS first, to stabilize the circulation and gas exchange and to determine whether other organs are

functioning, specifically the brain. If severe brain injury has occurred during the period of acute cardiac failure, ECLS is discontinued, avoiding the futile thoracotomy and the need for a left ventricular assist device placement. The survival for ECLS in adult cardiac failure is 40% to 50%.

Extracorporeal Life Support for Cardiac Arrest

- ECLS can be used in association with resuscitation to support cardiac and pulmonary function in cardiac arrest or profound shock. In this application, the ECLS circuit must be primed and available within minutes. Therefore, the ECLS for cardiopulmonary resuscitation cases are done primarily in established ECLS centers, which have both the equipment and the team to institute ECLS on a moment's notice. Survival with satisfactory neurological recovery has been described up to 40%.

CHAPTER 95 ■ WEANING FROM MECHANICAL VENTILATION

- A framework of seven stages of weaning has recently been proposed (Fig. 95.1).
- From a pathophysiologic standpoint, factor that affect weaning can be related to gas exchange or to the ventilatory pump. In a third group of patients, psychological factors may contribute to weaning failure.

IMPAIRED GAS EXCHANGE

- Conditions characterized by failure of the lungs as a gas exchange unit include those associated with ventilation-perfusion mismatching and (less often) conditions associated with increased shunt.

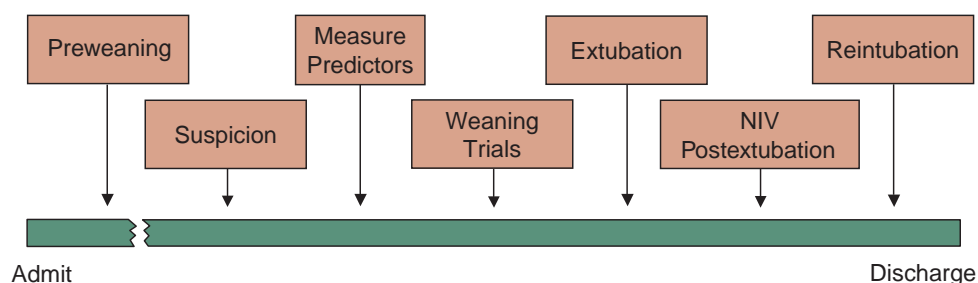

FIGURE 95.1. Seven stages of weaning. Stage 1 is preweaning, a stage that some patients never get beyond. Stage 2 is the period of diagnostic triggering, the time when a physician begins to think that the patient might be ready to come off the ventilator. Stage 3 is the time of measuring and interpreting weaning predictors. Stage 4 is the time of decreasing ventilator support (abruptly or gradually). Stage 5 is either extubation (of a weaning success patient) or reinstitution of mechanical ventilation (in a weaning failure patient). Stage 6 is use of noninvasive ventilation (NIV) after extubation. Stage 7 is reintubation. Failure to appreciate stage 2 probably leads to the greatest delays in weaning. (From Tobin MJ, Jubran A. Weaning from mechanical ventilation. In: Tobin MJ, ed. *Principles and Practice of Mechanical Ventilation*. New York, NY: McGraw-Hill; 2006:1185, with permission.)

- The ratio of dead space to tidal volume—an approximation of impaired gas exchange due to lung units with abnormally high ventilation–perfusion ratios—is normally about 0.30 at rest and less during exercise. In patients requiring prolonged mechanical ventilation, the ratio can increase to 0.74 or more.
- Patients can compensate for such an increase in dead space by increasing minute ventilation by as much as 2.5 times. Such an increase in minute ventilation poses a minor challenge when respiratory mechanics and respiratory muscles are normal; for example, hypercapnia is uncommon with pulmonary vascular disease. Likewise, in the presence of large shunts, increases in minute ventilation can be sufficient to prevent hypercapnia. Accordingly, an increase in dead space ventilation or shunt should not be considered the primary mechanisms responsible for weaning failure unless there is a concurrent abnormality in the mechanical load of the respiratory muscles or in their contractile performance or there are concurrent abnormalities in the control of breathing. For example, increases in dead space ventilation may develop during weaning trials as the result of rapid shallow breathing and dynamic hyperinflation. Finally, an increase in carbon dioxide production can probably only be a contributory factor and not a sole cause of weaning failure.

IMPAIRED VENTILATORY PUMP

Decreased Respiratory Drive

- Specific conditions such as central alveolar hypoventilation secondary to neurologic lesions (trauma, infections, infarction) can contribute to, or cause, weaning failure. In most weaning-failure patients, however, estimations of respiratory drive indicate that drive is increased, not decreased, as suggested by the increased measured airway occlusion pressure at 100 ms ($P_{0.1}$) in patient failure to wean after 3 week of mechanical ventilation.
- The high neuromuscular inspiratory drive, however, is poorly transformed into ventilatory output—the tidal volumes can be lower in weaning failure patients than in weaning success patients—and therefore associated with increased respiratory rate.

- In approximately 10% of patients, however, a decrease in drive relative to the ventilatory demands may still contribute to weaning failure with acute hypercapnia during a trial of spontaneous respiration, primarily because of (relative) respiratory center depression. Whether sleep deprivation decreases respiratory drive remains controversial.

Increased Mechanical Load

- From 30% to 50% of patients who fail a weaning trial usually experience greater inspiratory resistance; 100% of the patients experience greater dynamic elastance with up to a 200% increase of intrinsic positive end-expiratory pressure (PEEP). Abnormal mechanics arise from bronchoconstriction, bronchial edema, pulmonary edema, and lung inflammation. Rapid shallow breathing can aggravate the abnormalities in lung elastance, intrinsic PEEP, and carbon dioxide clearance. Expiratory muscle recruitment can also increase intrinsic PEEP and breathing effort.
- Increased mechanical load contributes to weaning failure by increasing work of breathing. Furthermore, in weaning failure patients, the mean inspiratory flow—or tidal volume to inspiratory time ratio—produced for a given level of neuromuscular inspiratory drive ($P_{0.1}$ to mean inspiratory flow ratio or *effective inspiratory impedance*) is higher than in patients who are successfully weaned (Fig. 95.2). The higher *effective inspiratory impedance* results entirely from a greater neuromuscular drive and not from a reduced mean inspiratory flow. This correlation indicates a worse load-capacity balance in weaning failure patients than in weaning success patients.

Respiratory Muscle Weakness

- In healthy subjects, maximum inspiratory airway pressure is usually more negative than -80 cm H_2O . In mechanically ventilated patients recovering from an episode or acute respiratory failure, maximum inspiratory airway pressure can range from less negative than -20 cm H_2O to about -100 cm H_2O . Values of maximal airway pressure during voluntary maneuvers depend greatly on a level of motivation and comprehension of the maneuver, often not obtainable in

FIGURE 95.2. Effective inspiratory impedance ($P_{0.1}/V_T/T_I$) during periods of unassisted breathing in long-term ventilator-dependent (VD) patients with chronic obstructive pulmonary disease (COPD) ($n = 12$), in patients with COPD who were successfully weaned (WS) from mechanical ventilation after a period of prolonged ventilation ($n = 8$), and in stable patients with COPD ($n = 9$). Effective inspiratory impedance was less in weaning successes and in stable patients than in patients who were ventilator dependent. Asterisks, $p < 0.05$, VD versus WS and Stable; horizontal bars, average values. (Modified from Purro A, Appendini L, De Gaetano A, et al. Physiologic determinants of ventilator dependence in long-term mechanically ventilated patients. *Am J Respir Crit Care Med.* 2000;161:1115.)

critically ill patients. Thus, it is not surprising that, in patients requiring short-term mechanical ventilation, measurements of maximum inspiratory airway pressure commonly do not differentiate between weaning successes and weaning failure patients.

- Pre-existing conditions that can cause respiratory muscle weakness include disorders such as neuromuscular diseases, malnutrition, endocrine disorders, and hyperinflation. The existence of pre-existing conditions should be clinically recognized before instituting mechanical ventilation, when ventilator support is being delivered, or when the patient fails a weaning trial.
- New-onset respiratory muscle weakness in critically ill patients may result from conditions that are unique to these patients and that include ventilator-associated respiratory muscle dysfunction (a reduction of diaphragmatic force generation that can cause decreases in diaphragmatic endurance), sepsis-associated myopathy, and intensive care unit (ICU) acquired paresis. New-onset respiratory muscle weakness may also result from conditions that are not unique to critically ill patients and that include acid-base disorders, electrolyte disturbances, decreased oxygen delivery, or medications.

Respiratory Muscle Fatigue

- Whether critically ill patients develop short-lasting or long-lasting contractile fatigue of the respiratory muscles has not been clear. Patients who fail a trial of weaning from mechanical ventilation are at particular risk of developing fatigue because they experience marked increases in respiratory load. The addition of a new injury to the respiratory muscles (secondary to the development of contractile fatigue) might be the ultimate determinant of whether some patients are ever successfully weaned.
- The *tension-time index* of the diaphragm—an index of the ability of the diaphragm to sustain a given inspiratory load calculated by multiplying two ratios: the respiratory duty

cycle (inspiratory time divided by the time of a total respiratory cycle) and the mean inspiratory pressure per breath divided by maximum inspiratory pressure—has been shown in research protocols to be a promising tool to predict time to failure before obvious clinical signs of fatigue.

Impaired Cardiovascular Performance

- Spontaneous respiratory efforts decrease intrathoracic pressure and thus increase the pressure gradient for systemic venous return. In addition, decreases in intrathoracic pressure increase left ventricular afterload, causing additional stress on the left ventricle. In patients with coronary artery disease, the increased stress can alter myocardial perfusion and cause transient left ventricular dilation.
- The occurrence of myocardial ischemia during periods of spontaneous respiration has been associated with a greater risk of weaning failure and greater risk of ventilator dependence. In weaning successes, oxygen transport increases, mainly resulting from an increase in cardiac index; in weaning failures, the increase in demand is met by an increase in oxygen extraction, resulting in a decrease in mixed venous oxygen saturation (Fig. 95.3). A decrease in mixed venous oxygen saturation is consistent with a failing cardiovascular response to an increased metabolic demand.

Psychological Factors

- Possible mechanisms for psychological dysfunction in mechanically ventilated patients include respiratory discomfort, severity of illness, sleep deprivation, sensory deprivation (Fig. 95.4), and medication side effects. The delivery of mechanical ventilation itself can cause psychological dysfunction. Mechanical ventilation limits mobility, fosters isolation, impairs communication, and interferes with or blocks patient control of the act of breathing. Anxiety and depression can decrease motivation, interfere with performing simple tasks, and can decrease self-esteem.
- Aggressive treatment of depression may increase the likelihood of weaning. Biofeedback, improving the patients' environment, communication, and mobility, and specialized weaning centers have been used to decrease psychological problems in ventilated patients.

PREDICTION OF WEANING OUTCOME

Respiratory Frequency to Tidal Volume Ratio

- The ratio of respiratory frequency to tidal volume (f/V_T)[†] is measured during 1 minute of spontaneous breathing (Fig. 95.5). Measurements of f/V_T in the presence of pressure support or continuous positive airway pressure will result in

[†]For example, for a spontaneous respiratory rate of 25 breaths/minute and a spontaneous tidal volume of 600 mL (0.6 L), the $f/V_T = 25/0.6 = 41.7 = 42$.

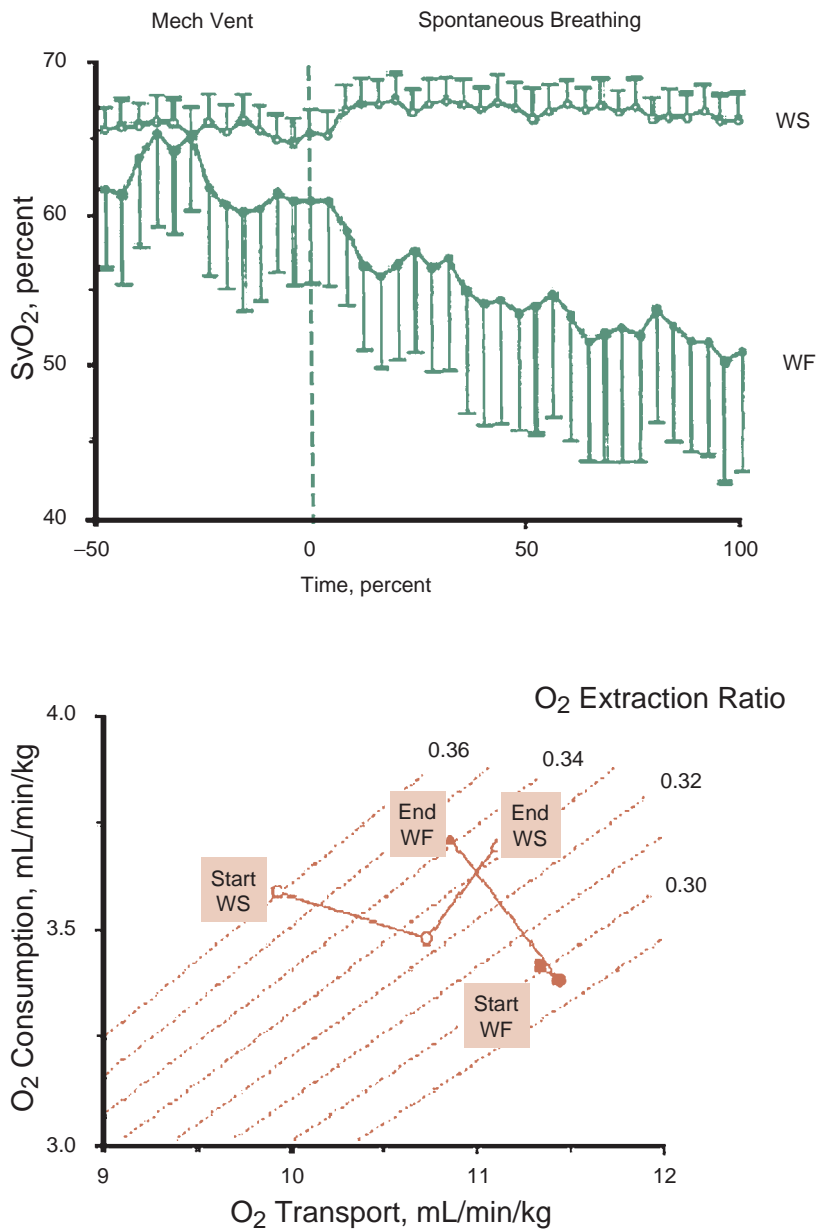

FIGURE 95.3. Top: Mixed venous oxygen saturation (SvO₂) during mechanical ventilation and a trial of spontaneous breathing in 11 weaning success (WS) patients (*open symbols*) and in 8 weaning failure (WF) patients (*closed symbols*). During mechanical ventilation, SvO₂ was similar in the two groups ($p = 0.28$). Between the onset (*dashed line*) and the end of the trial, SvO₂ decreased in the failure group ($p < 0.01$) whereas it remained unchanged in the success group ($p = 0.48$). Over the course of the trial, SvO₂ was lower in the failure group than in the success group ($p < 0.02$). Bars, standard error (SE). Bottom: Oxygen transport, oxygen consumption, and isopleths of oxygen extraction ratio in the success (WS, *open symbols*) and failure (WF, *closed symbols*) groups during mechanical ventilation (*squares*) and at the onset (*circles*) and end (*triangles*) of a spontaneous breathing trial. See text for details. (Modified from Jubran A, Mathru M, Dries D, et al. Continuous recordings of mixed venous oxygen saturation during weaning from mechanical ventilation and the ramifications thereof. *Am J Respir Crit Care Med.* 1998;158:1763.)

FIGURE 95.4. The environment in which ventilated patients are being cared for can promote sensory deprivation through the lack of windows with a view (*left*), bare walls (*middle*), and tedious ceiling (*right*). FIGURE 95.5. A time-series, breath-by-breath plot of respiratory frequency and tidal volume in a patient who failed a weaning trial. The arrow indicates the point of resuming spontaneous breathing. Rapid, shallow breathing developed almost immediately after discontinuation of the ventilator. (From Tobin MJ, Perez W, Guenther SM, et al. The pattern of breathing during successful and unsuccessful trials of weaning from mechanical ventilation. *Am Rev Respir Dis.* 1986;132:1111, with permission.)

inaccurate predictions of weaning outcome. The higher the f/V_T ratio, the more severe the rapid, shallow breathing and the greater the likelihood of unsuccessful weaning. An f/V_T ratio of 100 best discriminates between successful and unsuccessful attempts at weaning.

- The average sensitivity in all of the studies on f/V_T was 0.89, and 85% of the studies reveal sensitivities above 0.90.

Pulmonary Gas Exchange

- Mechanical ventilation is virtually never discontinued in a patient who has severe hypoxemia, such as arterial oxygen tension (P_{aO_2}) <55 mm Hg with inspired oxygen fraction (FiO_2) >0.40 . Arterial-to-inspired oxygen ratio (P_{aO_2}/FiO_2), alveolar-arterial oxygen tension gradient, and arterial/alveolar oxygen tension ratio (P_{aO_2}/P_{AO_2}) are indices derived from arterial blood gas measurements proposed as predictors of weaning outcome. Though threshold values of the efficiency of indices derived from arterial blood gas measurements cannot be recommended for weaning prediction, weaning attempts are not recommended in patients with borderline hypoxemia.

Minute Ventilation

- A minute ventilation of <10 L/minute was a classic index used to predict a successful weaning outcome. When prospectively assessed, however, minute ventilation has a high rate of false-negative and false-positive results and cannot be recommended as a predictor of weaning outcome.

Maximum Inspiratory Pressure

- A maximum inspiratory pressure value more negative than -30 cm H_2O was found to be associated with successfully weaning, whereas all patients with a maximum inspiratory pressure less negative than -20 cm H_2O failed a weaning trial. However, these threshold values have shown poor sensitivity and specificity.

Vital Capacity

- The normal vital capacity is usually between 65 and 75 mL/kg, and a value ≥ 10 mL/kg has been suggested to predict a successful weaning. Patients with a vital capacity <7 mL/kg are unable to tolerate as few as 15 minutes of spontaneous breathing. Vital capacity is rarely used as a weaning predictor, and it is often unreliable.

Airway Occlusion Pressure

- A $P_{0.1}$ values above 3.4 to 6.0 cm H_2O can help discriminating between weaning success and weaning failures. However, other investigators have found $P_{0.1}$ to be quite inaccurate. One mechanism that could contribute to the poor performance of $P_{0.1}$ is the limited reproducibility of the measurement. The within-individual coefficient of variation of $P_{0.1}$ is about 50%, and the interindividual coefficient of variation is as high as 60%.

WEANING TRIALS

Intermittent Mandatory Ventilation

- With intermittent mandatory ventilation (IMV) weaning, the ventilator's mandatory rate is reduced in steps of 1 to 3 breaths/minute, and an arterial blood gas is obtained about 30 minutes after each rate change. Unfortunately, titrating the ventilator's mandatory rate according with the results of arterial blood gases can produce a false sense of security. In difficult-to-wean patients, as the IMV rate is decreased, inspiratory work increases progressively not only for the spontaneous breaths but also for the assisted breaths, largely due to the inability of the respiratory center to adapt its output rapidly to intermittent support.

Pressure Support

- What exactly constitutes a "minimal level of pressure support" has never been defined. For example, pressure support of 6 to 8 cm H_2O is widely used to compensate for the resistance imposed by the endotracheal tube and ventilator circuit. It is reasoned that a patient who can breathe comfortably at this level of pressure support will be able to tolerate extubation.

FIGURE 95.6. Kaplan–Meier analysis of weaning time until successful extubation or death in patients undergoing usual weaning ($n = 70$) and in patients undergoing computer-driven weaning (CDW)—that is, computer-driven closed-loop knowledge-based algorithm ($n = 74$). The probability of remaining on mechanical ventilation was less with computer-driven weaning than with usual weaning (log-rank test, $p = 0.015$). (From Lellouche F, Mancebo J, Joliet P, et al. A multicenter randomized trial of computer-driven protocolized weaning from mechanical ventilation. *Am J Respir Crit Care Med*. 2006;174:894, with permission.)

Computer-driven Weaning Protocol

- A recent computer-driven pressure-supported ventilation weaning has reduced the median duration of weaning, mechanical ventilation, and ICU stay (Fig. 95.6). However, there was no difference from physician-driven weaning in terms of reintubation rate, hospital length of stay, ICU mortality, and hospital mortality.

T-Tube Trials

- Today, it is usual to limit a T-tube trial to once a day. If the trial is successful, the patient is extubated. If the trial is unsuccessful, the patient is given at least 24 hours of respiratory muscle rest with full ventilator support before another trial is performed.
- Tube trials ranging from 30 to 120 minutes have been studied. Whether the patient completes 30 minutes or 120 minutes,

there is no difference in percentage of patients who successfully are liberated from mechanical ventilation. However, it is unclear if this holds true in more chronic, difficult to wean patients.

- Patients are judged to have failed a T-tube trial when they develop severe tachypnea, increased accessory muscle activity, diaphoresis, facial signs of respiratory distress, oxygen desaturation, tachycardia, arrhythmias, hypertension, or hypotension.

Noninvasive Ventilation in Weaning

- Noninvasive positive pressure ventilation has been used to facilitate extubation in intubated patients with chronic obstructive pulmonary disease and acute hypercapnic respiratory failure.
- Insufficient data are available on the role of noninvasive ventilation in weaning from hypoxemic respiratory failure. See Chapters 91 and 96 for more detailed information.

CHAPTER 96 ■ ACUTE LUNG INJURY AND ACUTE RESPIRATORY DISTRESS SYNDROME

OVERVIEW

- The acute respiratory distress syndrome (ARDS) is characterized by nonhydrostatic pulmonary edema and hypoxemia associated with a variety of etiologies that cause both direct and indirect insults to the lungs. The process develops acutely (usually within 72 hours of the precipitating event), requires immediate recognition, and often leads to death despite maximal medical support. ARDS is a devastating injury to the lungs, characterized by diffuse pulmonary inflammation, hypoxemia, and respiratory distress. In 1994, the American–European Consensus Committee on ARDS changed the word “adult” back to “acute” because development of ARDS was not restricted to adults. The consensus meeting further defined diagnostic criteria to include (a) acute onset; (b) bilateral radiographic infiltrates; (c) pulmonary artery occlusion pressure (PAOP) ≤ 18 mm Hg, or no evidence of left atrial hypertension; and (d) $\text{PaO}_2/\text{FiO}_2$ ratio of ≤ 300 mm Hg for acute lung injury (ALI) and ≤ 200 mm Hg for ARDS.
- This definition is far from perfect. Respiratory distress, characterized by tachypnea, dyspnea, and acute respiratory alkalosis not relieved by correcting hypoxemia, is common to many pulmonary processes. Bilateral radiographic infiltrates may be seen with cardiogenic edema, pneumonitis, and several other entities. The $\text{PaO}_2/\text{FiO}_2$ ratio may be influenced by therapy, especially positive end-expiratory pressure (PEEP) and the FiO_2 itself. It seems specious to separate “acute lung injury” from ARDS when the two terms reflect only somewhat different severity of the same processes. Heart failure may be present at a PAOP < 18 mm Hg and may coexist with ARDS, but heart failure may not be present with a PAOP of ≥ 18 mm Hg. Nonetheless, although presently undergoing revision, this definition has stood the test of time and forms the basis for all investigation done on ARDS in the past decade.
- The Lung Injury Score (LIS) based on chest radiographic findings, degree of hypoxemia (using $\text{PaO}_2/\text{FiO}_2$ values), compliance of the pulmonary system (if ventilated), and PEEP levels attempts to better define the range of lung injury (Table 96.1). A patient was considered to have ARDS if the score was > 2.5 . The LIS value and the LIS did not add accuracy to the definitions of the consensus statement.
- Multiple risk factors for ALI/ARDS have been identified, with sepsis syndrome having the highest prevalence (30% to 50%). The pathogenesis for pulmonary and extrapulmonary causes for ALI may be different; the Consensus Committee categorized ARDS into direct versus indirect causes (Tables 96.2A and 96.2B). Secondary predisposing factors described in the

literature are alcohol abuse, chronic lung disease, and a low systemic pH.

- Although ARDS is usually considered a homogeneous entity, it should be considered the final common pathway of a very heterogeneous group of insults. Although the pulmonary injury is widespread, it does not uniformly affect lung tissue; this nonuniformity has important therapeutic consequences. There are also two broad etiologies of ARDS: In *pulmonary* ARDS (generally corresponding to “direct” disease), there is primary lung injury (e.g., pneumonia) that involves the alveolar epithelium and may be confined to single organ failure. In *extrapulmonary* ARDS (generally corresponding to “indirect” disease), the inflammatory effect of a remote

insult—usually sepsis—reaches the capillary endothelium via a systemic inflammatory response syndrome phenomenon, and lung failure becomes one more component of multiorgan dysfunction syndrome (MODS). Although there are important differences in pathophysiology, the outcome between ARDS of pulmonary and extrapulmonary origin does not appear to differ greatly. Although the vast majority of studies reviewed here consider ARDS to be a single entity, questions remain as to whether this is true.

- A recent study reported the incidence of ALI to be 78.8 cases per 100,000 and for ARDS to be 58.7 cases per 100,000.

OUTCOME

- The cause of death in ARDS patients is more often associated with MODS than deficient oxygenation. The overall mortality rate has declined from 68% in the 1980s to 36% in 1993, and presently ranges widely from 30% to 58%, depending on the specific patient group—based on age and etiology of lung injury—being studied. ARDS patients who leave the hospital seem to have no increased risk of subsequent death when matched for comorbidities.
- Patients with ARDS who die within the first several days do so because of the underlying condition and respiratory failure. Many of those who survive the original insult succumb to sepsis or MODS. Of those who survive ARDS, most return to their premorbid state of respiratory function by about 6 months after extubation.

PATHOPHYSIOLOGY

- The inciting process in ALI is the pathologic loss of integrity of the alveolar–capillary membrane complex associated with

exuberant inflammation, with increased endothelial and epithelial permeability and leakage of proteinaceous edema and cellular components into the interstitial and alveolar spaces. This occurs in response to some provocative stimulus, which may arise from various disease processes or physical or chemical insults, including primary pulmonary or extrapulmonary events (Fig. 96.1) (see Tables 96.2A and 96.2B). Histopathology changes of the lung are described in Table 96.3. Accumulation of proinflammatory mediators such as tumor necrosis factor- α (TNF- α), interleukin-1 β (IL-1 β), and IL-8 in the alveolar fluid of ARDS patients portends the amplified production of cytokine and toxic reactive oxygen and nitrogen radical species (Table 96.4). Activated complement components accumulate with fibrin and immunoglobulins to form alveolar hyaline membranes, further worsening compliance. Fibroproliferation and accelerated collagen deposition may begin early in the inflammatory sequence and continue into the proliferative phase (7 to 21 days), with thickening of the alveolar walls already denuded of type 1 pneumocytes.

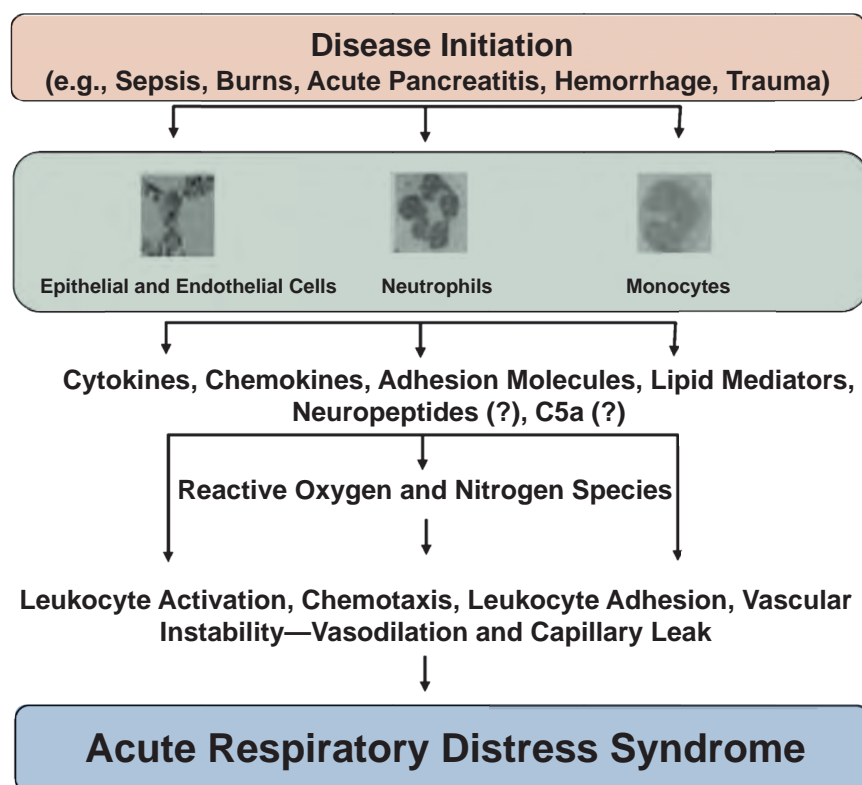

FIGURE 96.1. Pictorial detail of the pathogenesis of acute respiratory distress syndrome. (With permission from Bhatia M, Moochhala S. Role of inflammatory mediators in the pathophysiology of acute respiratory distress syndrome. *J Pathol.* 2004;202[2]:145–156.)

Although the original inciting event may resolve, judicious correction of persistent metabolic and infectious issues, and meticulous attention to appropriate ventilatory techniques, must continue in order to minimize iatrogenic contributions to self-sustaining inflammation (see Ventilator Associated Lung Injury below). Evolution into the *fibrotic phase* generally occurs after 3 to 4 weeks. Variable degrees of fibrosis and parenchymal tissue loss yield “diffuse alveolar damage,” the histologic correlate of advanced ARDS, characterized by widespread and severe damage to the alveolar-capillary unit. Micro- and macrocystic areas abut dilated ectatic bronchi, with fibrotic noncompliant septa and collapsed alveoli—no longer tethered open by healthy surrounding tissue—and interwoven with thrombosed capillaries

that provide no capacity for gas exchange (i.e., dead space ventilation). Hypoxemia from tenaciously collapsed, fibrotic, shunt-producing alveoli accompanies the hypercarbia and respiratory acidosis of large dead space fractions from non-gas exchanging overdistended alveoli, dilated cystic areas, and thrombosed non-CO₂-excreting pulmonary capillaries.

Clinical Presentation Physical Examination

- The clinical findings in ARDS may be roughly grouped into four phases (Table 96.5).

TABLE 96.3

HISTOPATHOLOGIC CHANGES IN ARDS

	Exudative phase	Proliferative phase	Fibrotic phase
Macroscopic	• Heavy, rigid, dark	• Heavy, gray	• Cobblestoned
Microscopic	• Hyaline membranes	• Barrier disruption	• Fibrosis

Vasculature	• Local thrombus	• Loss of capillaries	• Myointimal thickening
		• Pulmonary hypertension	• Tortuous vessels

TABLE 96.4**INFLAMMATORY MEDIATORS IN ARDS**

Inflammatory mediator	Function
TNF- α	Proinflammatory; neutrophil activation in ARDS
IL-1 β	Proinflammatory; neutrophil activation in ARDS
IL-6	Leukocyte growth/activation; proliferation of myeloid progenitor cells; acute-phase response; pyrexia
IL-10	Anti-inflammatory; inhibits release of proinflammatory cytokines
TGF- β	Resolution of tissue injury; proinflammatory
GM-CSF	Host defense; hematologic growth factor
PAF	Platelet activation; neutrophil activation and chemotaxis
ICAM-I	Neutrophil adhesion
C5a	Leukocyte chemoattractant; dual pro- and anti-inflammatory role
Substance P	Proinflammatory
Chemokines	Leukocyte activation and chemotaxis
VEGF	Endothelial cytokine; plays a role in angiogenesis and vascular permeability
IGF-I	Alveolar macrophage-derived growth factor; profibrotic
KGF	Epithelial-specific growth factor; important for lung development repair
Reactive oxygen and nitrogen species	Regulation of vascular tone, antimicrobial action

- The changes seen on the chest radiograph in ARDS are characteristic but nonspecific, rarely revealing the etiology of the syndrome. Acutely, pulmonary edema is seen. Interstitial infiltrates progress to a diffuse, fluffy, panacinar pattern.
- Whereas a two-dimensional chest radiograph may suggest diffuse homogeneous infiltrates, the chest computed tomog-

raphy (CT) scan usually demonstrates remarkably inhomogeneous lung involvement. Dependent regions of the lung appear to be much more involved than nondependent regions.

TABLE 96.5**PROGRESSION OF CLINICAL FINDINGS IN ARDS****PHASE 1: ACUTE INJURY**

- Normal physical examination and chest radiograph
- Tachycardia, tachypnea, and respiratory alkalosis develop

PHASE 2: LATENT PERIOD

- Lasts approximately 6–48 h after injury
- Patient appears clinically stable
- Hyperventilation and hypocapnia persist
- Mild increase in work of breathing
- Widening of the alveolar-arterial oxygen gradient
- Minor abnormalities on physical examination and chest radiograph

PHASE 3: ACUTE RESPIRATORY FAILURE

- Marked tachypnea and dyspnea
- Decreased lung compliance
- Diffuse infiltrates on chest radiograph
- High-pitched crackles heard throughout all lung fields

PHASE 4: SEVERE ABNORMALITIES

- Severe hypoxemia unresponsive to therapy
- Increased intrapulmonary shunting
- Metabolic and respiratory acidosis

ARDS, acute respiratory distress syndrome.
From Taylor RW. The adult respiratory distress syndrome. In: Kirby RR, Taylor RW, eds. *Respiratory Failure*. Chicago: Year Book Medical Publishers; 1986:208.

TREATMENT**Fluid Management**

- Adequate intravascular volume must be maintained to avoid tissue hypoperfusion, although we recommend that the minimal amount of fluid be given and that judicious attempts at diuresis be undertaken in the hemodynamically stable patient. However, a large study conducted by the National Heart, Lung, and Blood Institute (NHLBI) Acute Respiratory Distress Syndrome Clinical Trials Network found no difference in 60-day mortality when comparing liberal and conservative fluid management strategies.

Bronchodilators

- Aerosolized β -agonists can decrease airway resistance, even in patients without underlying chronic obstructive pulmonary disease or asthma. By reducing airway resistance, the work of breathing can be decreased.

Steroids

- Routine use of corticosteroids is not advocated, especially in the acute phase of ARDS. During the late phase, fibroproliferation often occurs in response to tissue injury and is associated with persistent inflammation. In this setting, fever and systemic inflammatory response syndrome are present in

the absence of infection. A small uncontrolled trial suggested that improvement in “late” ARDS patients—those mechanically ventilated for approximately 15 days—with progressive fibroproliferation may be seen when corticosteroid treatment begins during that period

Respiratory Support

- The indications for respiratory support are well defined and include hemodynamic instability, protection and maintenance of the airway, inability to maintain $\text{PaO}_2 > 55$ mm Hg on a $\text{FiO}_2 = 60\%$, need for positive airway pressure, and progressive ventilatory insufficiency with rising respiratory rate and hypercarbia. Lung CT studies have demonstrated the distribution of areas of alveolar collapse and distention characteristic of ARDS to be regional rather than diffuse. The presence of several or all of these features in most individuals with ALI mandates endotracheal intubation and mechanical ventilation to optimize gas exchange and minimize work of breathing. Noninvasive positive pressure ventilation has been employed in some instances for those with less severe pulmonary impairment and preserved mental status, although studies are few with fairly high rates of eventual endotracheal intubation.
- In 1990, a trial of mechanical ventilation, with limited tidal volume and plateau pressures compared to the higher values in common use at the time resulted in a reduction in mortality from 40% to 31% with the experimental protocol parameters. Although the trial has been criticized from a number of standpoints, none is sufficiently compelling to negate the persuasiveness of its results. In our practice, low tidal volume ventilation ($V_t = 6$ to 8 mL/kg ideal body weight) is considered standard, maintaining a plateau pressure < 30 cm H_2O . Tidal volumes exceeding these parameters have been implicated in generating lung injury caused by mechanical ventilation itself. This phenomenon, termed *ventilator-associated lung injury* (VALI), is a by-product of the interaction of mechanical ventilation and the cytokine proliferation that is a fundamental pathophysiologic feature of ARDS. As described below, components of VALI include (a) *barotrauma*, the appearance of air outside the airways and alveoli, attributed to airway pressures that exceed certain thresholds; (b) *volutrauma*, increased alveolar and capil-

lary permeability due to alveolar overdistention and leading to pulmonary edema; and (c) *atelectrauma*, the destructive repetitive opening and closing of stiff, collapsed, surfactant-depleted, fibrotic alveoli with thickened interstitium that are associated with cyclic positive pressure ventilation. Excessive alveolar stretch is associated with inflammatory cytokine proliferation, in particular during excursions into ranges of tidal volume that induce VALI. Of note, this cytokine proliferation can be limited by using a lung-protective ventilation strategy (using a pressure–volume curve to determine tidal volume and PEEP).

- The importance of limitation of tidal volume as a guide to appropriate mechanical ventilation in the acutely injured lung may be more easily understood when viewed within a conceptual framework of patchy, unevenly distributed alveolar injury. When such an injured lung receives a positive pressure breath, the gas distribution is impacted by the variability of compliance and resistance in the injured and healthy areas. Flow preferentially enters unaffected (i.e., low resistance, relatively high compliance) pulmonary tissue, risking unintentional overdistention and injury of these normal areas despite inflation with an “appropriate” tidal volume based on body weight. This is often termed *the baby lung phenomenon*, as the volume of unaffected lung parenchyma within the ARDS patient’s thorax more closely approximates that of a child than an adult. Delivered tidal volumes, therefore, must more closely approximate those appropriate for a smaller lung, usually on the order of 6 to 8 mL/kg; exceeding these volumes risks iatrogenic perpetuation of lung injury because a positive pressure breath inflates a smaller volume of lung tissue than would be predicted by ideal body weight.
- The importance of PEEP and recruitment maneuvers in providing efficient ventilator management of ARDS patients warrants further discussion. Although the traditional approach of oxygen supplementation may improve the PaO_2 within the limits of a marginal functional reserve capacity (FRC), such supplementation should be looked upon only as a temporizing measure. Prolonged high FiO_2 use risks toxicity and absorption atelectasis, leaving the underlying cause of hypoxemia neither identified nor corrected. Recovery of FRC by reinflation of atelectatic areas using recruitment maneuvers and PEEP will restore gas flow to previously nonaerated areas of lung. These modalities of treatment are commonly utilized in the modern strategy of ARDS treatment.

FIGURE 96.2. Atelectrauma and the interdependence of lung units. (With permission from Moloney ED, Griffiths MJ. Protective ventilation of patients with acute respiratory distress syndrome. *Br J Anaesth.* 2004;92[2]:261–270.)

- Areas of particularly tenacious atelectasis will often require an inspiratory time (T_i) equal to several inspiratory time-constants (one “time-constant” equals product of compliance and resistance, both easily measurable by current ventilators) to achieve inflation. Insufficient T_i may leave such areas persistently collapsed, worsening shunt fraction and compromising FRC and oxygenation. Despite the most heroic efforts, a substantial percentage of ARDS patients harbor lung tissue that is only variably “PEEP recruitable.” The benefit of recruitment maneuvers and PEEP can be understood within the context of the *Law of LaPlace* (actually the Young-LaPlace equation), which states that the pressure difference across a fluid interface is equal to the surface tension times the mean curvature of the surface.
- In pulmonary physiology and ARDS, this means that the pressure difference between alveolar gas and alveolar epithelium contracts the alveolus inward unless counteracted by surfactant.
- Furthermore, the relationship between surface tension and alveolar radius is inverse. Thus, the smaller the alveolar radius, the greater the force contracting it even further inward (i.e., toward collapse). Because surfactant decreases surface tension, the inward force within a collapsed alveolus is greater than that within its surfactant-replete, healthy, “non-collapsed” neighbor with lower surface tension, resulting in a temporary high-pressure requirement to open a collapsed alveolus. The alveolus may then be maintained open, with PEEP exceeding the alveolar closing pressure. Because low tidal volume (6 mL/kg) followed by PEEP in itself is generally ineffective in expanding collapsed alveoli, a “recruitment maneuver,” the temporary application of airway pressure far above any possible alveolar retractive force, may be warranted to open and stabilize collapsed alveoli, preventing exposure to repetitive cyclic collapse and associated destructive shear forces by maintaining an “open lung” (Fig. 96.2).
- Most clinicians feel that utilizing a level of PEEP above the lower inflection point on a pressure–volume curve (see below)

FIGURE 96.3. Pressure–volume curve of an idealized lung, showing both the inspiratory and expiratory limbs as well as the upper and lower inflection points.

improves FRC and oxygenation by inflating recruitable alveoli, and thus decreasing venous admixture.

- The selection of tidal volume is intimately linked to the pressure–volume curve. Optimal gas exchange with minimal alveolar injury is achieved when the lung is positioned on the vertical portion of the pressure–volume curve (Fig. 96.3).
- A not uncommon observation when monitoring gas exchange in ARDS is hypercarbia with mild acidemia, often more uncomfortable for the clinician to observe than the patient to experience. However, “permissive hypercapnia” is safe and acceptable when not contraindicated by underlying medical condition (e.g., elevated intracranial pressure), though it often warrants protocol-delivered sedation.

FIGURE 96.4. Intravenous versus inhaled vasodilator effects on pulmonary circulation. **A:** Shows two idealized alveoli, one occluded (left) and the other normal; both have hypoxic pulmonary vasoconstriction (HPV)-induced decreased pulmonary blood flow. **B:** Shows the result of using an intravenous vasodilator: HPV is removed to both the occluded and nonoccluded alveoli, resulting in significant shunt. **C:** Shows the result of utilization of inhaled nitric oxide (NO): HPV is reversed in the area of the ventilated alveolus, but not the obstructed one. NTP, nitroprusside. (With permission from Lunn RJ. Inhaled nitric oxide therapy. *Mayo Clin Proc.* 1995;70[3]:247–255.)

- The mode of mechanical ventilation used in ALI/ARDS has not been standardized. It is likely that the use of mechanical ventilation is more dependent on the comfort level of the practitioner than on “best evidence.”

Prone Positioning

- Several large studies have documented improvements in oxygenation without significant improvement in mortality. Considerable skill and experience are needed to pronate and support a critical patient bearing invasive monitoring and therapeutic devices. The risks to potential pressure-bearing ventral body structures—face, eyes, chest, and knees—and of accidental device removal must be weighed against the benefits.

Inhaled Vasodilators

- Aerosolized vasoactive medications, such as nitric oxide or prostaglandin-I, diffuse from ventilated alveoli and result in

relaxation of endothelial smooth muscle within remotely constricted vascular beds, thus improving ventilation/perfusion matching while vessels adjacent to collapsed alveoli remain unaffected. Selective vasodilation in ventilated areas decreases shunt fraction and contributes to alleviation of pulmonary hypertension (Fig. 96.4).

COMPLICATIONS

- Significant morbidity or mortality may occur during supportive therapy for ALI/ARDS, as summarized in Table 96.6.
- The additional inflammatory insult induced by suboptimal mechanical ventilation technique is termed *ventilator-associated lung injury*.
- *Barotrauma* refers to the presence of air outside the alveoli when receiving positive pressure ventilation. Air leaks track along the perivascular sheath to the mediastinum and pleural cavities, or along fascial planes to extrathoracic areas. It seems intuitive that such occurrences are related to pressures exceeding the limits of tissue structural integrity, but the issue is clearly more complicated, as musicians are repeatedly able

TABLE 96.6

COMPLICATIONS ASSOCIATED WITH ARDS

PULMONARY	COMPLICATIONS ATTRIBUTABLE TO INTUBATION AND EXTUBATION

to generate 150 cm H₂O airway pressure with no sequelae. It is speculated that barotrauma represents regional overinflation in areas of diseased lung, such areas thereby being particularly at risk for structural failure and air leak. *Volutrauma* occurs when excessive inspiratory volumes induce microvascular edema; the offending agent appears to be excessive *volume*, rather than the excessive *pressure* required to supply that volume.

- Compromised surfactant production and function leads to increased surface tension, provoking alveolar collapse with

increased venous admixture and subjecting alveolar epithelium to the tissue-destructive shear stresses of recruitment/derecruitment in the process known as *atelectrauma*.

- Finally, over the last few years, there has been recognition of the inflammatory cytokine release, as well as alveolar and interstitial neutrophil infiltration associated with ventilator-related pulmonary disruption, leading to MODS. While it is indisputable that “excessive” tidal volume ventilation augments systemic cytokine levels, the specific causal relationship with worse outcome has yet to be validated.

CHAPTER 97 ■ DROWNING

THE DROWNING PROCESS

- Drowning is the process resulting from primary respiratory impairment from submersion or immersion in a liquid medium.
- The drowning process is a continuum that begins when the victim's airway is initially below the surface of the water; he or she first will voluntarily hold his or her breath. Some victims will swallow significant quantities of water during this time. This period of voluntary breath holding, lasting a few seconds is followed by an involuntary period of laryngospasm secondary to water in the oropharynx or at the level of the larynx acting as a foreign body. During this period of breath holding and laryngospasm, the patient cannot breathe; therefore, oxygen is depleted and carbon dioxide is not eliminated. This results in the patient becoming hypercarbic, hypoxic, and acidotic.
- As the patient's arterial oxygen tension drops further, laryngospasm abates, and the patient then actively breathes water. Further evidence of the magnitude of negative pressure created during laryngospasm is the fact that the lungs of drowning victims frequently demonstrate significant hyperinflation at autopsy.
- The amount of liquid a drowning victim breathes varies considerably between victims. Studies comparing the biochemical changes occurring in humans after a drowning episode with those in experimental animals suggest that, while the volume of liquid actually inhaled varies considerably from one victim to another, only 15% of persons who die in the water aspirate in excess of 22 mL/kg of water, and the percentage is considerably less in those who survive. Changes occur in the lung, body fluids, and electrolyte concentrations, which are dependent on both the composition and volume of the liquid aspirated.

RESUSCITATION

- Irreversible damage to brain tissue is reported to begin approximately 3 minutes after the PaO₂ falls below 30 mm

Hg under normothermic conditions in otherwise normal people. Such data suggest that if the victim is rescued and effective resuscitation efforts are applied within 3 minutes of the cessation of respiration (i.e., submersion in water), the vast majority of such victims should be able to be resuscitated and suffer no permanent brain damage. After the 3-minute time frame has been exceeded, although some normal survivors are reported, it becomes less likely that normal survival will result from resuscitation efforts. This time frame may be prolonged if hypothermia occurs rapidly because it decreases the cerebral requirement for oxygen.

- Persons who become hypothermic due to immersion or submersion in extremely cold water will rapidly develop hypothermia, which protects the brain by decreasing its oxygen requirement and prolongs survival. It should be noted, however, that hypothermia is a two-edged sword; although it can protect the brain from oxygen deprivation, it also can cause death in the water secondary to its effect on the conduction system of the heart, resulting in circulatory arrest either by asystole or ventricular fibrillation.

PATHOPHYSIOLOGY

- It has consistently been shown that, acutely, drowning produces asphyxia (i.e., hypoxia, hypercarbia, and acidosis). The hypercarbia is due to absent or ineffective ventilation and is readily correctable when aggressive mechanical ventilation is instituted. The hypoxia that occurs initially is not as readily correctable and may be persistent for long periods of time. This hypoxia is first due to apnea and then primarily to intrapulmonary shunting from alveoli that are perfused but not being ventilated, or not being ventilated adequately. The acidosis is mixed, and the respiratory component rapidly disappears with effective ventilation. The patient is, however, frequently left with significant metabolic acidosis caused by anaerobic metabolism during the period of time that profound tissue hypoxia secondary to absent or ineffective respiration and cardiac output was present. The hallmark of

this high anion gap metabolic acidosis is an increased level of serum lactic acid.

Pulmonary

- In freshwater drowning, the aspirated water alters the surface tension properties of pulmonary surfactant. Thus, the alveoli become unstable and do not maintain their normal shape or patency, resulting in an increase in both absolute and relative intrapulmonary shunt. On the contrary, seawater does not change the surface tension properties of pulmonary surfactant, but, because it is hypertonic, it pulls fluid from the circulation into the alveoli, thus producing obstruction to gas exchange at the alveolar level. Bronchoconstriction also has been reported after aspiration of even small quantities of water.
- Freshwater, being hypotonic, is absorbed very rapidly into the circulation and, because of the transient hypervolemia that occurs and the change in the surface tension properties of pulmonary surfactant, pulmonary edema results. Pulmonary edema also occurs when seawater is aspirated, secondary to a semipermeable membrane effect because the seawater is hypertonic compared to plasma. Even though the etiology of the hypoxia is different between freshwater and seawater aspiration, the result of both is to increase intrapulmonary shunt.
- The treatment of the respiratory lesion requires providing mechanical ventilatory support in a fashion that will restore an adequate functional residual capacity and keep the alveoli open during all phases of the respiratory cycle, thus decreasing the intrapulmonary shunt. Obviously, if foreign material such as sand, silt, or plant life is aspirated into the lung, it may produce obstruction, and it should be removed via bronchoscopy.

Cardiovascular

- The cardiovascular changes that occur during a drowning episode can best be ascribed to inadequate oxygenation. Although fatal arrhythmia such as ventricular fibrillation is rarely documented in human drowning victims, ventricular fibrillation can occur with profound hypoxia, especially if very significant changes in serum potassium and serum sodium result from the movement of fluid and rupture of red blood cells.

Renal

- Detrimental changes in renal function are rarely seen in persons recovering from near-drowning. However, when present, they likely are the result of inadequate perfusion and oxygenation rather than anything specifically related to the drowning episode per se.

INITIAL RESCUE AND RESUSCITATION

- To ensure survival after a drowning episode, it is imperative that one never lose sight of the fact that time is of the essence. The longer a person is without the ability to breathe air, the more profound are the hypoxia and permanent damage to vital tissues.
- While removing the victim from the water, care should be taken to avoid complicating neck injuries when they are suspected. Routine stabilization of the neck is unnecessary unless the circumstances leading to the drowning episode suggest that trauma was likely. These circumstances include a history of diving, use of a water slide, signs of injury, or evidence of alcohol intoxication. If neck injury is suspected, gentle immobilization of the head should be accomplished, securing it in a neutral position. However, if the neck appears to be obviously deformed and the patient has pain with neck movement, the neck should be immobilized in the existing position. Drowning victims in cardiac arrest should receive standard advanced cardiac life support.
- Although the airway should rapidly be inspected for the presence of obstructing material, the abdominal thrust maneuver, which had been advocated by some in the past, has been thoroughly debated and found not to be of value in treating a drowning victim unless solid material is actually blocking the conducting airway.
- Drowning episodes in cold water may produce significant hypothermia. There are several methods of rewarming that have been recommended including, but not necessarily limited to, heating blankets, warmed intravenous fluids, warmed humidification of breathing circuits, gastric lavage, and cardiopulmonary bypass. The method used should be tailored to the resources available and the condition of the patient. It must be remembered, however, that rewarming peripheral tissues before the patient's circulation is capable of supplying adequate amounts of oxygenated blood can imbalance oxygen supply ratio and increase the degree of metabolic acidosis by accelerated production of lactic acid.

CHAPTER 98 ■ SEVERE ASTHMA EXACERBATION

DEFINITION AND CHARACTERISTICS OF SEVERE ASTHMA—DIFFERENT PHENOTYPES

- The National Asthma Educational and Prevention Program (NAEEP) and Global Initiative for Asthma (GINA) guidelines both assess disease severity on the basis of nocturnal symptoms, use of short-acting bronchodilators, frequency of exacerbations that affect daily activities, and baseline pulmonary function measurements before treatment (Table 98.1).
- The pathophysiology of asthma consists of three key abnormalities:
 - Bronchoconstriction
 - Airway inflammation
 - Mucous plugging
- Refractory asthma is not meant to describe only patients with “fatal” or “near-fatal” asthma, but it is meant to encompass the asthma subgroups previously described as “severe asthma,” “steroid-dependent and/or resistant asthma,” “difficult-to-control asthma,” “poorly controlled asthma,” “brittle asthma,” or “irreversible asthma.” Clinically, patients with refractory asthma may present with a variety of separate and/or overlapping conditions, including:
 - Widely varying peak flows (brittle asthma)
 - Severe but chronic airflow limitation
 - Rapidly progressive loss of lung function
 - Mucus production ranging from absent to copious
 - Varying responses to corticosteroids
- Whether these groups form distinct clinical, physiologic, and pathologic groups is unclear. The American Thoracic Society Workshop definition required one of two major criteria (see Table 98.1), and two of seven additional minor criteria. Numerous attempts at classifying potential phenotypes of severe asthma have been proposed, as shown in Table 98.2. Although these phenotypes may overlap, there is reasonable supporting evidence for the presence of at least six—and likely more—severe asthma phenotypes as defined by clinical parameters (natural history, clinical presentation, atopy, airflow obstruction), type of inflammation, and treatment-related parameter.
- From a clinical point of view, three categories of severely asthmatic patients seem to be of particular importance:
 - Those with frequent severe asthma exacerbations
 - Those with fixed airway obstruction
 - Those with oral steroid dependency
- Together, these three categories encompass most of the patients referred with difficult-to-control asthma.

Respiratory Mechanics

- The main pathophysiologic mechanism of acute severe asthma is pulmonary hyperinflation caused by a combination

of factors (Fig. 98.1). The driving force for expiratory flow is reduced because of an abnormally low pulmonary elastic recoil, the etiology of which is uncertain. Persistent activation of the inspiratory muscles during expiration causes outward recoil of the chest wall, further reducing the driving force for expiration. At the same time, resistance to airflow is greatly augmented because of severely reduced airway caliber and, perhaps, also narrowing of the glottic aperture during expiration. Expiration is prolonged so that the following inspiration starts before static equilibrium is reached. Consequently the end-expiratory alveolar pressure remains positive, a phenomenon known as *auto-PEEP* (positive end-expiratory pressure) or *intrinsic PEEP* (PEEP_i) or static PEEP_i (PEEP_i, st).

- It should be noticed that the lung is extremely inhomogeneous during acute severe asthma. The distribution of bronchial obstruction is uneven because of both anatomic reasons—variable amounts of secretions, edema, bronchospasm—and variable external compression exerted on the distal airways by intrathoracic positive pressure during expiration. Thus, illustratively, four parallel compartments can be recognized (Fig. 98.2):
 - Compartment A represents the portion of the lung with neither bronchial obstruction nor hyperinflation.
 - Compartment B is the part of the lung where the airways are entirely obstructed during the whole respiratory cycle (mucous plugging).
 - In compartment C, obstruction appears only during expiration, inducing alveolar hyperinflation and high PEEP_i.
 - In compartment D, partial obstruction of the airways is present throughout the respiratory cycle, causing a lesser extent of alveolar hyperinflation and PEEP_i than in compartment C.

FIGURE 98.1. Mechanisms responsible for dynamic hyperinflation in asthma.

TABLE 98.1

TERMS AND DEFINITIONS IN SEVERE ASTHMA

Severe persistent asthma (2)	Continual symptoms, frequent nocturnal symptoms, limited activity, frequent exacerbations, FEV ₁ or PEV <60% predicted, PEF variability >30%
Severe/refractory Asthma (5) Definition requires that at least one major criterion and two minor criteria are met, other disorders have been excluded, exacerbating factors have been treated, and patient is generally compliant.	<p>MAJOR:</p> <ol style="list-style-type: none"> 1. Treatment requires continuous or nearly continuous ($\geq 50\%$ of year) oral corticosteroids. 2. Treatment requires high-dose ($>880 \mu\text{g/d}$ fluticasone or equivalent) inhaled corticosteroids. <p>MINOR:</p> <ol style="list-style-type: none"> 1. Asthma symptoms needing short-acting β-agonist use on a daily or near-daily basis. 2. Need for additional daily treatment with a controller medication (e.g., long-acting β-agonist, theophylline, or leukotriene antagonist). 3. Persistent airway obstruction (FEV₁ <80% predicted, diurnal peak expiratory flow variability >20%). 4. One or more urgent care visits for asthma per year. 5. Three or more oral steroid bursts per year. 6. Prompt clinical deterioration with $\leq 25\%$ reduction in oral or intravenous corticosteroid dose. 7. Near-fatal asthma event in the past.
Severe asthma (4)	<p>Diagnosis requires at least three of the following:</p> <ol style="list-style-type: none"> 1. Seen by a consultant in asthma >2 y. 2. Has persistent symptoms and decreased quality of life 3. Has received maximal asthma therapy (high-dose inhaled corticosteroids [ICS]) with documented adherence 4. History of respiratory failure/intubation 5. Has repeated low FEV₁ <70% predicted
Status asthmaticus:	Severe airway obstruction and asthmatic symptoms persist despite the administration of standard acute asthma therapy.
Difficult-to-treat asthma:	Failure to achieve asthma control when maximally recommended doses of inhaled therapy are prescribed for at least 6–12 mo
Steroid-resistant Asthma ^a	Failure of FEV ₁ or PEF to improve >15% after 14-d course of at least 40 mg/d of prednisone
Steroid-dependent Asthma ^a	Asthma that can be controlled only with oral corticosteroids, but in contrast to corticosteroid-resistance, there is a response to this agent, although only when high doses are given.
Irreversible asthma	Persistent airflow obstruction despite maximum controller therapy; presumably related to airway and parenchymal structural alterations
Near-fatal asthma ^b	Attack associated with respiratory failure, intubation, and/or hemodynamic and metabolic compromise; usually requiring intensive care unit admission
Fixed airway obstruction	Persistent airflow obstruction despite maximal controller therapy; presumably related to airway and parenchymal structural alterations
Brittle asthma ^a	Unstable, unpredictable asthmatics with wide variability in PEF; type I—persistent PEF variability (>40%) despite controller therapy; type II—prone to sudden, dramatic falls in PEF
Asthma related to specific triggers or circumstances	<p><i>Premenstrual asthma:</i> Worsening of asthma 7 d premenstrually.</p> <p><i>Aspirin-induced asthma.</i></p>

FEV₁, forced expiratory volume in 1 s; PEV, peak expiratory velocity; PEF, peak expiratory flow; ICS, inhaled corticosteroids.

- Hyperinflation compromises the force-generating capacity of the diaphragm for a variety of reasons (Fig. 98.3).
- The imbalance between the load faced by the respiratory muscles and their capacity to develop force results in dyspnea and predisposes the respiratory muscle to the development of fatigue, which is a terminal event, likely to be present in an asthmatic crisis, necessitating intubation and mechanical ventilation.

Gas Exchange

- Widespread occlusion of the airways leads to development of extensive areas of alveolar units in which ventilation (V) is severely reduced but perfusion (Q) is maintained; that is, areas with very low \dot{V}/Q ratios, frequently lower than 0.1. Intrapulmonary shunt appears to be rare in the majority of

TABLE 98.2**PHENOTYPES OF ASTHMA**

Parameter	Description
Natural history	<ul style="list-style-type: none"> • Early-onset (childhood-onset) • Late-onset (adult-onset)

patients because of the collateral ventilation and the effectiveness of the hypoxic pulmonary vasoconstriction. Hypoxemia is, therefore, common in every asthmatic crisis of some severity; mild hypoxia is easily corrected with the administration of relatively low concentrations of supplemental oxygen. More severe hypoxemia and the need for higher concentra-

FIGURE 98.2. Effect of varying amounts of airway obstruction on end-expiratory alveolar volumes and pressures. (From Oddo M, Feihl F, Schaller MD, et al. Heliox improves pulsus paradoxus and peak expiratory flow in nonintubated patients with severe asthma. *Intensive Care Med.* 2006;32:501–510, with permission.)

tions of supplemental oxygen may relate to some contribution of shunt physiology.

- Dead space increases substantially in most severe cases due to alveolar overdistention, that is, areas with very high \dot{V}/\dot{Q} ratios. This is accompanied by increased CO_2 production from the increased work performed by the respiratory muscles. The respiratory muscles are unable to further increase minute ventilation, and thus hypercapnia ensues.

Cardiovascular System Effects

- Acute severe asthma may also compromise hemodynamics. During expiration, because of the presence of dynamic hyperinflation, increased intrathoracic pressure impedes venous return and increased right ventricular afterload. During the ensuing inspiration, forceful inspiratory muscle contraction

FIGURE 98.3. A: Actions of the diaphragm: When the diaphragm contracts, a caudally oriented force is being applied on the central tendon and the dome of the diaphragm descends (DI). Furthermore, the costal diaphragmatic fibers apply a cranially oriented force to the upper margins of the lower six ribs that has the effect of lifting and rotating them outward (insertional force, arrow 1). The zone of apposition makes the lower rib cage part of the abdomen and the changes in pressure in the pleural recess between the apposed diaphragm and the rib cage are almost equal to the changes in abdominal pressure. Pressure in this pleural recess rises rather than falls during inspiration because of diaphragmatic descent, and the rise in abdominal pressure is transmitted through the apposed diaphragm to expand the lower rib cage (arrow 2). All these effects result in expansion of the lower rib cage. On the upper rib cage, isolated contraction of the diaphragm causes a decrease in the anteroposterior diameter and this expiratory action is primarily due to the fall in pleural pressure (arrow 3). B: Deleterious effects of hyperinflation on the diaphragm.

FIGURE 98.4. Arterial pressure of an asthmatic patient when breathing air (A) and heliox (B). Pulsus paradoxus was lower when the patient was breathing heliox. E, expiration; I, inspiration. (From Manthous CA, Hall JB, Caputo MA, et al. *Am J Respir Crit Care Med.* 1995;151:310–314, with permission.)

renders intrathoracic pressure negative again, rapidly increasing venous return. Rapid filling of the right ventricle during inspiration shifts the interventricular septum toward the left ventricle, and leads to its incomplete filling during diastole, and thus to left ventricular diastolic dysfunction. The large negative intrathoracic pressure generated during inspiration increases left ventricular afterload and impairs systolic emptying.

- This combined effect leads to the appearance of pulsus paradoxus, defined as a reduction of >10 mm Hg of the arterial systolic pressure during inspiration (Fig. 98.4). A variation >12 mm Hg in systolic blood pressure between inspiration and expiration represents a sign of severity in asthmatic crisis.

TABLE 98.3

PATIENTS AT HIGH RISK OF ASTHMA-RELATED DEATH

- Patients with a history of near-fatal asthma requiring intubation and mechanical ventilation
- Patients who have had a hospitalization or emergency care visit for asthma in the past year
- Patients who are currently using or have recently stopped using oral glucocorticosteroids
- Patients who are not currently using inhaled glucocorticosteroids
- Patients who are overdependent on rapid-acting inhaled β_2 -agonists, especially those who use more than one canister of salbutamol (or equivalent) monthly
- Patients with a history of psychiatric disease or psychosocial problems, including the use of sedatives
- Patients with a history of noncompliance with an asthma medication plan

Global Initiative for Asthma. Global strategy for asthma management and prevention. Bethesda, MD: National Institutes of Health, National Heart, Lung, and Blood Institute; 2006.

TABLE 98.4

DIFFERENT PATTERNS OF FATAL ASTHMA

Variable	Scenario of asthma death	
	Type 1	Type 2
Time course	Subacute worsening (days). Slow onset–late arrival	Acute deterioration (hours). Sudden asphyxic asthma
Frequency	$\approx 80\%$ – 85%	$\approx 15\%$ – 20%
Airways	Extensive mucus plugging	More or less empty bronchi
Inflammation	Eosinophils	Neutrophils
Response to treatment	Slow	Faster
Prevention	Possible	(?)

Clinicopathologic Patterns of Life-threatening Asthmatic Attacks

- Patients at high risk of asthma-related death are described in Table 98.3.
- Two different patterns of fatal asthma are described Table 98.4.

Diagnosis

- There are four parameters that should be investigated before the diagnosis of severe asthma is made for the first time, which are the following:
 - Incorrect diagnosis. The diagnosis of severe asthma is based on a solid confirmation of asthma. In case of doubt, alternative diagnoses should be excluded (Tables 98.5 and 98.6).
 - Continuing exposure to sensitizing agents (see Tables 98.5 and 98.6).
 - Unrecognized aggravating comorbidities (see Tables 98.5 and 98.6).
 - Noncompliance with therapy.
- Clinical evaluation of exacerbations include symptoms, signs, and functional assessment (Table 98.7). In particular, analysis of arterial blood gases is important in the management of patients is useful for decisions regarding hospital admission or tracheal intubation, but it is not predictive of outcome (Table 98.8). Other relevant laboratory data are listed in Table 98.9.

THERAPEUTIC APPROACHES: MANAGEMENT OF ACUTE SEVERE ASTHMA

- The aims of treatment are to relieve airflow obstruction and hypoxemia as quickly as possible, and to plan the prevention of future relapses.
- Schematically, a management plan of acute severe asthma in adults is shown in Table 98.10. These, for acute severe asthma, include the therapies discussed in the following sections.

TABLE 98.5

ALGORITHM OF POSSIBLE STRATEGIES AND RECOMMENDATIONS FOR MANAGING PATIENTS WITH DIFFICULT-TO-CONTROL ASTHMA DESPITE MAXIMUM COMBINATION TREATMENT

Patients with uncontrolled asthma symptoms with:

1. Persisting refractory symptoms and poor lung function (reduced FEV₁) despite high dose ICS + LABA
2. Frequent use of oral steroids
3. Regular use of health care resources (doctors' consultations, emergency services, hospital admissions)

1. Review inhalation technique **YES**
2. Written self-management plan
3. Reassessment at next visit

POOR COMPLIANCE**NO****DIAGNOSTIC CONFIRMATION/VERIFICATION FOR DISEASES THAT MIMIC ASTHMA**

- Bronchiectasis
- Constrictive bronchiolitis
- COPD
- CHF
- Dysfunctional breathlessness
- Vocal cord dysfunction
- Upper airway obstruction
- ABPA
- Chung-Strauss syndrome
- Eosinophilic pneumonia
- Thyrotoxicosis

CONDITIONS ASSOCIATED WITH ASTHMA

- Chronic rhinosinusitis
- Gastroesophageal reflux
- Anxiety, panic-fear, depression
- Dysfunctional breathlessness
- Vocal cord dysfunction
- Obesity
- Obstructive sleep apnea

UNUSUAL ASTHMA TRIGGER

- Occupational exposure
- Domestic irritants
- Respiratory infections
- Drugs (aspirin, NSAIDs, ACE inhibitors, beta-blockers)
- Food (e.g., sulphite sensitivity)
- Smoking
- Inflamed upper airways
- Acid reflux
- Stress

YES**SHORT-COURSE ORAL STEROIDS****NEGATIVE RESPONSE**

1. Management of the condition
2. Reassess at next visit

1. Management of the condition
2. Reassess at next visit

1. Avoid triggers
2. Reassess at next visit

NO

1. Titrate down oral steroids (administer the lowest amount of oral steroid to control/stabilize symptoms).
2. Consider adding a steroid-sparing drug (e.g., azathioprine, methotrexate).
3. Add treatment for steroid-induced adverse effects (e.g., osteoporosis).
4. If uncontrolled, consider alternative therapeutic options (e.g., omalizumab, etanercept, high-dose IVIG).
5. Frequent periodic re-evaluations.

FEV₁, forced expiratory volume in 1 s; ICS, inhaled corticosteroids; LABA, long-acting β -agonists; COPD, chronic obstructive pulmonary disease; CHF, congestive heart failure; ABPA, allergic bronchopulmonary aspergillosis; NSAIDs, nonsteroidal anti-inflammatory drugs; ACE, angiotensin-converting enzyme.

Adapted from Holgate ST, Polosa R. The mechanisms, diagnosis, and management of severe asthma in adults. *Lancet*. 2006;368(9537):780–793.

Oxygen

- High-flow oxygen should be given to all patients with acute severe asthma, as these individuals are hypoxemic. Unlike patients with chronic obstructive pulmonary disease, there is little danger of precipitating hypercapnia with high-flow oxygen. Hypercapnia indicates the development of near-fatal asthma and the need for emergency specialist/anesthetic intervention. Oxygen therapy should be titrated against pulse oximetry (SaO₂ 92% to 94%) to maintain satisfactory oxygen saturation.

 β_2 -Agonist Bronchodilators

- Inhaled β_2 -agonists are the cornerstone of asthma treatment. Continuous or repetitive nebulization of rapid-acting β_2 -agonists is the safest and most effective means of reversing airflow obstruction and should be administered as early as possible.
- Continuous nebulization of β_2 -agonists is at least as efficacious as bolus nebulization in relieving acute asthma. In severe asthma, with peak expiratory flow (PEF) <50% of personal best or FEV₁ <50% predicted, and asthma that is poorly responsive to an initial bolus dose of β_2 -agonist, continuous nebulization should be considered. However, studies have shown no difference in the effects of continuous versus intermittent administration of nebulized albuterol. Although albuterol has been used occasionally intravenously (IV) for severe asthma attack, its use by this route does not lead to significant clinical improvements when compared with the inhalation route.
- The subcutaneous route of epinephrine (0.01 mg/kg, divided into three doses of approximately 0.3 mg given at 20-minute

TABLE 98.6**HISTORY AND PHYSICAL EXAMINATION OF PATIENTS WITH DIFFICULT-TO-CONTROL ASTHMA****Medical history****History of asthma development**

- Age of asthma onset
- Atopic syndrome and family history of asthma
- Management of disease and response to treatment
- Smoking history

Severity of disease

- Severe asthma exacerbations and hospitalization in past year
- Any admissions to asthma centers
- Any number of ICU admissions

Exogenous aggravating factors

- Exposure to allergens, occupational agents, chemicals
- Use of aspirin, NSAIDs, beta-blockers, ACE inhibitors, estrogens
- Influence of foods or food additives (nitrite, sulphate)

Endogenous aggravating factors

- Rhinosinusitis or previous surgery for nasal polyps
- Gastroesophageal reflux
- History of psychiatric disease
- Obstructive sleep apnea

Influence of menstruation**Miscellaneous****Adherence with medications****Adverse effects of treatment****Psychosocial circumstances****Physical examination (specific points of attention)**

Bel EH. Severe asthma. *Breathe*. December 2006;3(2):129–139.

intervals) or terbutaline (0.25 mg, which can be repeated every 20 minutes for three doses) might, however, be useful in several situations and should be considered:

- In children in whom inhaled agents are often difficult to administer. In addition, the pediatric population has a reduced susceptibility to β_1 toxicity, making subcutaneous administration a useful route of drug delivery.
- In seriously ill asthmatic patients with impending respiratory arrest in whom rapid delivery of β -agonists to the airway is desirable.
- In patients unable to cooperate secondary to depression of mental status, apnea, coma.

Steroids

- Systemic corticosteroids in adequate doses should be administered in all cases of acute asthma, especially if:
 - The initial rapid-acting inhaled β_2 -agonist therapy fails to achieve lasting improvement
 - The exacerbation develops even though the patient was already taking oral glucocorticosteroids

- Previous exacerbations required oral glucocorticosteroids
- Minimal or no side effects occur with a single large dose of IV steroid. Some enhancement of β -agonist effect may be seen as early as 1 hour; however, 4 to 6 hours are required for anti-inflammatory activity. One common approach is the IV administration of 60 to 125 mg of methylprednisolone every 6 hours during the initial 24 to 48 hours of treatment (Table 98.11), followed by 60 to 80 mg daily in improving patients, with gradual tapering during the next 2 weeks.

Anticholinergics

- Although ipratropium produces less bronchodilation at peak effect than a β -agonist and is associated with a less predictable clinical response, literature in general supports the use of ipratropium as adjunctive therapy in patients with acute severe asthma. The nebulizer dose is 0.5 mg.

Magnesium

- Magnesium's potential to reverse bronchoconstriction is multifactorial and is based on characteristics of inhibition of the calcium channel and decreased acetylcholine release.
- A single dose of IV magnesium sulphate (2 g) should be considered for patients with:
 - Acute severe asthma, with FEV₁ 25% to 30% predicted at presentation
 - Adults and children who fail to respond to initial treatment
 - Life-threatening or near-fatal asthma

Antibiotics

- Routine administration of antibiotics is not indicated and should be reserved for those with evidence of infection such as pneumonia or sinusitis. When an infection precipitates an exacerbation of asthma, it is likely to be viral in nature.

Helium–Oxygen Therapy

- A blended mixture of helium and oxygen (heliox) is available in mixtures of 60:40, 70:30, and 80:20. Heliox is less dense than air and can be delivered through a tight-fitting nonbreathing mask or, in the intubated patient, through the ventilatory circuit. This less dense gas mixture results in decreased airway resistance. Heliox may have potential benefit in delaying need for intubation while bronchodilators exert their effect, as well as decreasing peak airway pressures and auto PEEP in the mechanically ventilated patient.

Sedatives and Hypnotics

- Sedation should be used with caution during exacerbations of asthma because of the respiratory depressant effect of anxiolytic and hypnotic drugs. An association between the use of these drugs and avoidable asthma deaths has been demonstrated. Ketamine has sedative and analgesic properties that may be useful if intubation is planned.

TABLE 98.7**CLINICAL AND FUNCTIONAL ASSESSMENT OF SEVERE ASTHMA EXACERBATIONS^a**

Variable	Severe exacerbation	Imminent respiratory arrest
SYMPTOMS		
Dyspnea	At rest Hunched forward	
Speech	Single words, not sentences or phrases	
Alertness	Usually agitated	Drowsy or confused
SIGNS		
Respiratory rate	Often >30 breaths/min	
Heart rate	>120 beats/min	Bradycardia
Pulsus paradoxus	Often present >25 mm Hg	Absence suggests respiratory muscle fatigue
Use of accessory muscles and suprasternal reactions	Usually evident	Abdominal paradox (paradoxical thoracoabdominal movement)
Wheeze	Usually loud	Absence of wheeze “Silent chest”
FUNCTIONAL ASSESSMENT		
PEF (after initial bronchodilator, % predicted or % personal best)	<60% of predicted or personal best (<100 L/min adults) Or Response lasts <2 hours	
PaO ₂	<60 mm Hg Possible cyanosis	
PaCO ₂	>42 mm Hg Possible respiratory failure	
SpO ₂	<90%	

PEF, peak expiratory flow.

^aThe presence of several parameters, but not necessarily all, indicates the general classification of the exacerbation.

Adapted from Global Initiative for Asthma. Global strategy for asthma management and prevention. Bethesda, MD: National Institutes of Health, National Heart, Lung, and Blood Institute; 2006.

REFERRAL TO THE INTENSIVE CARE UNIT

- All patients transferred to the ICU should be accompanied by a physician suitably equipped and skilled to perform endotracheal intubation, if necessary. Indications for admission to intensive care facilities or a high-dependency unit include patients requiring ventilatory support and those with severe acute or life-threatening asthma who are failing to respond to therapy, as evidenced by:

- Deteriorating PEF
- Persisting or worsening hypoxia
- Hypercapnia
- Worsening acidosis
- Exhaustion, feeble respiration

- Drowsiness, confusion
- Coma or respiratory arrest

Admission Decisions

Criteria for Discharge from the Emergency Department versus Hospitalization

- Criteria for determining whether a patient should be discharged from the emergency department or admitted to the hospital have been succinctly reviewed and stratified based on consensus. Patients with a pretreatment FEV₁ or PEF <25% of predicted/personal best, or those with a posttreatment FEV₁ or PEF <40% of predicted/personal best, require hospitalization.

TABLE 98.8**STAGING SEVERE ASTHMA CRISIS BY ARTERIAL BLOOD GASES**

	Stage 1	Stage 2	Stage 3	Stage 4	Stage 5
PaCO	Normal	↓ PaCO ₂	↓ PaCO ₂	Normal	↑ PaCO ₂ (respiratory failure)
PaO ₂	Normal	Normal PaO ₂ (hyperventilation has led to normalization of PaO ₂).	↓ PaO ₂ (hyperventilation is now unable to compensate totally for a widened P(A - a)O ₂).	↓↓↓ PaO ₂ (inspiratory fatigue is now prominent).	↓↓↓ PaO ₂ . These findings indicate an impending respiratory arrest.

TABLE 98.9

LABORATORY INVESTIGATIONS AND DIAGNOSTIC TESTS FOR PATIENTS WITH DIFFICULT-TO-CONTROL ASTHMA

Diagnostic tests

- Peripheral blood
- Erythrocyte sedimentation rate
- Full blood count (eosinophils)
- Total serum IgE
- Specific IgE to common and less common allergens
- Free-T4, thyroid-stimulating hormone

Lung function

- Spirometry (pre- and postbronchodilator)
- Lung volumes
- Arterial blood gases
- Histamine challenge test

Radiology

- Chest radiography
- Sinus CT scan

Additional tests for comorbidities and alternative diagnoses

- Nasal endoscopy
- 24-hour esophageal pH monitoring or trial with proton pump inhibitors
- Polysomnography
- Bronchoscopy
- High-resolution CT scan of the thorax
- D-dimer
- ANCA
- IgG against *Aspergillus fumigatus*

Ig, immunoglobulin; CT, computed tomography; ANCA, antineutrophilic cytoplasmic antibody.
Bel EH. Severe asthma. *Breathe* 2006;3(2):129–139.

Indications for Mechanical Ventilation Support

- Careful and repeat assessment of patients with severe exacerbations is mandatory. Not all patients admitted to the ICU need invasive mechanical ventilation and a trial of 1 to 2 hours of non invasive ventilation (BiPAP) can be scheduled for patients in distress but fully alert. When used, noninvasive positive pressure ventilation should be started with low levels of inspiratory pressure support (5–10 cm H₂O) and PEEP (3–5 cm H₂O). Pressure support should be progressively increased by 2 cm H₂O every 15 minutes, the goal being to reduce respiratory rate <25 breaths/minute, while keeping peak inspiratory pressure <25 cm H₂O. Future prospective randomized controlled trials are required to definitely establish the role of noninvasive positive pressure ventilation in acute severe asthma.
- The exact time to intubate is based mainly on clinical judgment:
 - Patients presenting with apnea or coma should be intubated immediately.
 - Progressive exhaustion, patient fatigue, and worsening hypercapnia despite maximal therapy including noninvasive ventilation, together with altered level of consciousness, are indications for intubation.

Intubation

- A larger endotracheal tube reduces flow-resistive pressure during inspiration, but this is not important during controlled mechanical ventilation. Given the extraordinary high resistance of the patient's airways, the effect of the larger-bore tube on expiratory flow is also trivial. Intubation should be performed by the most skilled operator available to avoid repeated airway manipulation, which may induce laryngospasm and bronchoconstriction. Table 98.12 summarizes drugs used to facilitate intubation of patients with severe asthma.

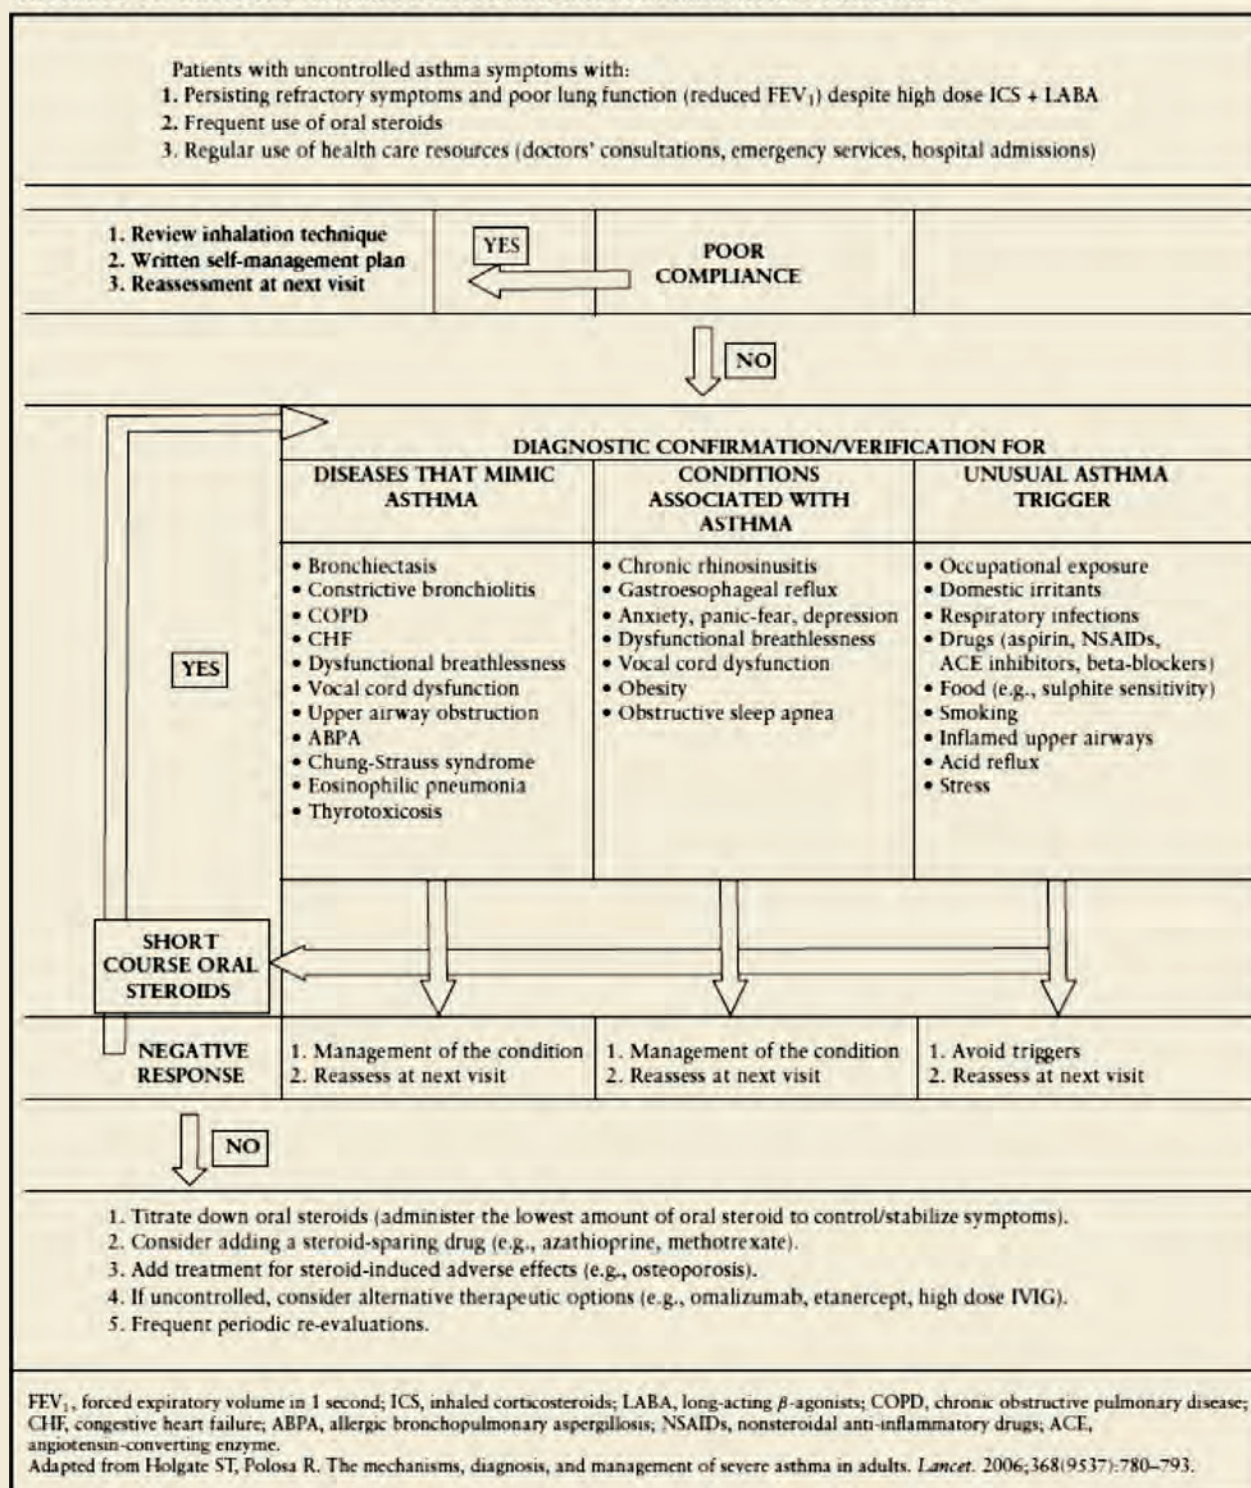

Invasive Mechanical Ventilation

- The main strategy of ventilatory support is to minimize hyperinflation and avoid excessive airway pressure development (overdistention). Thus, controlled hypoventilation or permissive hypercapnia is often required.
- For any level of minute ventilation and with constant (square wave) inspiratory flow rate, end-inspiratory lung distention is minimized by a combination of low tidal volume (V_T) and high respiratory rate. This is because in the inhomogeneous asthmatic lung, most of the tidal volume delivered by positive-pressure ventilation goes to the parts of lung parenchyma with almost normal mechanical characteristics. Because such “mechanically normal” areas represent only a small fraction of the total asthmatic lung, they become overdistended. Thus, the lower tidal volume would cause less end-inspiratory lung overdistention.
- When keeping minute ventilation, tidal volume, and respiratory rate constant, increasing inspiratory flow allows inspiratory time (T_I) to be reduced and thus expiratory time (T_E) to be increased. When minute ventilation is high (>10 L/minute), increasing inspiratory flow and thus reducing T_I allows a decrease in lung hyperinflation. At any given minute ventilation, inspiratory flow should be 60 to 80 L/minute, as further prolonging T_E by greater inspiratory flow will not significantly reduce hyperinflation.
- Four common causes of acute deterioration in any intubated patient are recalled by the mnemonic DOPE (tube Displacement, tube Obstruction, Pneumothorax, Equipment failure). Another common cause of deterioration common in asthmatics is the occurrence of dynamic overinflation (auto-PEEP),
- Dynamic hyperinflation can be monitored in two different ways:
 - By measuring the volume passively exhaled from end-inspiration to the static functional residual capacity in the course of a prolonged apnea and subtracting the delivered tidal volume (V_{EI}): Although this is the most accurate way of measuring dynamic hyperinflation and estimating the attendant risks of hypotension and barotrauma, the need for complete muscle relaxation, with its potential complications (see later discussion), and practical aspects of the measurement reduce its clinical applicability. Furthermore, it cannot measure the volume of air trapped behind closed airways (compartment C).
 - By measuring the average pressure developed in the airways at the end of expiration (PEEPi) after occluding the airways and allowing sufficient time for equilibration (the end-expiratory occlusion technique): This pressure represents the average recoil pressure of the respiratory

TABLE 98.11

PHARMACOLOGIC TREATMENT IN THE EMERGENCY DEPARTMENT

Agent	Dose
Salbutamol	2.5 mg (0.5 mL) in 2.5 mL normal saline by nebulization continuously, or every 15–20 min until a significant clinical response is achieved or serious side effects appear
Epinephrine	0.3–0.4 mL of a 1:1,000 solution SC every 20 min for three doses
Terbutaline	Preferable to epinephrine in pregnancy
β -Agonists IV	IV administration should be considered in patients who have not responded to inhaled or SC, in whom respiratory arrest is imminent
Corticosteroids	Methylprednisolone 60–125 mg IV or prednisone 40 mg <i>per os</i> .
Anticholinergics	Ipratropium bromide 0.5 mg by nebulization every 1–4 hours, combined with salbutamol
Methylxanthines	Theophylline 5 mg/kg IV over 30 min—loading dose in patients not already taking theophylline, followed by 0.4 mg/kg/h IV maintenance dose. Serum levels should be checked within 6 h.
Magnesium sulfate	Usually given as a single 2-g infusion IV over 20 min, only following consultation with senior medical staff. Nebulized salbutamol administered in isotonic magnesium sulfate provides greater benefit than if it is delivered in normal saline.

SC, subcutaneously; IV, intravenously.

system at the end of expiration and is an indirect measure of the end expiratory lung volume and thus of hyperinflation.

- The addition of PEEP during controlled mechanical ventilation in asthma patients results in a variable and unpredictable response. In some patients, extrinsic PEEP (PEEPe) causes overinflation; in others, functional reserve capacity and PEEPi are decreased; and in still others no response to PEEP is observed until PEEPe exceeds baseline PEEPi. This might be due to the great heterogeneity of the asthmatic lung with various combinations of the previously described compartments in each patient.
- When PEEPe is applied—a stepwise application of PEEP in increments of 2 cm H₂O every 5 minutes—with measurement of the plateau pressure at each step might be a useful bedside approach. If Pplat decreases, application of PEEPe is deflating

the lung and is beneficial; if plateau pressure (Pplat) increases, PEEPe should be withdrawn.

Weaning

- Once dynamic hyperinflation has abated sufficiently, as assessed by a substantial resolution of wheezing on chest auscultation and decrease of Pplat and PEEPi, weaning should be initiated using standard procedures. Suppression of respiratory muscle activity with controlled hypoventilation should be maintained as short as possible to prevent ventilator-induced diaphragmatic dysfunction. Weaning is normally rapidly achieved in patients with acute severe asthma. Weaning difficulty in the absence of persistent severe airway obstruction must raise the suspicion of myopathy induced by previous administration of neuromuscular blocking agents and corticosteroids.

TABLE 98.12

DRUGS USED FOR INTUBATION IN ACUTE SEVERE ASTHMA

Agents	Dose	Advantages	Side effects	Contraindications
Midazolam	1 mg (IV) slowly, every 2–3 min until the patient allows positioning and airways inspection	Amnesia Muscle relaxation	Hypotension Respiratory depression	
Ketamine	1–2 mg/kg (IV) at a rate of 0.5 mg/kg/min	No respiratory depression No hypotension Short-term bronchodilation	Increased laryngeal reflexes Increased laryngeal secretions Sympathomimetic effects (hypertension, tachycardia) Increased intracranial pressure Delirium Hallucinations (prevented by midazolam coadministration)	Atherosclerosis Hypertension Increased intracranial pressure
Propofol	60–80 mg/min initial IV infusion up to 2.0 mg/kg	Rapid onset and resolution of sedation Bronchodilation	Hypotension Respiratory depression	Hemodynamic instability

IV, intravenously.

CHAPTER 99 ■ ACUTE RESPIRATORY FAILURE IN CHRONIC OBSTRUCTIVE PULMONARY DISEASE

- Chronic obstructive pulmonary diseases (COPDs) are a group of disorders characterized by airflow limitation that is not fully reversible. There are several diseases under this designation (Table 99.1), the most common of which are chronic bronchitis and emphysema. These two disorders represent the extremes of the COPD spectrum and usually coexist in COPD patients. Bronchitis is predominantly a disease of the airways and presents as a chronic productive cough for at least 3 months during 2 consecutive years, whereas emphysema is a disease of the parenchyma and consists of permanent airspace enlargement associated with rupture of the alveolar septa.
- The common final pathway leading to COPD is an increased inflammatory response to inhaled particles or gases, of which the most common is cigarette smoke. This inflammatory process involves the airways and the lung parenchyma, leading to mucosal gland hypertrophy and disruption of alveolar septa with loss of elastic recoil. These alterations ultimately lead to the obstructive ventilatory defect that defines COPD. Some patients develop pulmonary hyperinflation caused by the loss of elastic recoil and increased airway resistance. During exacerbations, there might be a secondary dynamic pulmonary hyperinflation caused by the increased ventilatory requirement and shortened expiratory time. The capacity of the respiratory muscles to generate inspiratory pressure is limited by their shortened operating length and impaired geometric arrangement. Long-term steroid use and/or malnutrition also contribute to strength impairment in many patients with severe chronic disease.
- Rarely, the disease results from an inborn imbalance between the proteases and antiproteases present in the lung, as occurs in the autosomal recessive α_1 -antitrypsin deficiency.

CLINICAL FINDINGS

- There is initially a slow decline in lung function that goes unnoticed over the years. Cough is the first finding, usually

TABLE 99.1

DISEASES ASSOCIATED WITH CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Chronic bronchitis
Emphysema
Bronchiolitis
Bronchiectasis
Tuberculosis
 α_1 -Trypsin deficiency

after the patient has been a smoker for many years. The dyspnea worsens slowly over time, although sometimes patients deny the deterioration of lung function because they slowly adapt their level of activity to their exercise capacity. The decrease in lung function might become steeper during exacerbations, with a slow recovery to baseline levels after resolution of the decompensation

- The ratio of the forced expiratory volume in the first second of the exhalation (FEV₁) to the forced vital capacity is diagnostic of an obstructive ventilatory defect if <0.7 . The FEV₁ is a useful marker of the disease severity (Table 99.2) and is well suited as a longitudinal monitor of lung function.
- Both total lung capacity and residual volume may be increased because of loss of lung elastic recoil. The carbon monoxide diffusing capacity may be diminished with the progression of the disease, reflecting the loss of the functional parenchyma.

TABLE 99.2

CLASSIFICATION OF SEVERITY ACCORDING TO GOLD

Stage	Characteristics
0: At risk	Normal spirometry Chronic symptoms (cough, sputum production)
I: Mild COPD	FEV ₁ /FVC $<70\%$ FEV ₁ = 80% predicted With or without chronic symptoms (cough, sputum production)
II: Moderate COPD	FEV ₁ /FVC $<70\%$ 50% = FEV ₁ $<80\%$ predicted With or without chronic symptoms (cough, sputum production)
III: Severe COPD	FEV ₁ /FVC $<70\%$ 30% = FEV ₁ $<50\%$ predicted With or without chronic symptoms (cough, sputum production)
IV: Very severe COPD	FEV ₁ /FVC $<70\%$ FEV ₁ $<30\%$ predicted or FEV ₁ $<50\%$ predicted plus chronic respiratory failure

GOLD, Global Initiative for Chronic Obstructive Lung Disease; COPD, chronic obstructive pulmonary disease; FEV₁, forced expiratory volume in the first second of the exhalation; FVC, forced vital capacity. From Rabe KF, Hurd S, Anzueto A, et al. Global Strategy for the Diagnosis, Management, and Prevention of Chronic Obstructive Pulmonary Disease: Gold Executive Summary. *Am J Respir Crit Care Med*. 2007;176:532–555.

EXACERBATION

- COPD exacerbation can be defined as an increase in dyspnea, cough, or sputum production that requires therapy. The two most commonly identified precipitating factors are infection—viral, such as *Rhinovirus* spp. or influenza, and bacterial, such as *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Moraxella catarrhalis*, *Enterobacteriaceae* spp., or *Pseudomonas* spp.—as well as environmental exposure to air pollutants. However, in about one-third of cases, no underlying cause is identified. Infectious agents can also be recovered from some patients with stable COPD, indicating that in some instances, their presence in decompensated COPD represents an epiphenomenon.

Treatment of Exacerbations

- Admission criteria according to the American Thoracic Society/European Respiratory Society guidelines include:
 - High-risk comorbidities including pneumonia, cardiac arrhythmia, congestive heart failure, diabetes mellitus, renal failure, or liver failure
 - Inadequate response of symptoms to outpatient management
 - Marked increase in dyspnea
 - Inability to eat or sleep because of symptoms
 - Worsening hypoxemia
 - Worsening hypercapnia
 - Changes in mental status
 - Inability to care for oneself (i.e., lack of home support)
 - Uncertain diagnosis
- The mainstay of pharmacologic treatment is the use of bronchodilators, corticosteroids, and antibiotics, which are discussed in the following sections.

Bronchodilators

- β_2 -Agonists: The bronchodilators most commonly used are the inhaled short-acting β_2 -agonists because of their rapid onset of action. Same considerations of the section dedicated to severe asthma are applicable here. Long-acting β_2 -agonists can also be considered. Subcutaneous or intravenous administration should not be used unless there is contraindication for the inhaled route because of their increased systemic effects.

Corticosteroids

- Steroids are usually recommended for exacerbations of COPD. If feasible, prednisone can be given orally at a dose of 30 to 40 mg/day for 10 to 14 days. If the oral route is not an option, hydrocortisone or methylprednisolone can be substituted in equivalent doses. Some investigators advocate the use of much higher doses (methylprednisolone, 125 mg intravenously four times daily).
- Recently, the combination of salmeterol, 50 μ g, and fluticasone, 500 μ g, given twice daily, has been compared with placebo and resulted in a reduction in mortality of 3 years ($p = 0.052$), fewer exacerbations, and improved health status and lung function.

Antibiotics

- Antibiotics decrease mortality during exacerbations. These agents are indicated when there is increased production or change in the color of the sputum. For mild exacerbations, amoxicillin, sulfamethoxazole-trimethoprim, or doxycycline for 7 to 10 days is usually adequate. Patients requiring hospitalizations should receive penicillin/penicillinase (e.g., amoxicillin/clavulanate), a respiratory quinolone (levofloxacin, gatifloxacin, moxifloxacin), or a third-generation cephalosporin together with a macrolide (e.g., ceftriaxone plus clarithromycin). In addition to their antimicrobial activity, macrolides possess anti-inflammatory and mucoregulatory properties that may confer beneficial effects to patients with COPD.

Respiratory Support

- The goal of respiratory support in patients with exacerbations of COPD is to correct hypoxemia/acidemia and reduce the respiratory work, thus avoiding respiratory muscle fatigue.

Oxygen Therapy

- To improve the hypoxemia commonly present in exacerbations of COPD, controlled oxygen therapy is the cornerstone of hospital treatment. Long-term oxygen therapy is established as the standard of care for selected patients with advanced chronic stable hypoxemia due to COPD. However, in the acute setting, some patients have an impaired response to hypercapnia when treated with supplementary oxygen, leading to worsening of CO_2 retention. Venturi masks are more accurate sources of oxygen than are nasal prongs, but they are more likely to be removed by the patient.
- Controlled oxygen therapy must be started at a low inspiratory oxygen fraction—0.24 to 0.28—and titrated upward to reach a $\text{PaO}_2 \geq 60$ mm Hg or $\text{SaO}_2 \geq 90\%$ without significant retention of CO_2 . A clinically significant increase in PaCO_2 has been arbitrarily defined as a raise in CO_2 of 6.5 mm Hg, especially if clinical mental deterioration occurs.

Noninvasive Mechanical Ventilation

- Noninvasive positive pressure ventilation is an alternative treatment for patients admitted to the hospital with hypercapnic respiratory failure secondary to acute exacerbation of COPD that is associated to a lower rate of complication than invasive ventilation. Many studies have shown that noninvasive positive pressure ventilation increases pH, reduces PaCO_2 , reduces the severity of breathlessness in the first 4 hours of treatment and decreases the length of hospital stay. More importantly, mortality and the intubation rate are consistently reduced by this intervention. In clinical-physiological terms, the expected elevation of pH after 1 hour of treatment should be around 0.03 (95% CI, 0.02 to 0.04) and the expected reduction in PaCO_2 in the same interval around -3.0 mm Hg (95% CI, -5.1 to -0.2).
- Unfortunately, noninvasive ventilation is not appropriate for all patients. Failure rates between 9% and 50% have been reported. One important signal that this procedure is not working for a patient is the progression—even slight—of

hypercapnia or acidosis 30 to 60 minutes after the procedure, and deterioration of the mental status.

- The classic indications for noninvasive mechanical ventilation in exacerbated COPD patients are:
 - Respiratory distress with respiratory rate >30 to 35 breaths/minute
 - Respiratory acidosis with a pH <7.35, and with normal or high standard base excess
 - PaO₂ <45 mm Hg.
- Noninvasive mechanical ventilation is contraindicated for patients with profound bradypnea, defined as a respiratory rate <12 breaths/minute, severe hypercapnic encephalopathy with Glasgow Coma Scale score <10, cardiac and/or respiratory arrest, and hemodynamic instability.
- There are many approaches to set the noninvasive ventilation. An easy way is to set the expiratory pressure at 5 cm H₂O, the inspiratory pressure at 10 cm H₂O—resulting in a “delta P” of 5 cm H₂O—and to increase the delta P in increments of 5 cm H₂O, up to 20 to 25 cm H₂O or the maximum tolerated, over 1 hour. An alternative approach is to adjust the inspiratory pressure in order to obtain a tidal volume of 6 to 8 mL/kg and a respiratory rate of 25 to 30 breaths/minute, setting the end-expiratory pressure to 5 cm H₂O to offset the inspiratory threshold induced by intrinsic PEEP.
- If inspiratory comfort is not achieved, especially when wasted inspiratory efforts are visible without a prompt response from the ventilator, meaning that the patient effort is not enough to easily trigger the assisted breath, trials of 2 cm H₂O elevations in the PEEP/CPAP levels must be performed in order to further reduce the extra load imposed by the intrinsic PEEP. During these trials of augmentation of external PEEP, the minimum inspiratory pressure should be provided that maintains a stable tidal volume. Oxygen should be offered to keep oxygen saturation >85% to 90%.
- The choice for an appropriate mask is an important aspect of noninvasive mechanical ventilation. In general, patients benefit from a facial mask that covers the mouth and the nose; this is more efficient than the nasal type to deliver effective inspiratory pressures. Leaks directed at the eyes, sores in the nasal area, and a dry mouth are frequent causes of extreme discomfort to patients. The total face mask may be better tolerated by some patients, but not all, and greatly reduces the skin sores. However, one has to be aware that the anatomic dead space may increase a bit with this mask, which also imposes some challenges to the mechanical ventilator in terms of synchrony and PEEP maintenance.

Invasive Mechanical Ventilation

- Invasive mechanical ventilation can be either the initial choice in patients with COPD exacerbation or the strategy to be applied after failure of a trial of noninvasive ventilation.
- Assuming that all appropriate measures to improve airflow obstruction have already been taken (see section on asthma), minimization of dynamic hyperinflation is a key objective of the ventilatory support of these COPD patients.
- There is no optimal ventilation modality to support exacerbated COPD patients. The peak airway pressure may reach high values in the volume-controlled mode, but this is of limited clinical relevance because most of this pressure is dissipated in the large airways and, consequently, it does not reflect the alveolar pressure. One limitation of the volume-

controlled mode is the impossibility of continuously monitoring the plateau pressure, as the use of an inspiratory pause every breath may worsen dynamic hyperinflation. On the other hand, in the pressure-controlled mode, conditions of fluctuating airway resistance and auto-PEEP entail the risk of variable tidal volume, with sometimes unacceptably low alveolar ventilation. Furthermore, with this latter mode, severe respiratory alkalosis may develop if airway obstruction subsides rapidly.

- Although there is no clear advantage of one over the other, volume-controlled ventilation is currently the preferred mode by most investigators. The use of decelerating-flow waveform usually minimizes peak pressure, allowing full delivery of the tidal volume, with less interruption by opening of the pop-off safety valve. By forcing a slower flow at the end of inspiration, this flow waveform could result in two theoretical benefits: (i) less overdistention of alveoli distal to the least obstructed airways, and (ii) slightly better CO₂ exchange. When initiating mechanical ventilation in the pressure-controlled mode, one must keep in mind that the inspiratory time should be set in proportion to the inspiratory time constant in order to deliver the desired tidal volume with the lowest possible plateau pressure. Thus, patients with increased airways resistance will need a longer inspiratory time. For a fixed respiratory rate, the increase in inspiratory time always occurs at the expense of a shortening of the expiratory time, which might aggravate pulmonary hyperinflation. Therefore, the ideal inspiratory time would optimize delivery of tidal volume without increasing air trapping. That will occur if, when looking at the flow-volume curve, both end-inspiratory and end-expiratory flows are equal or close to zero.
- After choosing the best respiratory rate and inspiratory and expiratory times, the physician has to decide on how much PEEP to apply. The sequence approach has been described in Chapter 96.
- As soon as possible, the ventilation mode should be switched from controlled to assisted ventilation in order to decrease muscle atrophy. There are no objective indicators of the best moment to start assisted ventilation; therefore, at least daily trials of assisted ventilation should be made, with close monitoring of patient comfort and plateau pressure. Humidification should be achieved with a heated humidifier, not with heat and moisture exchangers. The latter devices are undesirable for three reasons:
 - They increase expiratory airway resistance, which would hardly be of any help to reduce hyperinflation.
 - When inserted between the tracheal tube and the Y-piece of ventilator tubing, they increase dead space and, therefore, contribute unnecessarily to hypercapnia.
 - The efficacy of any inhalational medication will be blunted by the heat and moisture exchanger.
- Weaning from the ventilator should be initiated as soon as possible in order to avoid mechanical ventilator-associated complications. According to recent published experiences of two specialized weaning units, 19% of patients with COPD exacerbation remained partially dependent on the ventilator. The classic rapid shallow breathing criterion (<80 breaths/minute/L) was met by 56% of COPD patients who failed the weaning trial. General patient condition and subjective dyspnea seemed to be more effective predictors of success of extubation than quantifiable indexes. Using

spontaneous breathing trials or progressive reduction in pressure support is equally effective to wean the patient from the ventilator. Automatic algorithms for pressure support reduction are available today, which resulted in a faster weaning process when compared with the physician-driven approach.

- If the spontaneous breathing trial is chosen, it can be applied for at least 30 minutes, up to 2 hours once a day. After tracheal decannulation, the use of intermittent or continuous support with noninvasive mechanical ventilation for at least 24 hours is strongly recommended, using settings sim-

ilar to those used during conventional ventilation weaning. The last technique is associated with higher rates of extubation success, lower length of stay in the intensive care unit and/or hospital, and a lower mortality at 60 days. A recent alternative strategy of weaning implies early use of PSV and early extubation with support “switched” to noninvasive mechanical ventilation using the same ventilatory settings as before tracheal decannulation. This approach is associated with less ventilator-associated pneumonia, a shorter length of stay in the intensive care unit, and a lower mortality rate.

CHAPTER 100 ■ PULMONARY EMBOLISM (PE)

- PE remains an underrecognized and lethal entity
 - Estimates suggest it affects more than 600,000 patients per year in the United States.
 - PE causes or contributes to 50,000 to 200,000 deaths per year.
 - Incidence of PE causing, contributing to, or accompanying death in hospitalized patients relatively constant at 15% for the past 40 years.
 - Antemortem diagnosis of fatal PE fixed at about 30% over same time period.
 - Observational studies of PE reported unexpectedly high mortality rates.
 - In one study, overall 3-month mortality in patients with PE was 17% with an in-hospital mortality of 31% when PE was associated with hemodynamic instability.
 - In another, 90-day mortality was 14.5% in hemodynamically stable PE patients and 51.9% in those with hemodynamic instability.
 - PE-attributable mortality was 34% and 62.5% in the respective groups.
 - In fatal PE it is long appreciated that two-thirds of PE deaths will occur within 1 hour of presentation.
 - Anatomically massive PE accounts for only one-half of the deaths.
 - Remainder can be attributed to smaller submassive or recurrent emboli.
 - Several important implications of these observations:
 - Evidenced-based approach is nearly impossible to define for hemodynamically unstable PE.
 - Reasonable to propose that outcome from PE is related to embolism size and underlying cardiopulmonary function.
 - Similar hemodynamic and clinical outcomes will manifest from an anatomically massive PE in patients with normal cardiopulmonary function and an anatomically submassive embolism in patients with impaired cardiopulmonary function.
- Understanding of PE physiology will allow for application of physiologic risk stratification used for diagnostic evaluation and therapeutics.
 - Combination of embolism size and underlying cardiopulmonary status that produces cardiac arrest is associated with a predicted mortality of 70%.
 - Implies that 30% of arrested PE patients will survive and warrants continued use of chest compressions to mechanically fracture the embolism and consideration toward thrombolysis or embolectomy even without a definitive diagnosis when PE is highly suspected
 - Combination of embolism size and cardiopulmonary status that fails to produce right ventricle (RV) dilatation is associated with a 0% to 1% mortality.
 - Provided therapeutic anticoagulation is achieved
 - Combination of embolism size and cardiopulmonary status that produces hemodynamic instability or shock is associated with a 30% mortality rate.
 - Presence of shock has traditionally defined the threshold for thrombolysis.
 - Syncope represents an intermediary position between shock and cardiac arrest as failure to recover consciousness results in cardiac arrest, and patients who regain consciousness have a high incidence of hemodynamic instability.
 - Outcomes and mortality associated with emboli in transit and PE patients with a patent foramen ovale (PFO) have not been well reported.
- Spectrum of PE most likely to confront the intensivist is predominantly confined to two situations:
 - Patient presenting with undifferentiated shock or respiratory failure
 - An established hospital or intensive care unit (ICU) patient who develops PE after admission
 - In either situation, the diagnostics and therapeutics are challenging

- Differentiating PE from other life-threatening cardiopulmonary disorders can be exceedingly difficult

PREVENTION OF VENOUS THROMBOEMBOLISM (VTE)

Principles of Prophylaxis

- Prophylaxis is defined as any measure “designed to preserve health and prevent the spread of disease.”
- Use of pharmacologic, mechanical, or vena caval interruption as a means for reducing occurrence of VTE qualifies as a measure intended to preserve health
- The Agency for Healthcare Research and Quality (AHRQ) has identified “appropriate use of prophylaxis to prevent venous thromboembolism in patients at risk” as the number one opportunity for improvement of patient safety, supporting more widespread implementation.
- Choice of primary prophylaxis is based on patient’s risk of bleeding and thrombosis and is presented in Table 100.1.

Risk Factors

- Virchow’s triad of stasis, vessel trauma, and hypercoagulability remain fundamental risk factors for VTE
- Risk factors can be considered:
 - Clinical (i.e., multiple trauma or major abdominal surgery, acute myocardial infarction or stroke, need for mechanical ventilation)
 - Or patient-related (prior history of VTE, malignancy, inherited coagulopathy)
- With respect to lower extremity deep VTE, observational studies of medical-surgical ICU patients have identified these as risk factors:
 - Mechanical ventilation
 - Treatment with neuromuscular blockers
 - Presence of a central venous line (CVL)
 - CVL, in particular, reported to confer an increased relative risk (RR) of 1.04 for each day catheter is in place

TABLE 100.1

VENOUS THROMBOEMBOLISM PROPHYLAXIS OF CRITICAL CARE PATIENT

Bleeding risk	Thrombosis risk	Prophylaxis recommendation
Low	Moderate	LDH 5,000 units sq twice a day
Low	High	LMWH <ul style="list-style-type: none"> • Dalteparin • Enoxaparin
High	Moderate	GCS or IPC → LMWH when bleeding risk subsides
High	High	GCS or IPC → LMWH when bleeding risk subsides

LDH, low dose heparin; LMWH, low molecular-weight heparin; GCS, graded compression stockings; IPC, intermittent pneumatic compression devices.

Adapted from *Chest*. 2003;124(6S):357S–363S.

- Among 261 medical-surgical ICU patients, multivariate regression analysis defined as independent risk factors for VTE:
 - Exposure to platelet transfusions
 - Use of vasopressors
- The two most powerful patient-related risk factors are prior history of VTE and malignancy.
 - Malignancy most common acquired hypercoagulable state encountered in the ICU
 - End-stage renal disease identified as an independent risk factor for ICU-acquired deep vein thrombosis (DVT)
 - Activated protein C resistance from factor V Leyden (FVL) is the most common hereditary defect predisposition for DVT.
 - In order of descending prevalence among the general population predisposing development of DVT:
 - Prothrombin gene mutation 20210A
 - Antithrombin, protein C and S deficiency
 - Elevations in homocysteine and coagulation factors VIII, IX, and XI
 - Heparin-induced thrombocytopenia (HIT), an acquired platelet disorder, results in increased risk of both venous and arterial thrombosis
- Cancer and the presence of a CVL are the two most powerful risk factors for upper extremity DVT (UEDVT).
- CVL at the site of the upper extremity DVT present in 60% of patients and 46% were diagnosed with cancer
- Underscoring the possible additive nature of two risk factors:
 - 76% of patients with cancer also had an indwelling CVL
 - A review of cancer patients with an indwelling CVL showed reported prevalence of UEDVT, symptomatic or asymptomatic, from 6.7% to 48%
 - Prospective registry of 592 patients with UEDVT
 - Presence of an indwelling CVL the strongest independent predictor of occurrence (odds ratio, 7.3)
 - Nearly 30% of patients will develop an UEDVT with no apparent cause
 - Inherited thrombophilia (FVL), prothrombin G20210A mutation, anticoagulant protein deficiencies causative
 - Evaluated prospectively for median follow-up of 5.1 years, recurrence of primary UEDVT reported to be 4.4% in those with inherited thrombophilia compared to 1.6% in those without

Prevalence/Incidence

- DVT in the setting of critical illness underappreciated
- Systematic screening shows 10% of medical-surgical ICU patients have existing proximal lower extremity DVT on admission to ICU
- When no form of prophylaxis is used, incidence of DVT during ICU stay is variable but high
- Patients undergoing major general surgery have an event rate of 25% without DVT prophylaxis:
 - 9% of patients will have clinically detectable DVT
 - 7% will have proximal DVT
 - In trauma patients not receiving prophylaxis, 58% developed a DVT
 - One-third of which were proximal

- Patients undergoing elective hip surgery and not receiving prophylaxis had a 50% incidence of DVT.
 - 23% clinically detectable and 20% proximal
- Pooled incidence of detectable DVT in neurosurgical patients is 22%.
 - Incidence in acute spinal cord injury patients is as high as 90% when prophylaxis was not used.
- Incidence of DVT in critically ill medical patients reported to be 1% to 15%
 - Depends on screening technique used
- No studies specific to critically ill performed regarding upper extremity DVT
 - No prospective studies using systematic screening techniques available to assess prevalence or incidence
 - Has been an increase over the past several decades attributed to the greater use of transvenous pacemakers and CVLs
 - Symptomatic PE reported to occur in 7% to 9% of these patients
 - Using systematic ventilation/perfusion scanning in patients previously diagnosed with upper extremity DVT have reported high-probability scans in 13%.

Pharmacologic Prophylaxis

- Little data available regarding anticoagulant prophylaxis in critical care setting
- Two published randomized trials of thromboprophylaxis versus placebo in medical-surgical ICU patients:
 - Prospective, double-blind randomized controlled trial (RCT) of unfractionated heparin (UFH), 5,000 U administered subcutaneously (SQ) twice daily versus placebo
 - Rate of objectively confirmed DVT was reduced from 29% to 13%
 - Patients requiring mechanical ventilation (MV) \geq 48 hours for chronic obstructive pulmonary disease (COPD) exacerbations, treatment with the low-molecular-weight heparin (LMWH) nadroparin once daily versus placebo
 - Decreased DVT rates from 29% to 16%
 - Another prospective trial, only abstracted, demonstrated the efficacy of UFH versus placebo as thromboprophylaxis.
 - Reducing the DVT rates from 31% to 11%
- In acutely ill hospitalized medical patients and high-risk surgical patient
 - Comparison of enoxaparin, 40 mg or 20 mg, with placebo administered once daily for 6 to 14 days (MEDENOX)
 - Resulted in fewer DVTs in those receiving 40-mg dose
 - Randomized, placebo-controlled trial of dalteparin for the prevention of VTE (PREVENT)
 - Dalteparin, 5,000 IU once daily, halved rate of VTE with low risk of bleeding
 - Does SQ administration of LMWH have sufficient bioavailability to achieve therapeutic plasma levels (≥ 0.3 IU/mL) in critically ill?
 - Prospective, controlled, open-labeled study of enoxaparin, 40 mg once daily in critically ill patients with normal renal function demonstrated significantly lower anti-Xa levels when compared with medical patients in the normal ward.
 - Body weight seems to have negative correlation with anti-Xa levels.
 - Calls into question whether once-daily dosing is appropriate for the critically ill
- Fondaparinux, a synthetic factor Xa inhibitor in doses of 2.5 mg SQ daily:
 - Reported to decrease VTE rates by half versus placebo in older acutely ill medical patients (ARTEMIS)
 - More effective than enoxaparin, 30 mg twice daily, for VTE prophylaxis after elective major knee surgery
 - Equivalent to dalteparin, 5,000 IU daily, for the prevention of VTE in high-risk abdominal surgery (PEGASUS)
 - Patients requiring MV and those with severe sepsis and septic shock excluded from these trials and most were not in ICU
- Notion that these are drugs superior to placebo in prevention of VTE is supported.

Mechanical Prophylaxis

- Graded compression stockings (GCS), intermittent pneumatic compression devices (IPC), and venous foot pumps (VFP) attractive and without bleeding risk
- No RCTs available to guide use in medical-surgical ICU patients
- In an unblinded study of 422 trauma patients, more DVT occurred in patients in whom IPC devices were used than with LMWH (2.7% vs. 0.5%).
- Use of IPC did not appear to have additional benefit when used with either UFH or LMWH in randomized pilot trial for VTE prophylaxis in patients undergoing craniotomy.
- IPC less effective in preventing PE when used in addition to UFH versus LMWH alone in prospective, randomized, multicenter trial involving acute spinal cord injury patients.
- Poor fitting GCS may lead to undue constriction and stasis of the limb on which it is applied, increasing risk of subsequent clot.
- Mechanical prophylaxis in isolation not shown to reduce risk of death or PE
 - Mechanical VTE prophylaxis alone not likely to be effective in ICU and, unless bleeding is of great concern, these devices should be deferred in favor of pharmacologic prophylaxis

Inferior Vena Cava Filters (IVCF)

- Idea of interrupting IVC to prevent transit of lower extremity thromboses to pulmonary circulation attributed to Trousseau in 1868
- IVC interruption most often carried out by percutaneous insertion of a filter or “umbrella” via the femoral or jugular vein
- Performed nearly 50,000 times a year
- Categorical indications for IVCF placement include:
 - Contraindications to anticoagulation (absolute or relative)
 - Complications of previously instituted anticoagulation (failure, bleeding, thrombocytopenia, drug reactions)
 - As prophylactic adjunct to anticoagulation in patients thought to be unable to withstand another embolic event
 - Failure of previous IVCF

- In association with another procedure (thrombectomy, embolectomy, or thrombolysis)
- Methodologically sound literature in support of specific indications for filter placement lacking
- Consequently, recommendations for filter placement largely opinion
- The first and only randomized controlled trial (RCT) of IVCs for the prevention of PE in patients with documented proximal LEDVT followed patients for 2 years in initial report, and results of a longer-term follow-up in same patients reported after 8 years
 - Initial report, 400 patients were randomized to receive a filter or no filter in addition to anticoagulation with UFH or LMWH
 - At 12 days, fewer patients suffered symptomatic or asymptomatic PE in filter group
 - Bleeding and mortality unaffected
 - At 2 years, number of patients suffering symptomatic PE no longer significantly different
 - As a result of more symptomatic PE between years 1 and 2 in the filter group
 - Recurrence of DVT significantly higher in filter group
 - Placement of an IVCF had no effect on survival
 - At 8-year follow-up patients with filters still had higher DVT rates
 - Symptomatic PE was lower than in patients without filter
 - Mortality still unaffected
 - No differences in edema formation, occurrence of varicose veins, trophic disorders, ulcer formation, or postthrombotic syndrome have been shown between those with and without a filter.
 - Filter placement in SVC may also be considered for prevention of symptomatic PE due to acute upper extremity DVT.
 - IVCF use not systematically studied in critical care outside the setting of major trauma, where the deployment of retrievable IVCs (R-IVCF) has been favored.
 - Only about one in five of these devices in fact retrieved, suggesting that they have simply become permanent filters
 - A small study of morbidly obese patients undergoing R-IVCF placement prior to gastric bypass surgery reported a 95% success rate when filter retrieval was attempted. Still, 21% developed VTE postoperatively.
- No RCT of IVCF for prevention of PE, generalizable to the critically ill, yet published
- Use recommended for those in whom anticoagulation is contraindicated or failed altogether
- For symptomatic patients reported pooled sensitivity for CUS in excluding a proximal DVT is 97%, but only 62% in asymptomatic patients
- CUS lacks sensitivity in detection of distal DVT, yielding pooled sensitivities of 73% and 53% for symptomatic and asymptomatic patients, respectively
- Negative serial CUS over 7- to 10-day period may effectively rule out clinically important DVT.
 - Only validated in symptomatic outpatients
- Alternative to both venography and CUS is computed tomography venography (CTV) of the lower extremities and the pelvic veins as continuation of CT angiography of pulmonary arteries
 - In setting of diagnostic workup for PE, CTV has reported sensitivity and specificity of 70% and 96%, respectively, for all DVT.
 - Comparable to CUS in one study, and superior to CUS for detection of iliofemoral DVT (yielding 100% sensitivity and specificity)
 - PLOPED investigators reported CTV and CUS diagnostically equivalent
 - Reporting 95.5% concordance between CTV and CUS for diagnosis or exclusion of LEDVT
 - Choice of imaging technique can be made on the basis of safety, expense, and time constraints
- In case of upper extremity DVT:
 - First-line diagnostic test is color duplex ultrasound with a three-step protocol involving compression, color, and color Doppler
 - Reported sensitivity and specificity ranging from 78% to 100% and 82% to 100%, respectively
 - With vessel incompressibility but the presence of isolated flow abnormalities in combination with persistent clinical likelihood, contrast venography should be considered.
 - Magnetic resonance venography (MRV) has shown disappointing results.
 - Sensitivities are 50% and 71% for MRV with and without gadolinium enhancement, respectively.

Treatment of DVT

- The mainstay of therapy for all forms of VTE is anticoagulation.
- See section for treatment of PE for further details
- For larger clot burden involving the iliofemoral system, some suggest thrombolytics.
 - A Cochrane review concluded that thrombolysis reduces postthrombotic syndrome and maintains venous patency after DVT when compared to traditional anticoagulation.
 - Optimum drug, dose, and route of administration have to be determined.
 - Endovascular catheter-directed thrombolysis is another promising treatment for acute iliofemoral thrombosis.

Diagnosis of DVT

- Physical examination unhelpful
- Gold standard for DVT lower limb venography
 - Adequately performed, able to detect all clinically important forms of DVT
 - Including calf thrombosis, thrombosis of the pelvis, and IVC
 - Due to technical nature of test, risk of radiocontrast-induced nephrotoxicity, and need to transport patient from ICU rarely performed outside research settings
- Compression ultrasound (CUS) most commonly reported method of detecting DVT in ICU setting

PULMONARY EMBOLISM (PE)

- Combination of mechanical obstruction and neurohumoral factors combined with patients underlying cardiopulmonary status results in increased pulmonary vascular impedance and induction of pressure load on the RV.

- Effect of neurohumoral influence is significantly underappreciated
 - Release of factors from platelets in imbedded clot, which include:
 - Serotonin
 - Adenosine diphosphate (ADP)
 - Thrombin
 - All precipitate vasoconstriction in the pulmonary artery system
 - Development of pressure load precipitates RV decompensation and decreases RV output
 - As the heart is two hydraulic pumps linked in series
 - Diminished output of the RV will result in diminished left ventricle (LV) preload
 - Consequence of diminished LV preload is decreased CO and resultant loss of mean arterial pressure (MAP)
 - RV perfusion pressure is the difference between MAP and right ventricular end diastolic pressure (RVEDP)
 - PE increases RVEDP
 - Through induction of a RV pressure load and the development of right ventricular decompensation
 - This increases RV myocardial oxygen demand
 - Because of diminished gradient between MAP and RV subendocardium
 - Induces further RV decompensation and resultant RV ischemia
 - RV compensates through Starling mechanism
 - Increases RV volume
 - Results in left septal shift of the intraventricular septum, further jeopardizing LV filling
 - Pericardial restraint, further limits of LV filling, and further impairments of LV distensibility additionally decrease LV preload
 - Pathophysiologic sequence results in a vicious cycle of ventricular decompensation that manifests as hemodynamic instability and shock
 - PE has a spectrum of presentations and the most extreme form of PE will result in gross hemodynamic instability and cardiac arrest.
 - Care of the critically ill patient often proceeds along two parallel pathways:
 - Physiologic resuscitation
 - Generation of a differential diagnosis that eventually leads to a definitive diagnosis and treatment
 - Gas exchange abnormalities in PE are exceedingly complex.
 - A function of size and character of embolic material
 - Magnitude of occlusion against background of patients underlying cardiopulmonary status
 - Interval time since embolic event
 - Multiple causes of hypoxia have been attributed to:
 - An increase in alveolar dead space
 - Ventilation perfusion abnormalities
 - Right-to-left shunting
 - In the case of cardiogenic shock, a low mixed venous O₂
 - Although seemingly counterintuitive, multiple inert gas technique suggests a low V/Q relationship develops and precipitates hypoxia in PE.
 - Consequent to redistribution of blood flow away from embolized area
 - Resulting in excessive perfusion in unembolized lung regions and subsequent reperfusion through atelectatic area of previous clot
- There is significant correlation observed between magnitude of angiographic obstruction and mean pulmonary artery pressure (mPAP), right atrial pressure (RAP), PaO₂, and pulse.
 - Pulmonary vascular resistance (PVR) of > 500 dyne. s. cm⁻⁵ correlative with a degree of obstruction exceeding 50%
 - Depression in SpO₂ common
 - May occur with as little as 13% angiographic obstruction
 - Commonly the only clinical manifestation when obstruction is < 25%
 - When pulmonary vascular obstruction is 25% to 30%, pulmonary hypertension begins to develop (normal mPAP, 20 mm Hg)
 - Patients without underlying cardiopulmonary disease are unable to generate a mPAP > 40 mm Hg.
 - Reported maximal pressure healthy RV can generate
 - In patients without underlying cardiopulmonary disease:
 - A large single embolus
 - Or the cumulative incremental effects of multiple recurrent emboli generating obstructions over 50%
 - Needed to precipitate RV failure
 - Consequently mPAP > 40 mm Hg represents either significant underlying cardiopulmonary disease or the effects of multiple embolic events occurring over a prolonged time period, enabling the development of the right ventricular hypertrophy.
 - Relationship between PVR and extent of anatomic obstruction is hyperbolic not linear.
 - Direct increases in PVR occur when anatomic obstruction exceeds 60%.
 - In population with no underlying cardiopulmonary disease:
 - Increase in pulmonary arterial pressure (PAP) and setting of PE almost uniformly indicative of severe pulmonary vascular obstruction
 - PAP characteristically related to mPAP but generally not elevated until the latter is >30 mm Hg and anatomic obstruction exceeds 35% to 40%
 - PAP can be elevated without decreased cardiac output in patients with PE
 - However, decreased cardiac output without increased PAP suggests alternative non-PE-related diagnosis
 - Patients with previous cardiopulmonary disease characteristically manifest significantly greater degrees of cardiovascular impairment with less anatomic vascular obstruction.
 - Best exemplified in European Pulmonary Embolism Trial where 90% of patients presenting in shock had prior cardiopulmonary disease
 - 56% with prior cardiopulmonary disease presented in shock compared to only 2% of patients without cardiopulmonary disease
 - With prior cardiac disease the level of mPAP disproportionately elevated compared to that of anatomic obstruction
 - Strongly suggests underlying cardiopulmonary hemodynamics dominates presentation process
 - With mean angiographic obstruction of only 23%, significant elevations in mPAP reported in population with previous cardiopulmonary disease
 - Increment in mPAP directly related to pulmonary capillary wedge pressure (PCWP)
 - In patients with prior cardiopulmonary disease PAP reported to be unreliable indicator of magnitude of embolic event

- Limited its usefulness in assessment of extensive vascular obstruction and life-threatening disease
- No apparent consistent relationship between the extent of embolic obstruction and right ventricular impairment in patients with previous cardiopulmonary disease

Readily Available Diagnostic Studies

- Development of differential diagnosis in the undifferentiated shock patient or existing patients in ICU usually predicated on elements derived from:
 - The history
 - Physical findings
 - Readily available diagnostic studies:
 - Electrocardiogram (ECG)
 - Chest x-ray (CXR)
 - Arterial blood gas (ABG) analysis

Electrocardiogram

- Since description in 1935 of $S_1Q_3T_3$ pattern in a limited number of patients with PE-induced cor pulmonale
 - Plethora of ECG manifestation reported
 - Several important points from large series regarding ECG findings for PE helpful:
 - Normal ECG distinctly unusual
 - Reported in a minority of patients without cardiopulmonary disease (14%–30%)
 - Rhythm disturbances uncommon
 - Incidence of atrial fibrillation and flutter as presenting component of PE exceedingly small as are first-, second-, or third-degree heart blocks
 - Most common ECG findings related to abnormalities in ST-T wave segment:
 - Occurring in 42% to 49% of patients
 - Anterior T-wave inversion pattern the most common abnormality in PE
 - Occurs in 68% of patients
 - The ECG sign most correlative with severity of underlying embolic event:
 - 90% of patients with anterior T-wave inversion had Miller score >50% (mean 60%), and 81% of those had a mPAP elevation >30 mm Hg
 - Early appearance of T-wave inversion reported to be an even stronger marker of severity of event
 - It is similarly correlative with efficacy of thrombolytic therapy as T-wave normalization occurs in patients with successful thrombolytic therapy

Chest Radiograph

- CXR cannot be used to include or exclude PE.
 - It is helpful in contributing diagnostic assessment by excluding other diseases that may mimic PE and defining abnormalities necessitating further evaluation.
 - May provide a crude assessment of severity
 - Normal CXR in angiographic-proven PE unusual
 - Occurs in 16% to 34% of patients without cardiopulmonary disease
 - Appears to be association between severity of thromboembolic event and:
 - CXR findings defined by relationships between PAP, oxygen saturation

- CXR findings when normal CXR view compared to those with parenchymal and vascular abnormalities
 - Vascular abnormalities including relative oligemia in the area of embolic event were correlative with the severity of PE.
 - Other findings on CXR suggestive of PE include:
 - Abrupt cutoff of pulmonary artery
 - Relative or focal oligemia
 - Distention of the proximal portion of the pulmonary artery

Arterial Blood Gas

- Hypoxia in PE not uniform
 - PaO_2 readings >80 mm Hg seen in 12% to 19% of patients
- A normal PaO_2 does not exclude PE
 - Occurs in approximately 14% of patients
- In patients without underlying cardiopulmonary disease likely these small changes in oxygen saturation reflect low levels of severity in PE.
 - Appears to be no correlation between arterial oxygen saturation or PaO_2 and magnitude of the embolic event in patients with cardiopulmonary disease
 - Change in oxygen saturation or requirement of escalating levels of inspired oxygen should prompt consideration toward evaluation for PE
 - If capable of measuring dead space (V_d/V_t) or end-tidal CO_2 , these should similarly be used given the physiologic imprint of increased dead space with PE

DIAGNOSTIC THERAPEUTIC APPROACH

Risk Stratification

- Contemporary approach to physiologic risk stratification depicted in Figure 100.1
- Combination underlying cardiopulmonary status and embolic size that precipitates cardiac arrest surprisingly associated with mortality of only 70%
 - Underscores necessity of aggressively pursuing patients with suspected underlying PE presenting with cardiac arrest, as about 30% with PE and cardiac arrest survive
- At other extreme, predicted mortality of patients with hemodynamically stable PE and normal RV very low when treated with appropriate anticoagulation
- Combination of embolic size and cardiopulmonary status precipitating decompensation resulting in shock associated with 30% mortality
 - Syncope and emboli in transit have predicted mortalities just below that of shock patient
- An anatomic obstruction of approximately 30% necessary to elevate PAP and precipitate RV dilatation
 - Presence of hemodynamic deterioration or shock in PE represents the failure of compensatory mechanisms to maintain forward flow and is associated with significant increases in mortality; shock traditionally used as discriminator to define likelihood of survivorship from PE.
 - Presence of shock in PE associated with three to seven times increase in mortality

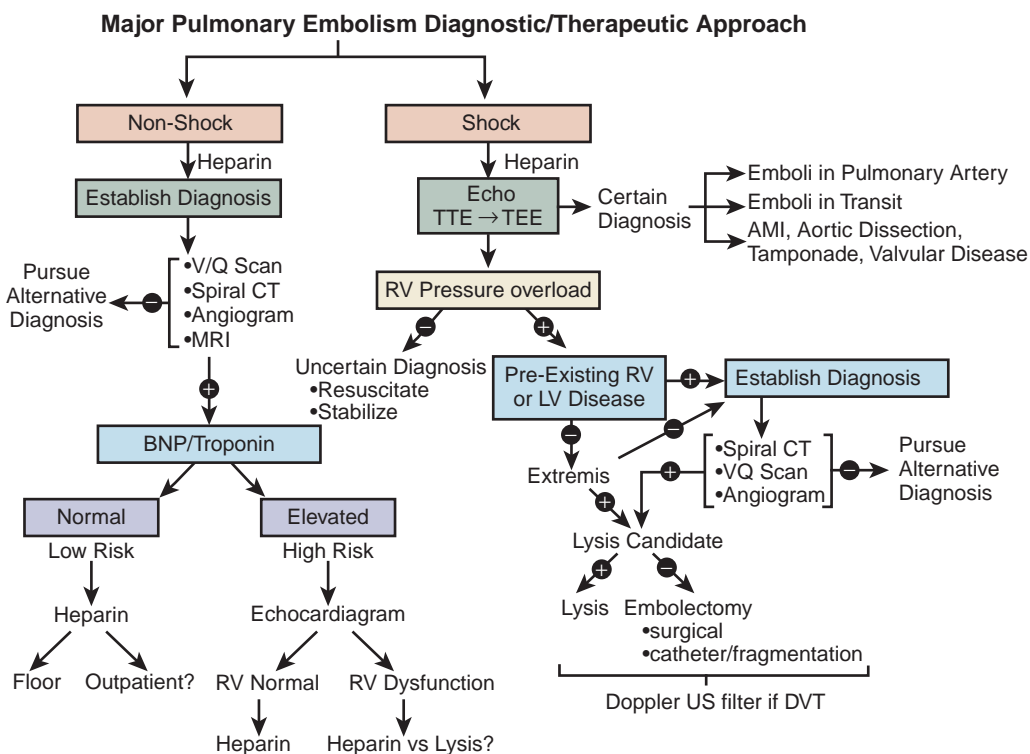

FIGURE 100.1. Diagnostic therapeutic approach to pulmonary embolism. AMI, acute mesenteric ischemia; CT, computed tomography; DVT, deep vein thrombus; LV, left ventricle; RV, right ventricle; TEE, transesophageal echocardiography; TTE, transthoracic echocardiography; US, ultrasound; V/Q, ventilation/perfusion.

- Vast majority of patients with anatomically massive PE do not present in shock
 - Without underlying cardiopulmonary disease, associated anatomically massive PE presents with a normal cardiac output
 - Hemodynamically stable patients not in shock, who have experienced submassive or massive PE, have similar mortality rates
 - Anatomically massive PE unaccompanied by physiologic decompensation resulting in shock and hemodynamic instability does not appear to be associated with increased mortality
- Spiral CT scanning supplanted ventilation/perfusion scanning as diagnostic modality of choice in PE
 - In patients with elevated creatinine or inability to tolerate CT scan, V/Q scanning is a reasonable alternative given the overwhelming experience using this technique
 - Pretest probability characterizations are pivotal in the diagnosis of PE whether CT scanning or ventilation/perfusion scanning is used
- Further risk stratification of hemodynamically stable patients with PE may be undertaken using brain natriuretic peptide (BNP) and troponin levels.
 - Patients with hemodynamic stability and confirmed PE with normal BNP and troponin levels have an excellent predicted outcome.
 - Presence of elevated BNP and troponin define a high-risk population.
 - Warrant admission and close observation
- Patients with suspected PE and hemodynamic instability at high risk for rapid deterioration and sudden death
 - Demands expeditious approach to diagnosis, resuscitation, and therapy
 - Echocardiography ideal first assessment of hemodynamically unstable patient
 - Findings suggestive of PE include:
 - Right-sided thrombi
 - RV dilatation
 - Hypokinesis
 - Tricuspid regurgitation
 - Paradoxical shifting of ventricular septum
 - Echocardiographic findings of acute myocardial infarction, tamponade, aortic dissection, or valvular disease may be equally useful in confirming the diagnosis and excluding PE.
 - In patients without underlying cardiopulmonary disease
 - Magnitude of abnormalities on echocardiogram correlate with the degree of pulmonary artery outflow obstruction
 - An obstruction of 30% is necessary to produce RV dilatation
 - Presence of RV dysfunction not specific for PE
 - May be seen in spectrum of diseases ranging from RV infarct with cardiomyopathy to cor pulmonale and antecedent pulmonary hypertension
 - Echocardiographic findings reported to be useful in differentiating PE from non-PE events
 - Patients with baseline cor pulmonale or recurrent PE characteristically have evidence of RV hypertrophy with thickness measuring >5 mm and minimal septal shift

- Acute RV failure secondary to PE should not be associated with RV hypertrophy nor accompanied by a septal shift
- In patients with pre-existing cardiopulmonary disease, it is imperative to establish diagnosis of PE
 - Spiral CT scanning has supplanted V/Q scans in the critically ill population
 - In patients with confirmed PE candidacy for either medical thrombectomy with thrombolytic therapy or surgical embolectomy should be undertaken
 - Crucial to recognize that absence of RV pressure overload in unstable patient in whom PE is being considered effectively excludes PE as cause of hemodynamic instability
 - In appropriate clinical context, patients without underlying cardiopulmonary disease who are in extremis and with anticipated arrest, with evidence of RV dilatation and high pretest probability for PE, may be considered as candidates for medical embolectomy with thrombolytic therapy or surgical embolectomy without complete workup

Resuscitation and Stabilization

- Escalating oxygen requirements may necessitate intubation and mechanical ventilation.
- Intubation may precipitate cardiovascular collapse with major PE for several reasons:
 - Sedative hypnotics used for intubation can mitigate the catecholamine surge on which a patient is dependent and similarly produce vasodilatation, which impairs the perfusion pressure gradient to RV subendocardium, provoking further ischemia and cardiac decompensation.
 - Excessive lung ventilation on initial intubation may create air trapping and diminish venous return.
 - Initiation of MV can increase the pulmonary vascular resistance and further jeopardize RV function.
- Volume expansion with 1 to 2 L of crystalloid solution is initial treatment for hypotension in patients with undifferentiated shock
 - In patients with PE-related shock, increases in RV pressure and volume generate significant increases in systolic wall stress, provoking myocardial ischemia.
 - Excessive fluid resuscitation further dilates the RV and produces increased wall stress, resulting in further RV decompensation.
 - In patients with anatomically massive PE and low cardiac output who were normotensive and required vasopressors on presentation, increased cardiac output with a 500-mL fluid challenge was reported.
 - Increase in cardiac output was consistently proportional to baseline RV end diastolic volume index.
 - Therefore, fluid may be used judiciously in normotensive patients without evidence of significant RV dysfunction.
 - In patients with echocardiographic evidence of severe RV dysfunction, fluid resuscitation may provoke increased wall stress, ischemia, and RV dysfunction.
 - When measured RV pressures are high or there is evidence of severe RV dysfunction, early consideration should be given to vasopressor therapy.
- No controlled human trials related to vasoactive support in PE
 - Extrapolation from animal models suggests that norepinephrine improves RV dysfunction through vasoconstriction that augments MAP and enhances perfusion pressure gradients to RV subendocardium
 - Additionally, norepinephrine possesses modest inotropic properties shown to provide complementary enhancement of RV function
 - May be reasonable to consider use of inhaled nitric oxide to decrease pulmonary vascular afterload in patients with evidence of pressor dependant severe RV dysfunction
 - Small reports suggest that inhaled prostacyclin and nitric oxide will increase cardiac output, decrease PAP, and improve gas exchange in cases of shock-related PE.
- Presence of shock or hemodynamic decompensation with proven PE an indication for either medical embolectomy with thrombolytic therapy or surgical embolectomy
- Use of thrombolytic therapy controversial in patients hemodynamically stable; it is acknowledged as the therapeutic choice in hemodynamically unstable patient
 - There is greater rapidity in rate of resolution when comparing heparin to thrombolytic therapy in terms of the percentage resolution detected by perfusion scanning and angiography up to day 7 of diagnosis; thereafter there is no difference in the degree of embolic resolution.
 - By 1 year, the extent of angiographic resolution was 77% in the heparin group and 78% in the urokinase group (Tables 100.2 and 100.3).
 - There does not appear to be any difference related to the effectiveness of thrombolytic agents provided they are given in equivalent doses over a similar timeframe.
 - Assessing efficacy of thrombolytic therapy difficult in first several hours
 - Mortality in group that underwent successful embolectomy was 0% compared to 30% mortality in group that failed to respond to thrombolytic therapy
 - As continuous echocardiography and imaging studies are not available, monitoring of end-tidal CO₂ proposed to monitor the efficacy of thrombolytic therapy
 - End-tidal CO₂ significantly increases in patients who survived with thrombolytic therapy compared to those with no appreciable change in end-tidal CO₂ measurements in patients who did not survive
 - Unsuccessful thrombolysis reported to occur in approximately 8% of patients undergoing therapy
 - In limited literature that compares repeat thrombolysis to surgical thromboembolectomy, there appears to be significant survival benefit in undertaking surgical embolectomy.
 - Mortality in patients undergoing surgical embolectomy after failed thrombolytic therapy was reported to be 7% compared to 38% of patients who underwent repeat thrombolysis.
 - Recurrent PE significantly higher in patients who underwent repeat thrombolysis and was the cause of death in a significant number
 - Patients who underwent surgical thromboembolectomy also had the placement of vena cava filters
- Thrombolytic therapy in hemodynamically stable patients remains a controversial topic.

TABLE 100.2

RATE AND EXTENT OF PERFUSION SCAN RESOLUTION IN UROKINASE PULMONARY EMBOLISM TRIAL (UPET)

	Heparin 25.4%		Urokinase 26.2%	
	Absolute resolution (%)	Resolution (%)	Absolute resolution (%)	Resolution (%)
24 hours	2.7	8.1	6.2	22.1
Day 2	4.9	17	8.0	25.8
Day 5	9.3	35.5	11.3	40.6
Day 14	14.7	58.2	14.9	52.0
1 year		77.2		78.8
No CPD → 90% resolution		91% of patients		88% of patients
CPD → 90% resolution		72% of patients		77% of patients

CPD, cardiopulmonary disease.

From Urokinase pulmonary embolism trial. Phase 1 results: a cooperative study. *JAMA*. 1970;214:2163–2172; and Urokinase pulmonary embolism trial. *Circulation*. 1973;47(Suppl):1–108.

- Long-term outcome of patients with thrombolytic therapy not well described but it appears that most undergo an uneventful course
 - Mortality is approximately 8%
 - Major bleeding reported in 9.6%
 - Recurrent PE reported in 7.6%
 - Mean vascular obstruction diminished from 64% to 29% within 48 hours, and RV function was reversible within 48 hours in 80% of patients
 - Lung scan improved 45% within 6 to 8 days of therapy
 - Predictive indicators of poor hospital course in patients receiving thrombolytic therapy were initial pulmonary vascular obstruction >70% and hemodynamic instability at presentation associated with persistence of paradoxical septal motion on echocardiography.
 - Long-term mortality related to older age, persistence of vascular obstruction >30% after thrombolytic therapy and cancer
- Surgical embolectomy indicated for patients presenting in shock or cardiopulmonary instability and an inability to tolerate thrombolytic therapy
- Ideally, these emboli are large and located centrally and consideration of embolectomy is undertaken prior to cardiac arrest.
- Requires preoperative localization via CT documentation and ideally echocardiographic of right heart function
- In the era of modern surgical embolectomy there was a 6% operative mortality and only 12% late deaths from disease other than PE
- The overall improvement in operative mortality related to surgical thromboembolectomy most likely relates to preoperative selection of patients who had not experienced cardiac arrest and the use of cardiopulmonary bypass.
- Approach to hemodynamically stable patients with PE and RV dysfunction remains controversial and contentious
 - Use of BNP, which is indicative of right ventricular stress, and troponin levels, which are indicative of myocardial ischemia, have been used in the stratification.
 - Biomarkers reported to allow for severity characterization of patients with PE
 - Where there is absence of elevation in BNP or troponin predicted outcome is excellent and these patients do not warrant intensive care evaluation
 - Elevations in BNP and troponin levels are associated with a higher mortality and are evolving as discriminators for use of thrombolytic therapy in patients with PE

TABLE 100.3

RANDOMIZED TRIALS: LYSIS VERSUS HEPARIN

Study	Early				Late

CHAPTER 101 ■ OTHER EMBOLIC SYNDROMES (AIR, FAT, AMNIOTIC FLUID)

GAS EMBOLISM

- Gas embolism is defined as the entrance of gas into the vascular compartment.
- Air and other gases, CO₂ and nitrogen, may result in gas emboli
- Gas may reach any organ
 - Most significant damage is to the organs with high oxygen consumption rates, such as brain and heart
- Gas embolism can be venous or arterial
- Most frequently, it is an iatrogenic problem that may be fatal (Table 101.1)
 - Highest-risk surgical procedures for venous air embolism (VAE) are: sitting neurosurgical operations, posterior fossa and neck surgery, laparoscopic procedures, total hip arthroplasty, cesarean section, and central venous line procedures—both placement and removal.
 - During a neurosurgical procedure in the sitting position, air usually enters through the noncollapsing veins, including the dural venous sinuses and emissary veins.
 - While true incidence of VAE is unknown, as most cases are asymptomatic and the sensitivity of detection methods differs significantly, incidence is reported to be between 7% and 50% using Doppler detection methodology.
 - One study that used the transesophageal detection method reported an incidence of 76%.

Pathophysiology

- Severity of gas embolism related to volume of gas entering circulation as well as rate of gas accumulation
- Fatal gas volume in humans is unknown, but in a canine model, it is 7.5 mL/kg
- Estimated fatal volume for humans is between 200 and 300 mL
 - With underlying impaired cardiac contractility, volume of air needed to cause cardiac arrest is less than in adults with normal cardiac function
- Entry of air into pulmonary venous system acutely increases pulmonary artery pressure, degrades gas exchange, and provokes cardiac dysrhythmias.
- Mean arterial pressure (MAP) decreases rapidly, perhaps secondary to an immediate decrease in cardiac output or due to a reflex mechanism resulting in the release of vasoactive substances.
- A “paradoxical” gas embolism can occur with a right-to-left shunt.
 - As in patient with a patent foramen ovale

- Term *paradoxical* used as the right-sided pressures need be higher than those on the left side for passage of the gas from right to left heart
 - These may be increased with the application of positive end-expiratory pressure (PEEP), the Valsalva maneuver, and/or a venous air embolism (VAE), creating a right-to-left shunt
 - Hypoxemia and hypercapnia seen with gas embolism primarily related to V/Q inequality
- Arterial gas embolism (AGE) is caused by entry of gas into the arterial system.
 - Can be caused by venous gas embolism entering arterial circulation via a right-to-left shunt or directly via the pulmonary capillary bed by overloading of the pulmonary filtering capacity
 - In compressed air diving, the cause of AGE is pulmonary overpressurization by failing to exhale or due to regional gas trapping during ascent.
 - Leads to alveolar rupture and entry of gas into pulmonary capillaries
 - Iatrogenic causes include accidental air injection during cardiopulmonary bypass or angiography
 - Can also be caused by pulmonary barotrauma during mechanical ventilation
 - Rarely a complication of thoracic trauma and lung surgery
 - Gas distribution to organs dependent on blood flow
 - Gas entering coronary circulation may result in a typical infarct
 - Gas passing into cerebral circulation may cause ischemic stroke

Diagnosis

- Most important diagnostic tool is patient history
 - If patient has undergone high-risk procedure, a high index of suspicion for gas embolism required
- Most common symptoms and signs are acute dyspnea and hemodynamic instability
 - Numerous nonspecific symptoms and signs including nausea, vomiting, respiratory distress, tachypnea, wheezing, chest tightness, pallor, sweating, tachycardia, bradycardia, hypotension, and sudden cardiac arrest
 - Neurologic symptoms may include acute dizziness, unconsciousness, paresthesias, paraparesis, paraplegia, and/or seizures
 - So-called mill-wheel murmur is auscultated in precordial area
 - Secondary to the presence of air in the cardiac chambers
 - Hemodynamic changes may be initial signs of gas embolism
 - Hypotension and acute increase in pulmonary arterial pressure (PAP) observed at early periods of gas embolism

TABLE 101.1**ETIOLOGY OF GAS EMBOLISM**

Decompression injury	
Vascular entrance of gas	Central line placement and removal Arterial catheterization Invasive radiologic procedures Intra-aortic balloon rupture IV fluid administration Rapid IV infusion systems
Gastrointestinal procedures	Gastrointestinal endoscopy Laparoscopic surgery Endoscopic retrograde cholangiopancreatography
Neurosurgical procedures	Sitting-position craniotomies Posterior fossa surgery Cervical laminectomy Spinal fusion Deep brain stimulator placement Lumbar puncture Epidural catheter placement
Neck procedures	Radical neck dissection Thyroidectomy Nd:YAG laser surgery
Ophthalmologic procedures	Eye surgery
Cardiac procedures	Extracorporeal bypass Coronary angiography
Obstetric and gynecologic procedures	Cesarean section Intravaginal, intrauterine gas insufflation during pregnancy
Orthopedic procedures	Hip surgery Spinal surgery Gas insufflation during arthroscopic surgery
Urologic procedures	Transurethral prostatectomy Radical prostatectomy
Thoracic procedures	Lung biopsy Lung trauma Thoracoscopy Chest tube placement

- Central venous pressure (CVP) may increase, along with a right ventricle (RV) pressure increase due to elevated PAP or air in RV
- Differential diagnosis is noted in (Table 101.2)
- End tidal CO₂ (PetCO₂) routinely used in operating room and increasingly available for intubated ICU patients
 - Case reports of sudden and severe drop in PetCO₂ values in gas embolism
 - Rapid progressive fall in PetCO₂ a sign of gas embolism despite normal blood pressure
 - Sudden or progressive drop in PetCO₂ not specific sign of gas embolism
 - May indicate presence of important complication
 - Pulmonary thromboembolism, pneumothorax, or airway obstruction
- Pulse oximetry is standard of care for operating room procedures as well as for ICU patients
 - Sudden drop in pulse oximetric measured oxygen saturation (SpO₂) a common finding of gas embolism
 - Typically indicates a severe disturbance of pulmonary function

TABLE 101.2**DIFFERENTIAL DIAGNOSIS OF GAS EMBOLISM**

Pulmonary embolism	Thromboembolism Fat embolism
Respiratory failure	Pulmonary edema Acute bronchospasm Pneumothorax
Stroke	
Cardiac events	Myocardial infarction Pericardial tamponade Arrhythmias with hemodynamic compromise
Shock	Cardiogenic Septic Hypovolemic
Hypoglycemia	

- Chest x-ray (CXR) may show air in vascular compartments and heart
- Electrocardiogram (ECG) changes may be observed related to myocardial ischemia.
 - Often, first change noted is peaking of the P wave; S-T segment depression can follow peaking of P wave, depending on the severity of gas embolism
- Hemoconcentration, related to a shift of intravascular fluid to extravascular space, may be observed.
- Precordial Doppler a sensitive indicator that can be used to detect gas embolism
 - Placed on left parasternal border (second or third intercostal space) during a high-risk procedure and appears to be very accurate in diagnosing gas embolism
- Transthoracic echocardiography (TEE) the most sensitive method for detecting gas embolism
 - Considered gold standard, but is costly and more invasive than precordial Doppler
 - TEE increasingly used for routine intraoperative monitoring for detection of VAE during high-risk surgeries such as sitting craniotomies.
 - A patent foramen ovale (PFO) can be detected with TEE
 - May allow identification of patients at high risk for paradoxical gas embolism
- Esophageal Doppler a sensitive indicator of air embolism
 - Optimal position for VAE detection at level of superior vena cava (SVC) above its junction with right atrium (RA)
- Air embolism after catheter removal through the residual tract reported many times in literature
 - Proper maintenance of entrance site should be performed
- VAE via disconnected line or fractured catheter hub may also occur
- CO₂ embolism can occur during laparoscopic surgery.
 - Most commonly occurs when pneumoperitoneum created through a tear in a vessel in the abdominal wall or peritoneum
 - If CO₂ embolism is suspected, insufflation of gas should be discontinued
- Application of PEEP not helpful in preventing air embolism during sitting-position craniotomies
 - Furthermore, it may be harmful
- Low CVP may increase the negative pressure gradient between the atrium and wound site and, thus, the risk for VAE.
 - Increasing CVP to upper normal limits can decrease the risk for VAE
- Aggressive resuscitation and CPR is started immediately following collapse of patient.
 - Aggressive volume resuscitation recommended to increase right arterial pressure (RAP)
 - Can prevent further air entry into the venous circulation
 - FiO₂ = 1.0 maximizes oxygenation of patient
 - Can also decrease volume of embolus via elimination of nitrogen component of embolus
 - Aspiration of air from RA with existing CVL may remove up to 60% of air
 - Our experience with this technique not uniformly positive
 - Catheter type and position very important for successful removal of air
 - Multiorifice catheters are superior to single-lumen catheters

Prevention and Treatment

- Gas embolism in ICU is mostly iatrogenic and mostly preventable
- Patient positioning after suspected VAE controversial
 - Recent studies that compared different positions in canine models of VAE showed no benefit of left lateral recumbent and LLR head-down over supine positions
 - Claimed that placing patients with suspected VAE in supine position might afford better opportunity to administer supportive therapy, including ventilatory support and oxygen, to establish access for catecholamine delivery and perform CPR
 - Trendelenburg position may not decrease incidence of cerebral microembolism compared to the supine position
- Positioning of patients during central venous line (CVL) placement and removal also a matter of debate
 - Our practice is to place patients who will have a SCV or internal jugular vein (IJ) CVL inserted in head-down position
 - Only situation in which this may not be appropriate is if the patient has elevated intracranial pressure (ICP) or severely compromised pulmonary function
 - Policy also utilized for removal of CVLs
 - Placement or removal of femoral CVLs would indicate that patient be placed in reverse Trendelenburg
 - Placement or removal of CVLs should essentially never be done while patient is sitting
 - If cooperative, patient may be asked to perform Valsalva maneuver (i.e., breath holding during expiration and humming), which can increase venous pressure

Treatment for Arterial Gas Embolism

- Mechanical ventilation (MV) in intubated patients can decrease the time it takes to eliminate air from cerebral arteries if performed at FiO₂ = 1.0.
 - Hyperventilation currently not recommended in MV patients
- Seizures after cerebral embolism may not respond to benzodiazepines.
 - Although barbiturates can suppress seizure activity in these patients
- Hypotension should be avoided, as this can increase bubble entrapment and decrease cerebral blood flow (CBF).
 - Short period of hypertension can facilitate bubble redistribution through the arterioles to the capillaries and veins

Hyperbaric Oxygen Therapy (HBO)

- HBO therapy recommended for cerebral air embolism and is gold standard for AGE
- Patients breathe FiO₂ = 1.0 at supra-atmospheric pressures with HBO
 - Pressure in chamber decreases volume of air bubbles and creates hyperoxia

- With HBO, alveolar PO₂ can reach 2,000 mm Hg
 - Hyperoxia creates diffusion gradient for O₂ and N₂ in air bubble
 - Majority of oxygen dissolved in plasma
 - High levels of oxygen carried to tissues can help to reduce cerebral ischemia
 - HBO prevents further brain edema development by reducing vascular permeability
- Optimal time to start HBO unclear
- Immediate treatment has best response
- Delayed therapy, >6 hours after injury, may still have benefits
- Decision for HBO therapy for delayed cases based on patients clinical status and transport risk

FAT EMBOLISM

- Fat embolism in patient with severe crush injury was first described by Zenker in 1862
- Still no single definition for fat embolism syndrome (FES)
- Fat embolus is a pathophysiologic condition, and FES is a clinical condition that occurs with fat embolus
 - Classic presentation of FES is petechial rash, respiratory distress, and confusion, with onset of 24 to 48 hours following pelvic or long bone fracture
 - Clinically most crucial part of FES is respiratory insufficiency
 - Can easily be confused with other concomitant problems such as lung contusion, aspiration, and pulmonary edema
 - Mental status changes may be secondary to cerebral contusion, drugs, and systemic inflammatory response syndrome (SIRS), in addition to FES
 - If petechial rash is delayed or absent, diagnosis may be very difficult
 - FES resulted in a 10% to 20% mortality rate in the 1960s and, although it has declined since then, mortality still remains high
- FES reported to occur most commonly with long bone fractures, it is also associated with:
 - Bone marrow transplantation
 - Sickle cell disease
 - Pancreatitis
 - Liposuction
 - Soft tissue injuries
 - Extracorporeal circulation
 - Burns
 - Decompression sickness or high altitude
 - Osteomyelitis
 - Fatty liver
 - Epilepsy
- Diagnostic criteria for FES proposed by Gurd are widely used, but not universally accepted.
 - Clinical features of FES divided into major and minor features (Table 101.3)
 - Diagnosis of FES requires presence of one major and four minor criteria according to Gurd
 - Fat embolism index score is defined for predetermined and designated clinical signs and symptoms (Table 101.4)
 - Score of 5 or more is diagnostic of FES, and negative if <5

TABLE 101.3

CLINICAL FEATURES OF FAT EMBOLISM

Major	Petechial rash Respiratory symptoms and bilateral infiltrates on chest radiograph Altered mental status
Minor	Tachycardia Fever Retinal fat or petechia Anuria, oliguria, fat globules in urine Sudden drop in hemoglobin level Sudden thrombocytopenia High erythrocyte sedimentation rate Fat globules in sputum

Epidemiology

- Difficult to estimate the true incidence of fat embolism
 - No universal definition
 - Many cases with fat embolus may not develop FES
 - True incidence of FES probably higher than the reported rates of 19% in patients with major trauma
 - Occurrence of fat embolism in autopsy reports in trauma patients ranges between 52% and 96%
 - Only 1% to 5% of patients develop FES
 - Incidence of FES related to femoral shaft fractures reported as 0.9% to 13.2%
 - Depending on type of fracture and time of stabilization
 - Most recent data suggest an incidence of FES 0.9% to 11% among trauma patients with long bone fractures
 - FES seldom occurs with fractures of the upper limb
 - Patients with nailing of lower extremity found to have embolic showers in 41% of cases
 - Only 16% defined as severe
 - Fat emboli noted by TEE in:
 - 94% of pathologic femur fractures
 - 59% severe, defined as FES with respiratory distress
 - 62% of femur fractures (6% severe)
 - 94% of tibial fractures (none severe)
 - Paradoxical embolus may occur in patients with PFO and increases mortality risk
 - Hypoxemia seen in 35% to 74% of these patients
 - An alveolar-arterial gradient above 20 mm Hg observed in nearly all patients with uncomplicated long bone and pelvic fractures

TABLE 101.4

FAT EMBOLISM INDEX SCORE

Symptom or sign	Points*
Petechiae	5
Diffuse alveolar infiltrates	4
Hypoxemia (PaO ₂ <70 mm Hg)	3
Confusion	1
Fever ≥38.5°C	1
Tachycardia ≥120 beats/min	1
Tachypnea ≥30 breaths/min	1

*A positive fat embolism syndrome score is ≥5 points.

- Incidence of full-blown FES decreased from 22% to 1.4% after implementation of internal fixation in patients with long bone fractures
- Timing of fracture fixation has important impact on incidence of FES
 - Early surgery resulting in lesser risk by as much as fivefold
 - Reports have shown no difference between plating versus nailing
- Incidence of FES increases with:
 - Number of fractures
 - In military situations, in those with femoral shaft fractures from high-velocity missile wounds of the thigh
 - Absent in those with low-velocity missile wounds without fracture

Pathophysiology

- Two explanations of pathophysiologic mechanisms of FES are mechanical and biochemical theories, these are likely intimately related.
- When bones fracture, or medullary channel is manipulated or pressurized
 - Fat cells disrupted and enter venous circulation
 - Large fat globules and spongiosa bone fragments obstruct pulmonary capillaries
 - Smaller fat globules bypass pulmonary circulation and enter systemic circulation
 - Major systemic emboli occur with migration of fat globules through pulmonary capillary circuit
 - As previously mentioned, with an intracardiac defect such as a PFO there can be direct access of fat particles to the systemic circulation.
 - PFO seen in 20% to 30% of population
 - Mechanical obstruction of the pulmonary artery (PA) with fat may be an important reason for immediate death after trauma.
 - Obstruction of cerebral capillaries may be cause of altered mental status observed in FES
 - Petechial hemorrhages may be secondary to the presence of fat emboli in the subcutaneous capillaries
 - Manipulation of the bone medulla during surgery increases intramedullary pressure, normally ranges between 30 and 50 mm Hg
 - In animal models, intramedullary pressure of 300 to 400 mm Hg results in fat emboli in vena cava blood even when bone intact
- According to biochemical theory, increased levels of free fatty acids (FFAs) after bone fracture or manipulation have a direct toxic effect on pneumocytes.
 - FFAs can be freely moving in circulation or accumulate in pulmonary capillaries
 - Capillary leakage, clot formation, and platelet adhesion resulting from toxic effects of FFAs lead to organ damage
 - Lipase released from pneumocytes breaks down bone marrow fat to glycerol and free fatty acids, the latter in toxic concentrations
 - FFA damage to pulmonary endothelium results in capillary damage and nonhydrostatic pulmonary edema
 - Role of PMNLs in FES not clear
 - IV injection of fat may result in accumulation of PMNLs in pulmonary capillaries
 - Lung tissue damage, as well as neutrophil and platelet activation, leads to the release of vasoactive substances:
 - Histamine, serotonin, and bradykinin
 - Result is inflammation and edema, with resultant respiratory distress and multiorgan system failure
 - Manipulation of bone, with resultant fat embolism, is the reason for the hypercoagulable state seen after orthopedic surgery
 - Includes increased platelet aggregation and tissue factor release
 - NO, phospholipase (PL)-A₂, O₂-free radicals, and proinflammatory cytokines such as tumor necrosis factor (TNF)- α , interleukin (IL)-1 β , and IL-10 play a role in pathogenesis of FES-induced acute respiratory distress syndrome (ARDS)
 - Alveolar macrophages are probably the major source of inducible NO synthase, producing NO in the lung
 - Neurologic signs of FES likely occur via several mechanisms:
 - Cerebral blood vessel occlusion by fat emboli
 - Disruption of blood–brain barrier due to toxic FFAs
 - Obstruction due to alteration in the solubility of fat in blood

Clinical Presentation and Diagnosis

- No universal definition for FES
 - Diagnosis of FES requires high index of suspicion in proper setting
 - Is a diagnosis of exclusion
 - Severity of symptoms and signs depends on size of fat embolus
 - Classical triad for fat embolism includes respiratory insufficiency, altered mental status, and upper extremity and thoracic petechiae
 - All three are seldom seen together
 - Most commonly used criteria for FES defined by Gurd
 - Major and minor signs and symptoms
 - One major and four minor criteria required for FES diagnosis (see Table 101.3)
- Clinical signs do not usually appear within 12 hours after injury
 - Major signs appear within 24 hours in 65% and within 48 hours in 85% of patients
 - Most common signs and symptoms of FES are:
 - Hypoxia, fever, tachycardia, anemia, and altered mental status
 - Early fever, >38.5°C, a common sign and may be seen at emergency department presentation
 - In trauma patients with fractures, early fever raises suspicion of fat embolism
 - Petechiae important findings, but present in one-third of patients
 - Microscopic examination of petechiae reveal fat droplets obstructing capillaries
 - Respiratory involvement the most common feature, with tachypnea, dyspnea, and bilateral diffuse infiltrates evident on CXR
 - Cyanosis observed if hypoxia is significant, but anemia along with FES can prevent the occurrence of cyanosis even with significant hypoxia

- The PaCO₂ decreases secondary to hyperventilation
 - If pulmonary deterioration continues, it may rise
- CXR shows diffuse bilateral pulmonary infiltrates
 - 70% of patients show CXR changes within 24 and no later than 48 hours after injury
- Early clinical signs of FES are actually signs of SIRS
 - Clinical presentation of FES very similar to ARDS with multiple organ failure
 - Retinal examination may reveal exudates, hemorrhages, and, rarely, fat globules
- High-resolution chest CT scan findings of FES include ground glass opacities, which may be associated with thickened interlobular septa
 - Patchy distribution resulting in a “geographic” appearance, which represents the existence of normal and abnormal lung areas with sharp borders and nodular patterns, also observed
 - Resolution of the abnormalities occurs within 2 weeks
- Cerebral manifestations can occur with a wide range of symptoms ranging from confusion, drowsiness, and lethargy to convulsions and coma
 - Pulmonary contusion along with long bone fractures may increase the risk for cerebral fat embolism
 - Typically cerebral CT scan reveals no abnormalities
 - Cerebral MRI may demonstrate hypointense lesions, disruption of the blood–brain barrier, and multiple diffuse foci of hyperintensity in the white matter of the subcortical, periventricular, and centrum semiovale regions, as well as changes related to vasogenic edema, petechial hemorrhages, or hemorrhagic infarcts involving gray and white matter ranging in size from a few millimeters to several centimeters.
 - Transcranial Doppler study in trauma patients with long bone fractures can detect cerebral fat embolism.

Treatment

- No specific treatment for FES
- Therapy is mostly supportive
- General goals for hypoxic respiratory failure instituted for presumed FES:
 - Methylprednisolone prophylactically may reduce incidence of FES and can reduce the degree of hypoxemia associated with long bone fractures of the lower extremity.
 - High-dose prophylactic steroids with aspirin can result in significant normalization of blood gases, coagulation proteins, and platelet numbers.
 - Prophylactic steroids did not improve mortality in any of the studies
 - Fluid loading, which dilutes the amount of free fatty acids, or increased glucose intake, which decreases free fatty acid mobilization, not found helpful
 - FES may lead to cerebral edema and increased ICP
 - If there are signs of cerebral edema, ICP monitoring recommended
 - Analgesia and sedation appropriately titrated to allow for frequent neurologic examinations of patient
 - Ethanol shows no benefit in prevention of fat embolism
- Early fixation of long bone fractures helpful to prevent occurrence of FES

- Long bone fixation may result in additional embolizations and FES
- But delayed stabilization of fracture in patient with multiple injuries increases incidence of pulmonary complications (ARDS, fat embolism, and pneumonia) as well as hospital and ICU stay

AMNIOTIC FLUID EMBOLISM (AFE)

- Ricardo Meyer first described entry of amniotic fluid into the maternal circulation in 1926
- AFE not recognized as syndrome until 1941 with report of sudden death of woman during labor with fetal mucin, amorphous eosinophilic material, and squamous cells in pulmonary vessels
- AFE an uncommon and catastrophic syndrome that occurs during pregnancy or shortly after delivery
 - Pathophysiology thought to involve embolization of amniotic fluid
 - But syndrome results from biochemical mediators released after embolization occurs
 - Suggested that syndrome be renamed as the “anaphylactoid syndrome of pregnancy” because of similarities among the characteristics of AFE, septic shock, and anaphylactic shock
- AFE an important cause of maternal death in developed countries
 - With high morbidity and mortality rates
 - Associated mortality and morbidity has dramatically decreased to approximately 16% recently
 - May be due to improved recognition of the disorder
 - So that even mild cases are included in the analysis
 - As well as to improvements in resuscitation

Epidemiology

- True incidence is not known
- AFE thought to account for up to 10% of maternal deaths in United States
- United Kingdom AFE registry investigated maternal and fetal morbidity and mortality rates between 1997 and 2004
 - Data of 44 women with AFE studied
 - Maternal death rate 29.5% (13 patients)
- Incidence of pulmonary embolism (PE) cases associated with pregnancy and/or delivery 0.8% of total PE cases in Japan
- AFE found in 73.3% (33 of 45) of the PE cases with vaginal delivery and in 21.2% (7 of 33) of PE cases with cesarean delivery
- AFE identified in 19 patients between 1971 and 1988 in Swedish studies
 - Occurred during labor in 70% of the women
 - After vaginal delivery in 11%
 - During cesarean section in 19%
- In the Maternal Health Study Group of the Canadian Perinatal Surveillance System between 1991 and 2002, total rate of AFE was:
 - 14.8 per 100,000 multiple deliveries
 - 6.0 per 100,000 singleton deliveries
 - Mortality rate was 0.8 per 100,000 singleton deliveries
 - None was fatal in multiple deliveries

- In 1,094,248 deliveries during a 2-year period, 53 singleton pregnancies had the diagnosis of AFE, for a population frequency of 1 per 20,646 pregnancies
- A series of 10 cases of AFE had a maternal mortality rate of 22%
 - Neonatal survival rate was 95%
 - Routine discharge was reported as 72%

Pathophysiology

- Pathophysiology of AFE remains unclear
- Uterine contractions during normal labor force amniotic fluid into the maternal venous circulation through small tears in the lower uterine segment or high endocervical canal
- For AFE to occur, there must be a pressure gradient favoring the entry of amniotic fluid from the uterus into the maternal circulation, as well as ruptured membranes
- Small tears in lower uterine segment and endocervix common during labor and delivery
 - Now thought to be the most likely entry site
 - Two separate life-threatening processes seem to occur either simultaneously or in sequence: cardiorespiratory collapse and coagulopathy

Cardiorespiratory Collapse

- Conventional explanation states particulate matter such as fetal squamous cells, lanugo, and meconium contained in the amniotic fluid produce pulmonary vascular obstruction, leading to pulmonary hypertension, right- and left-sided heart failure, hypotension, and death.
- Current evidence suggests mechanical origin less likely than immunologic reaction.
 - Pulmonary vasospasm causes physiologic PA obstruction in reaction to abnormal substances such as leukotrienes and metabolites of arachidonic acid in amniotic fluid.
 - Arachidonic acid metabolites implicated in inflammatory response, and may in part be responsible for AFE
 - Presence of these metabolites in AFE suggests a possible humoral mechanism
 - Humoral pathways invoking a proinflammatory response with release of cytokines and arachidonic acid metabolites in AFE, anaphylaxis, and shock may be responsible for the similar clinical presentation
 - Complex inflammatory cascade with mediator release leads to SIRS and development of multiple organ system failure
- Mild to moderate PAP elevations only transiently noted in AFE
 - Biphasic model proposed to explain hemodynamic abnormalities
 - Acute pulmonary hypertension and vasospasm the initial hemodynamic response
 - Resulting right heart failure and accompanying hypoxia could account for the cases of sudden death or severe neurologic impairment
 - Limited hemodynamic data obtained by invasive pulmonary artery monitoring or echocardiography during the hyperacute phase of AFE demonstrated left ventricle (LV), not RV, failure as dominant finding
 - Myocardial dysfunction may be the result of a sudden increase in maternal plasma endothelin levels that occurs with introduction of amniotic fluid, which contains a high concentration of endothelin.

Disseminated Intravascular Coagulation (DIC)

- DIC commonly observed as late sequela of AFE
 - May be attributed to antithrombin- or thromboplastin-type effects of amniotic fluid or even complement activators
 - Amniotic fluid has highly potent, total thromboplastinlike activity
 - Procoagulant activity increases with duration of gestation
 - Amniotic fluid has relatively strong antifibrinolytic activity
 - Also increases during gestation

Clinical Presentation

- Symptoms of AFE commonly occur during labor (80%) and delivery, or in immediate postpartum period
 - AFE can also develop 4 to 48 hours postpartum or after cesarean delivery, amniocentesis, or removal of the placenta, or with first- and second-trimester abortions
- Risk factors associated for AFE are:
 - Older age
 - Multiparity
 - Marked exaggeration of uterine contraction following rupture of the uterine membranes
 - Markedly exaggerated uterine contraction due to the use of oxytocin or other uterine stimulatory agents
 - Prolonged gestation
 - Instrumented vaginal delivery
 - Eclampsia
 - Polyhydramnios
 - Fetal distress
 - Large fetal size
 - Meconium staining of the amniotic fluid
 - Cesarean section
 - Uterine rupture
 - High cervical laceration
 - Premature separation of placenta
 - Intrauterine fetal death
 - Blunt abdominal trauma, surgical intervention, cervical suture removal, and saline amnioinfusion other rare causes of AFE (Table 101.5)
- Classic clinical presentation of AFE is the sudden onset of dyspnea, respiratory failure, and hypotension, followed by cardiovascular collapse and DIC.
 - Cardiorespiratory collapse almost invariably present
 - Presenting symptom in 51% of patients was respiratory distress, hypotension in 27%, coagulopathy in 12%, and seizures in 10%
 - Fetal bradycardia (17%) and hypotension (13%) also common presenting features
 - Typically patient in active labor with intact amnion and develops sudden respiratory failure and circulatory collapse, followed by a systemic thrombohemorrhagic disorder
 - In some women, postpartum consumptive coagulopathy appears to be the sole presenting sign
 - Abrupt fetal bradycardia followed by coagulopathy can occur
 - Acute hypoxia immediately followed by an initial increase in blood pressure, with subsequent hypotension, suggestive of left atrium (LA) and LV failure, can be observed in AFE

TABLE 101.5**RISK FACTORS OF AMNIOTIC FLUID EMBOLISM**

Older age
 Multiparity
 Physiologic intense uterine contractions
 Medical induction of labor
 Instrumental vaginal delivery
 Prolonged gestation
 Cesarean section
 Uterine rupture
 Polyhydramnios
 High cervical tear
 Premature placental separation
 Intrauterine fetal death
 Large fetal size
 Meconium staining of the amniotic fluid
 Placental abruption
 Eclampsia
 Fetal distress
 Trauma to abdomen
 Surgical intervention
 Saline amnioinfusion

- Cardiogenic pulmonary edema due to LV failure occurs
- Seizures occur in 10% to 20% of patients
- Profound hypoxia and right-sided heart failure follow pulmonary arterial spasm and may account for the 50% mortality rate within the first hour
- DIC is a common finding, seen in up to 83%
 - Half of these patients develop coagulopathy within 4 hours of initial presentation
- Presenting manifestation of DIC is profound hemorrhage, prompting an extensive search for anatomic causes of bleeding
- There are three identified phases of AFE in humans:
 - Phase 1: Pulmonary—Respiratory distress and cyanosis
 - Phase 2: Hemodynamic—Pulmonary edema and hemorrhagic shock
 - Phase 3: Neurologic—Confusion and coma
- Manifestations occur in combination, separately, and in different magnitudes
 - Of patients surviving initial cardiorespiratory insult, 40% to 50% progress into phase 2
 - Characterized by coagulopathy, hemorrhage, and shock
 - Left-sided heart failure is evident and is the most reported sign in humans
 - Increased pulmonary capillary wedge pressure (PCWP) and CVP are characteristics of pulmonary edema
 - In phase 3, acute symptoms disappear, and injury to the brain, lung, and renal systems are noted
 - Phase 3 may last weeks
 - Patients may die as a result of severe brain and lung injury
 - Infection and multiple organ system failure may also cause death

Diagnosis

- Septic shock
- Acute myocardial infarction
- Cardiomyopathy
- Anaphylaxis
- Aspiration
- Placental abruption
- Eclampsia
- Uterine rupture
- Transfusion reaction
- Local anesthetic toxicity
- Diagnosis of AFE considered when pregnant woman with one or more risk factors suddenly develops respiratory distress, bleeding, or shock
- Several methods suggested for diagnosing AFE
 - None of these diagnostic tests is reliable
- The initial presenting signs often seen on ECG and the pulse oximeter
 - Former may show tachycardia with a right-heart strain pattern and ST-T-wave changes
 - Pulse oximetry may reveal a sudden drop in oxygen saturation
 - Clinical diagnosis is made most frequently in 65% to 70% of cases during labor and much less frequently in 11% of cases in the postpartum period
- Initial laboratory data should include:
 - Arterial blood gas (ABG) analysis to determine adequacy of ventilation and degree of hypoxemia
 - Diagnostic markers for AFE based on peripheral blood samples introduced
 - Sialyl Tn (STN), mucin-associated disaccharide antigen carried by apomucins, zinc coproporphyrin, and complement factor consumption
 - Significantly higher serum STN levels were found in patients with clinically apparent AFE
 - Monoclonal antibody THK-2, an antibody directed to STN, may be a specific pathologic marker for AFE
 - Fetal megakaryocytes and syncytiotrophoblastic cells can be found in maternal pulmonary circulation by monoclonal antibodies (CD-61—GPIIIa, β -hCG, and factor VIII-vW hPL antibodies) and may be diagnostic.
 - Laboratory tests to evaluate the development of DIC are:
 - Anti-thrombin III level
 - Fibrinopeptide A level
 - D-dimer level
 - Prothrombin fragment 1.2 (PF 1.2)
 - Thrombin precursor protein
 - Platelet count
 - Global tests, including the prothrombin time (PT), partial thromboplastin time (PTT), and fibrinogen level, are helpful
- When correlated with clinical signs and symptoms, other diagnostic tools may be employed to support the presumptive diagnosis of AFE.
 - Echocardiography may show severe pulmonary hypertension and RV dilatation
 - Displaced intraventricular septum pressing on LV
 - TEE may show RV failure with leftward deviation of the interventricular septum and severe tricuspid regurgitation.
 - CXR a helpful diagnostic tool, but it is limited by a lack of specificity
 - In mothers with AFE, 24% to 93% of CXRs show a pulmonary edema pattern

- AFE is largely a diagnosis of exclusion
- Differential diagnosis includes:
 - Air or thrombotic pulmonary emboli

- Multiple patchy, nodular infiltrates and small pleural effusion may also be seen
- Histologic examination demonstrates foreign material in the pulmonary capillaries, arterioles, and arteries.
 - Special stains such as TKH-2, a monoclonal antibody to fetal glycoprotein sialyl Tn antigen, have been applied to pathologic specimens

Treatment

- Treatment is supportive.
 - Despite the decline in mortality, no new therapies have emerged
 - Aggressive resuscitation indicated depending on the clinical presentation
 - Management strategies include:
 - Improving oxygenation, support of circulation, and correcting coagulopathy
 - Arterial and PA catheters should be placed to help guide the therapy when hemodynamic deterioration is severe
 - If fetus is sufficiently mature and undelivered at the time of maternal cardiac arrest, cesarean section should be instituted as soon as possible.
 - Maternal oxygenation to $\text{PaO}_2 > 60$ mm Hg achieved by administering oxygen via face mask to all nonintubated patients
 - Tracheal intubation and MV instituted in patients with refractory hypoxemia or seizures, or in the comatose individual
 - Vasoactive drug therapy must be tailored to clinical situation.
 - Dopamine is suggested to enhance cardiac output and support blood pressure.
 - In severe shock, epinephrine or norepinephrine may be required.
 - In <4 hours, half of patients who survive develop DIC, with massive hemorrhage.
 - Therefore, blood products should be prepared ahead of time, and replacement with typed-and-crossed packed red blood cells, or with O-negative blood, is essential.
- Treatment of DIC requires the transfusion of packed red blood cells and blood products.
- Large-bore IV access is essential.
- Platelets, cryoprecipitate, and fresh frozen plasma should be administered as guided by laboratory assessment of the thromboelastogram (TEG) or international normalized ratio (INR)/PT/PTT, fibrinogen, and fibrin and fibrin degradation products.
- Plasma exchange, cardiopulmonary bypass, aprotinin, and recombinant activated factor VII (rVIIa) in the management of the associated coagulopathy are used to treat AFE.
- Successful use of uterine arterial embolization to control massive bleeding in two cases of AFE has been described.
- During CPR and chest compressions, and before delivery, uterus should be displaced to the left to avoid compressing the aorta and inferior vena cava, which would compromise maternal venous return to the heart.
 - Uterus can be displaced manually or by placing a wedge under the patient's right hip.

Prognosis

- AFE remains one of the most feared and lethal complications of pregnancy.
- Prognosis and mortality of AFE have improved significantly with early diagnosis and prompt and early resuscitative measures.
 - Parturient with a known history of atopy or anaphylaxis also at a high risk of AFE
 - In the National Amniotic Fluid Embolism Registry known history of drug allergy and atopy was found in 41% of the 46 patients with AFE
 - Mainstay of a successful outcome remains the identification of high-risk patients
 - In some cases, death is inevitable despite early and appropriate management
 - Neonatal survival is reported as 70%
 - Although there are many new developments with respect to knowledge of the diseases, AFE continues to be a catastrophic illness

SECTION XIV ■ NEUROLOGIC DISEASE AND DYSFUNCTION

CHAPTER 102 ■ ELEVATED INTRACRANIAL PRESSURE

DEFINITION OF INTRACRANIAL PRESSURE (ICP)

- ICP is the pressure of compartment inside skull.
 - Brain is almost completely incompressible.
 - Expansion of volume in any component within skull causes an increase in pressure of cranial compartment.
 - Increased ICP can lead to decreased cerebral blood flow (CBF) resulting in:
 - Decreased oxygen delivery to brain
 - Neuronal dysfunction due to:
 - Global ischemia
 - Herniation of brain with compression of vital structures
 - Death
 - Principles of increased ICP defined by Monroe-Kellie doctrine

CAUSES OF INCREASED ICP

- Intracranial hypertension complicates many neurologic disorders.
- Head trauma can result in diffuse brain edema, increased blood flow, and mass lesions such as subdural, epidural, or intraparenchymal hemorrhage.
 - Brain edema following head injury is primarily cellular edema, although vasogenic edema can occur transiently.
- Ruptured aneurysm can cause subarachnoid hemorrhage, resulting in vasospasm and hydrocephalus.
- Ischemic or hemorrhagic strokes can result in mass lesion and cellular edema.
- Obstructive or communicating hydrocephalus from multiple causes can result in increased cerebrospinal fluid (CSF) volume.
- Fulminant hepatic failure can cause significant cerebral edema.
- Brain tumors or infection can occupy volume within intracranial space.

PHYSIOLOGY OF THE INTRACRANIAL SPACE

Monro-Kellie Doctrine

- Intracranial compartment partially divided into two compartments by tentorium cerebelli

- Shelf of dura divides skull into the supratentorial compartment
 - Containing cerebral hemispheres
- And infratentorial compartment
 - Containing brainstem and cerebellum
- Increased ICP in supratentorial compartment can cause uncal herniation
 - With temporal lobe herniating through incisura of tentorium and compressing midbrain
- Continued increase in ICP in superior fossa or increased ICP in posterior fossa can cause tonsillar herniation
 - With tonsils of cerebellum herniating through foramen magnum with compression of medulla

CIRCULATION OF CEREBROSPINAL FLUID

- CSF contained within ventricles of brain provides a buffer to changes in other volumes within intracranial space.
- Choroid plexus, located within lateral and fourth ventricles, secretes CSF
 - CSF drains from lateral ventricles through two foramina of Monro into third ventricle
 - From third ventricle drains via cerebral aqueduct into fourth ventricle
 - From fourth ventricle it drains into subarachnoid space through two lateral foramina of Luschka and median foramen of Magendie and into central canal of the spinal cord
 - In subarachnoid space CSF is resorbed at arachnoid villi
 - Normal total CSF volume in adult is 150 mL
 - In a day, 450 mL of CSF is secreted
 - Thus CSF volume recirculated three times each day
 - Increased secretion or decreased absorption can cause communicating hydrocephalus
 - Blockage of circulation of CSF can cause obstructive hydrocephalus
 - Absorption of CSF pressure dependent, secretion is not

ICP PRESSURE: VOLUME CURVE

- ICP is a nonlinear function of increasing volume in the intracranial space (Fig. 102.1).
- Early increases in volume of mass lesion result in CSF displacement from cranial compartment into spinal compartment.
 - Cause little increase in ICP

FIGURE 102.1. The left graph illustrates the nonlinear nature of the relationship between the volume of intracranial contents and intracranial pressure. The right graph shows the actual intracranial pressure (ICP) and jugular venous oxygen saturation (SjO_2) tracings in a patient who developed a delayed intracranial hematoma. Initially the rise in ICP was minimal as the brain was able to compensate for the increasing volume from the hematoma. Later when these compensatory mechanisms were exhausted, there was a very rapid increase in ICP associated with compromise of cerebral blood flow and a decrease in SjO_2 .

- Once maximal amount of CSF is displaced from intracranial compartment, ICP increases rapidly.
- As ICP increases cerebral perfusion pressure decreases and blood flow to the brain decreases.

CEREBRAL PERFUSION PRESSURE (CPP)

- See above
- Pressure autoregulation is the intrinsic ability of cerebral vasculature to maintain flow constant over a wide range of CPP values.
- Dynamic pressure autoregulation is commonly dysfunctional in injured brain.
 - When impaired, the lower limit of autoregulation shifted upward from 50 to 60 to 90 mm Hg.
 - When entirely absent, perfusion passively follows CPP.
- Loss of normal autoregulation requires careful maintenance of sufficient mean arterial pressure (MAP) and adequate control of ICP to avoid brain hypoperfusion.
- Extremely elevated MAP should also be avoided as it can cause increased ICP.

BRAIN METABOLISM

- See above
- 15% of blood flow goes to brain
 - Normal CBF is 50 to 55 mL per 100 g/minute
 - Each 100 g of brain tissue requires at least 20 mL of blood flow per minute to function normally
 - Between 8 and 20 mL/100 g/minute of blood flow, brain tissue survives for at least a period of time but does not function normally
 - Below 8 mL/100 g/minute brain tissue dies
 - Brain consumes 20% of oxygen used by body
 - Using 3.5 mL of oxygen per 100 g/minute
 - Brain dependent on delivery of glucose in blood as it has almost no intrinsic energy stores
- CBF thresholds determined in normal brain
 - Seem to hold true for brain-injured patients
 - Low CBF, particularly in early postinjury period, highly predictive of a poor outcome
 - Traumatic brain injury (TBI) patients with CBF < 18 mL/100 g/minute had significantly worse outcome compared to patients with higher CBF

- Within 12 hours of injury
 - Every 10 mL/100 g/minute increase in CBF associated with threefold increase in probability of surviving

COMMONLY MONITORED PARAMETERS IN PATIENTS WITH ELEVATED ICP

Intracranial Pressure

- Elevated ICP can be measured and treated
 - Normal ICP in adult is <10 mm Hg
 - ICP value of 20 to 30 mm Hg is mild intracranial hypertension
 - ICP above 40 mm Hg is severe, life-threatening intracranial hypertension
 - Goal of treatment should be to maintain ICP below 20 to 25 mm Hg
 - TBI patients with elevated ICP have worse outcome than those with ICP below 20 mm Hg
- Gold standard for monitoring ICP is ventriculostomy catheter inserted through burr hole into one of the lateral ventricles.
 - Catheter connected to drainage system and can be used to monitor ICP through fluid-coupled external pressure transducer
 - Most accurate measurement of ICP and stable over time
 - Allows drainage of CSF for control of ICP
- Problems associated with ventriculostomy catheters include:
 - Blockage of catheter
 - Displacement of catheter from ventricle
 - Infection
 - Antibiotic-impregnated ventriculostomy catheters reduce risk of infection from 9.4% to 1.3%

Cerebral Perfusion Pressure

- See above
- CPP defined as MAP minus the ICP
 - Measured using a combination of ICP monitor and an arterial line or a noninvasive blood pressure monitor
 - The second major parameter monitored and treated in patient with elevated ICP
 - Can be supported by maintaining mean arterial pressure (MAP) with IV fluids and vasopressors and by lowering ICP
 - For most patients, a CPP of at least 60 mm Hg is adequate

Brain Oxygenation

- See above
- Brain tissue oxygenation measured either by:
 - Positron emission tomography (PET) imaging techniques to obtain a single time point sample across entire brain
 - Using probes to continuously monitor:
 - Brain tissue pO_2 (PbtO₂)
 - Jugular venous oxygen saturation (SjvO₂)

Brain Tissue Oxygen Tension

- Insertion of PbtO₂ probe allows continuous monitoring of O₂ tension in local region of brain
- Location of probe is critical and determines nature of pO₂ information obtained (Fig. 102.2)
 - If inserted near focal lesion, O₂ can be monitored in tissue at greatest risk should injury expand
 - Insertion in uninjured brain allows monitoring of local area that should be representative of overall less-injured O₂ status of brain
 - Provides information that is similar to SjvO₂ monitoring
- Normal values and critical threshold values for PbtO₂ are somewhat less accepted.

- In anesthetized subjects, PbtO₂ in normal brain ranges from 20 to 40 mm Hg.
 - Comparing PbtO₂ values to PET measurements of O₂ extraction fraction (OEF) shows PbtO₂ value associated with OEF of 40% (mean value in normal subjects) was 14 mm Hg.
- Values of PbtO₂ indicating tissue hypoxia/ischemia probably <14 mm Hg
 - Serial measurements of both SjvO₂ and PbtO₂ suggest a PbtO₂ of 8.5 mm Hg and indicates a similar level of oxygenation as SjvO₂ of 50%
 - PbtO₂ <15 mm Hg associated with poor outcome
 - Treatment protocol keeping brain PbtO₂ >25 mm Hg may reduce mortality when compared to patients treated similarly with no PbtO₂ probe

Jugular Venous Oxygen Saturation

- See above
- Episodes of SjvO₂ desaturation associated with worse neurologic outcome
 - Increased SjvO₂ may indicate decreased oxygen uptake in brain

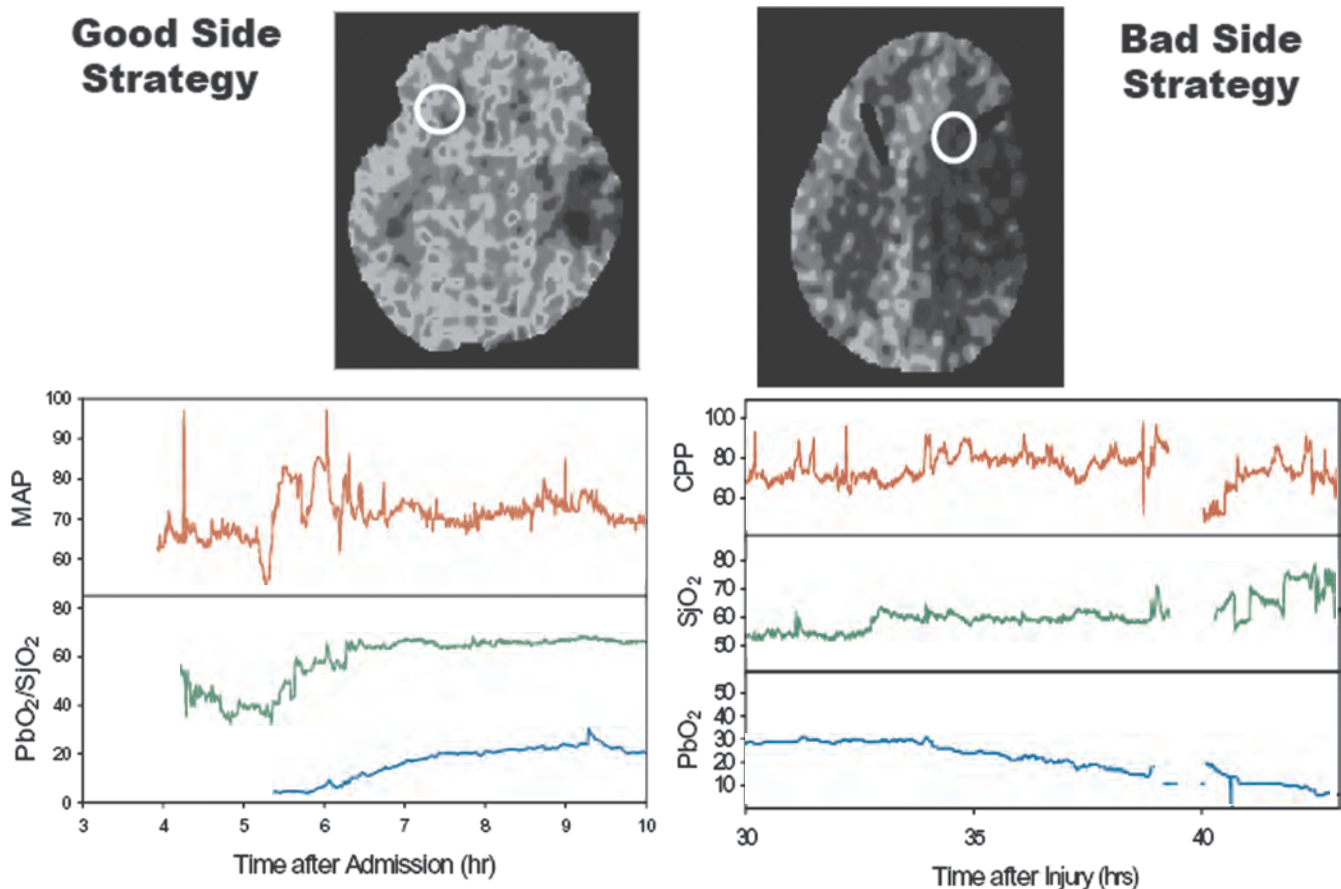

FIGURE 102.2. Location of the brain tissue oxygen tension (PbtO₂) catheter relative to the injured brain determines the nature of the pO₂ information that will be obtained. On the left is a patient where the PbtO₂ catheter was placed in relatively normal brain opposite a temporal contusion. The PbtO₂ reflected the global oxygenation of the brain measured with jugular venous oxygen saturation (SjvO₂). On the right is a patient where the PbtO₂ catheter was placed near a contusion. As this contusion evolved, the PbtO₂ decreased even though the global measures (SjvO₂ and cerebral perfusion pressure [CPP]) remained unchanged. MAP, mean arterial pressure.

- Major limitation of SjvO_2 monitoring is it cannot detect local ischemia within brain
- Normal values for SjvO_2 better established than for PbtO_2
 - In 50 normal young males SjvO_2 ranged from 55% to 71% (mean 61.8%)
 - Normal SjvO_2 values may be as low as 45%
 - Normal SjvO_2 lower than normal SvO_2 , indicating that brain normally extracts oxygen more completely from arterial blood than do other organs

WHAT IS THE MOST IMPORTANT PHYSIOLOGIC END POINT (ICP, CPP, OR BRAIN OXYGENATION)?

- Some have advocated ICP is not important as long as CPP is maintained.
 - Led to the use of CPP-directed therapy where induced hypertension was used to drive CPP to high levels, even though ICP was also increased by therapy
 - All these physiologic parameters related to outcome
 - No clear evidence that one parameter is more important than others
 - Table 102.1 presents normal values and treatment thresholds for these parameters
- Best circumstance when ICP, CPP, and $\text{PbtO}_2/\text{SjvO}_2$ are all maintained in normal range
 - This should probably be goal of management
 - When not possible, it is important to understand limitations of each monitor when making therapeutic decisions

IMMEDIATE CONCERNS FOR TREATMENT

Identification of Patients with Increased ICP

- Patient with mildly increased ICP can present with headache and blurred vision.
 - Further increases in ICP associated with decreased level of consciousness and symptoms of herniation
 - Herniation of temporal lobe over edge of tentorium can compress cranial nerve III, causing ipsilateral pupillary dilation and decreased reaction to light

TABLE 102.1

NORMAL VALUES AND TREATMENT THRESHOLDS FOR PHYSIOLOGIC PARAMETERS

	Normal	Treatment threshold
ICP	0–10 mm Hg	20–25 mm Hg
CPP	50 mm Hg	60 mm Hg
SjvO_2	55%–71%	50%
PbtO_2	20–40 mm Hg	8–10 mm Hg

ICP, intracranial pressure; CPP, cerebral perfusion pressure; SjvO_2 , jugular venous oxygen saturation; PbtO_2 , brain tissue oxygen tension.

- Direct compression of brainstem can cause contralateral posturing or hemiparesis
 - If the brainstem is displaced and compressed against opposite side of tentorium, there may be ipsilateral symptoms, called Kernohan notch phenomenon.
- Further symptoms of herniation are hypertension, bradycardia, and widening pulse pressure, the Cushing triad.
- Respiratory abnormalities may include:
 - Cheyne-Stokes respiration
 - Hypoventilation
 - Central neurogenic hyperventilation
- If elevated ICP suspected, noncontrast computed tomography (CT) scan of brain is needed to evaluate for mass lesions, hydrocephalus, subarachnoid hemorrhage, or other treatable causes

Initial Stabilization and Management of Patients with Elevated ICP

- Initial steps in managing elevated ICP defined by ABCs of trauma resuscitation
 - Episodes of hypoxemia ($\text{PaO}_2 < 60$ mm Hg) or hypotension (systolic blood pressure < 90 mm Hg) associated with significantly worse outcome in patients with TBI
 - Airway protection essential
 - Patients with Glasgow Coma Scale (GCS) of 8 or less should be intubated to protect airway
 - Patients with GCS above 8 may also need intubation if they cannot adequately protect their airway
 - Supplemental oxygen and mechanical ventilation (MV) may be necessary to avoid hypoxemia
 - Blood pressure supported with fluid resuscitation and vasopressors, as necessary
 - Hypotension should not be attributed to brain injury unless all other possible causes excluded
 - Patients with elevated ICP should be cared for in dedicated neurological intensive care unit with a neurosurgeon included in care team
- Immediate aggressive management of elevated ICP initiated in patients with signs and symptoms of herniation include:
 - Mild hyperventilation, to a PaCO_2 of 30 to 35 mm Hg
 - Can reduce ICP by constricting cerebral blood vessels
 - Once fluid resuscitation completed, osmotic therapy with either mannitol or hypertonic saline initiated
 - Standard dose for mannitol is IV bolus of 1 g/kg
 - With subdural hematoma and signs of herniation, early preoperative administration of mannitol 1.4 g/kg significantly improves outcome
 - Only give once fluid resuscitation is completed as it can cause hypotension in incompletely resuscitated patient
 - Alternative osmotic agent is hypertonic saline
 - May have advantage in hypotensive patient since it does not induce diuresis
 - Resuscitation with hypertonic saline demonstrated to result in less hypotension compared with mannitol
 - Has not clearly been shown to result in an improved outcome
- If a surgical lesion identified:
 - Patient immediately taken to operating room for evacuation of lesion

- Invasive monitoring devices inserted either at bedside or in operating room if surgery is required
 - Minimally, ICP monitor, preferably a ventriculostomy drain inserted
 - Other monitoring devices used if available include:
 - PbtO₂ monitor
 - SjvO₂ catheter
 - Arterial line and a Foley catheter should also be placed
 - Central venous line may be needed, especially if hypotension is present or large doses of mannitol are needed

TREATMENT OF ELEVATED INTRACRANIAL PRESSURE: PRINCIPLES OF CENTRAL NERVOUS SYSTEM RESUSCITATION

General Measures

- Specific factors that may aggravate intracranial hypertension include:
 - Obstruction of venous return (head position, agitation)
 - Respiratory problems (airway obstruction, hypoxia, hypercapnia)
 - Fever
 - Severe hypertension
 - Hyponatremia
 - Anemia
 - Seizures
- Routine management of patient at risk for intracranial hypertension should include measures to prevent these factors.
- Also important to maintain normal brain oxygenation and CPP

Minimize Obstruction to Venous Return

- Elevation of head of bed and keeping head in neutral position to minimize compression of venous return from the brain are standard practice for management of ICP.
- Elevation of head to 30 degrees results in reduction in ICP without reduction in either CPP or CBF in most patients.
- **When head elevation is used, both the ICP and blood pressure transducers must be zeroed at the same level (i.e., at the level of the foramen of Monro).**
- In multiple-trauma patients increased intra-abdominal pressure may also impede venous return from the brain, decrease blood pressure (BP), and increase ICP.
 - Abdominal decompression can improve control of ICP when abdominal compartment syndrome is present.

Prevent Fever

- Fever is common during recovery from head injury.
 - Experimentally postinjury fever worsens outcome from fluid percussion injury.
 - Fever is a potent cerebral vasodilator and can raise ICP.
 - Fever can raise cerebral metabolic requirements.
 - Efficient external cooling systems and intravascular cooling devices available to maintain normal body temperature
 - Infectious causes should be investigated appropriately and treated

Prevent Seizures

- Seizures occur in approximately 15% of patients with head injury.
 - Risk related to severity of injury
 - In 4,541 head injury patients, standardized incidence ratio for developing seizures was:
 - 1.5 after mild injuries with no increase over expected number after 5 years
 - 2.9 after moderate injuries
 - 17.0 after severe injuries
 - Patients often sedated and pharmacologically paralyzed to treat intracranial hypertension
 - Clinical monitoring often not helpful
 - Continuous electroencephalogram (EEG) monitoring may be useful for this high-risk group of patients
 - Use of anticonvulsants to prevent seizures controversial
 - Seizures dramatically increase cerebral metabolic rate
 - But no clear relationship between occurrence of early seizures and worse neurologic outcome
 - No difference in incidence of seizures with prophylactic phenytoin
 - In a double-blind study of 404 severely head-injured patients randomly receiving phenytoin or placebo for 1 year, phenytoin reduced incidence of seizures during first week but not thereafter

Maintain Brain Oxygenation

- Brain oxygen delivery (DO₂) dependent on oxygen content of blood (CaO₂) and CBF
 - Blood O₂ content can be increased by ensuring adequate Hgb concentration and increasing PaO₂
 - For the brain, but not other organs, optimal hemoglobin (Hgb) concentration approximates 10 g/dL
 - Lower Hgb concentration reduces oxygen-carrying capacity of blood more than it improves viscosity
 - Higher Hgb concentration increases viscosity and reduces CBF even though it increases oxygen-carrying capacity
 - Increasing PaO₂ after hemoglobin is nearly 100% saturated increases CaO₂ minimally
 - By the amount of oxygen dissolved in blood
 - If tissues are ischemic small increases in CaO₂ important
 - PET imaging suggests impaired O₂ diffusion in injured brain tissue
 - May also be mitochondrial dysfunction in injured brain
 - Hyperoxia may improve tissue oxygenation under these conditions
 - There is an increased PbtO₂ and decreased extracellular lactate concentration in brain, measured by microdialysis, when patients with very low baseline PbtO₂ were placed on 100% oxygen.
 - Reduction in lactate accumulation suggests increased PbtO₂ altered ischemic cerebral metabolism favorably.

Maintain Cerebral Perfusion Pressure

- Initial volume resuscitation aimed at achieving euvolemia
 - Once ICP monitor in place, further BP management aimed at maintaining CPP to at least 60 mm Hg
 - IV fluid boluses used as initial treatment of low CPP
 - All IV fluids given should be isotonic to avoid worsening cerebral edema

- If fluid resuscitation is insufficient to maintain CPP, treat with pressors
 - Suggestion that norepinephrine results in more predictable BP than dopamine
 - Treating to a CPP >60 mm Hg not shown to improve outcome but does increase acute respiratory distress syndrome risk

First-line Therapies of Intracranial Hypertension

Sedation and Paralysis

- Sedative/analgesic drugs blunt effect of routine nursing care on ICP.
 - Routine paralysis of all patients with severe head injury increases the risk of pulmonary complications and prolongs the intensive care unit stay.
 - However, ICP raised by agitation, posturing, or coughing is prevented by narcotics and nondepolarizing muscle relaxants that do not alter cerebrovascular resistance.
 - Reasonable regimen is morphine and lorazepam for analgesia/sedation
 - Cisatracurium or vecuronium as a muscle relaxant, with dose titrated to twitch response to stimulation (1 to 2 of 4 of a train of four)
 - Neurologic examination cannot be closely monitored while patient is paralyzed.
 - If safe and appropriate, muscle relaxants can be withheld once a day, usually before morning rounds, to obtain a brief neurologic examination.

Osmotic Therapy to Reduce Intracranial Pressure

- One mainstay of treatment of elevated ICP is osmotic therapy with mannitol or hypertonic saline.
 - Treatment can be initiated prior to insertion of ICP monitor if signs and symptoms of herniation are present.
 - Initial dose of mannitol is 1 g/kg
 - Once ICP monitor is inserted, bolus doses can be given to maintain ICP <20 to 25 mm Hg.
 - Bolus dosing of 0.25 mg to 0.5 mg/kg every 2 to 6 hours can be given if serum osmolality <320 mOsm/kg H₂O.
 - Dosing to serum osmolality >320 not demonstrated to improve outcome and increases risk of acute renal failure
- Mannitol reduces ICP through two mechanisms:
 - First is immediate expansion of intravascular volume, resulting in reduced hematocrit and reduced blood viscosity, causing decreased ICP and increased CBF and DO₂
 - Second involves establishment of osmotic gradients between plasma and cells
 - Resulting in decreased cellular volume
 - Long-term treatment with mannitol results in buildup of mannitol within the cells
 - Effect is more marked with continuous infusion of mannitol
- Mannitol more widely studied, but hypertonic saline may be more effective at lowering ICP
 - Studies small and no demonstration of statistical significance in outcome
 - Usual dose form is boluses of 7.5% hypertonic saline

- Other agents include hypertonic saline hetastarch, 7.5% hypertonic saline/6% dextran solution
 - Large randomized controlled studies necessary to define role of hypertonic saline in the treatment of increased ICP

Drainage of Cerebrospinal Fluid

- Placement of ventriculostomy catheter allows drainage of CSF during episodes of increased ICP.
 - Drainage of 3 to 5 mL of CSF can reduce ICP.
 - If CSF is drained continuously, drainage system should not be set lower than 10 cm above the level of foramen of Monro.
 - Approximated by the external auditory canal

Hyperventilation

- Hyperventilation to PaCO₂ of 30 to 35 mm Hg can reduce ICP by constricting cerebral blood vessels and reducing cerebral blood volume.
 - Effect of changes in PaCO₂ on cerebral vessels mediated by change in pH induced in the extracellular fluid
 - Effects of hyperventilation on ICP are immediate
 - Duration of effect brief because pH of brain, in normal individuals, soon equilibrates to the lower PaCO₂ level
- Long-term hyperventilation to PaCO₂ of 25 to 30 mm Hg demonstrated to result in worse outcomes after TBI
 - Possibly secondary to reduction in CBF
 - Recommendation is to use hyperventilation only in patients with intracranial hypertension rather than as routine in all head-injured patients
- For patients chronically hyperventilated, abruptly returning PaCO₂ to normal can result in a dramatic increase in ICP.
 - This phenomenon occurs after 24 hours of hyperventilation.
 - Associated with vasodilation of cerebral vessels as CSF pH equilibrates at new lower PaCO₂ level
 - Hyperventilation should be withdrawn over several days to avoid this increase in ICP.

Additional Treatments for Refractory Intracranial Hypertension

- All treatments outlined below shown in clinical studies to significantly reduce ICP, even when refractory to initial treatments
 - None demonstrated to improve neurologic outcome
 - No data to suggest which of these is most effective or has least morbidity
 - For these reasons, such additional therapies are usually applied selectively
- When refractory intracranial hypertension occurs:
 - Consider whether a delayed intracranial hematoma may have developed
 - Follow-up CT scan may be indicated before these additional treatments
 - Any surgical intracranial hematoma should be evacuated

Pentobarbital Coma

- If CSF drainage and mannitol fail to control elevated ICP, other techniques to be considered.
 - Administration of pentobarbital to achieve burst suppression on EEG

- Routine use of barbiturates in unselected patients not consistently effective in reducing morbidity or mortality after severe head injury
- Nonetheless, a randomized multicenter trial demonstrated barbiturate coma in patients with refractory intracranial hypertension resulted in twofold greater chance of controlling ICP.
- Simple dosing scheme from randomized clinical trial is:
 - Loading dose of 10 mg/kg IV over 30 minutes
 - Followed by 5 mg/kg/hour for 3 hours
 - Followed by maintenance dose of 1 mg/kg/hour
 - Maintenance dose titrated to achieve level of 35 to 50 $\mu\text{g/mL}$
 - Continuous EEG used to monitor for burst suppression for maximal therapeutic effect
- Significant hypotension may develop during administration of the loading dose
 - Consider placement of pulmonary artery catheter for continuous cardiac monitoring
 - Initial loading dose requires close monitoring of BP
 - Hypotension during induction usually responds to fluid bolus
 - Higher doses of pentobarbital can cause myocardial depression and require inotropic or even vasopressor support.
- Goal of treatment is to reduce ICP to < 20 to 25 mm Hg
- After ICP is controlled for 24 to 48 hours, pentobarbital can be weaned and stopped
 - If ICP increases during reduction of pentobarbital, stop titration and increase dose until ICP controlled
 - Pentobarbital is thought to work through multiple mechanisms
 - Alterations in vascular tone
 - Decreased cerebral metabolism
 - Decreased free radical production
- Pentobarbital coma associated with significant morbidity
 - Hypotension is common and may require concomitant administration of vasopressors.
 - Pentobarbital coma increases risk of pneumonia, pressure ulcers, and paralytic ileus.
- PT characteristics that may indicate a favorable ICP response to barbiturates include:
 - Younger age
 - Diffuse rather than focal brain injury
 - Relatively high level of brain electrical activity
 - High cerebral metabolic rate prior to treatment
 - Preservation of CO_2 reactivity may predict good ICP response to barbiturates

Decompressive Craniectomy

- Kocher initially described in 1901, craniectomy for control of elevated ICP has long history
- Initially showed improved outcome resulting in increased usage
 - Follow-up studies did not demonstrate same improved outcome and craniectomy became less popular
 - More recently benefits have been seen and is being used for control of elevated ICP
- Can be considered in patients with elevated ICP uncontrolled by CSF drainage and osmotic therapy
 - If injury primarily involves single hemisphere, a hemi-craniectomy can provide adequate decompression.

- Large bone flap should be removed with particular focus on decompressing anterior temporal lobe and visualization of floor of middle fossa.
- Diffuse injury involving both hemispheres may necessitate bifrontal craniectomy, with removal of large bone flap and decompression of both temporal lobes and both frontal lobes.
- Demonstrated to result in significant decrease in ICP
 - Retrospectively suggested to improve outcome
 - Two randomized clinical trials currently under way
 - Craniectomy also useful in treatment of elevated ICP secondary to malignant middle cerebral artery stroke
 - Significant reduction in mortality and improved outcome if performed prior to development of symptoms of herniation

Hypothermia

- Hypothermia has several potentially neuroprotective effects, including:
 - Reducing cerebral metabolism and decreasing ICP
- Randomized, controlled trial in humans did not show a significant improvement in neurologic outcome
 - But ICP was better controlled during hypothermia
- Routine induction of hypothermia not indicated at present
 - May be effective adjunctive treatment for increased ICP refractory to other medical management

Steroids

- Multiple randomized, controlled studies demonstrated no benefit in treating patients with traumatic brain injury with steroids.
 - Increased risk of death in patients receiving methylprednisolone for 48 hours after injury
 - Steroids not recommended for treatment of head injury
 - Steroids not recommended for treatment of cellular edema accompanying stroke
- Steroids useful in treating vasogenic edema associated with brain tumors or selected infections such as neurocysticercosis
 - Dosing schemes relatively arbitrary with typical dosing scheme for patient with significant symptomatic vasogenic edema from a tumor being dexamethasone, 4 mg IV every 6 hours

Completion of Treatment

- Treatment titrated off once ICP has been controlled below 20 mm Hg for 24 to 48 hours
 - ICP monitors removed if ICP stable below 20 mm Hg for 48 hours after interventions stopped
- Patients may develop delayed increase in ICP secondary to blossoming of contusions, evolution of a stroke, or development of new mass lesions

OUTCOME WITH INTRACRANIAL HYPERTENSION

- Patients with TBI classified based on initial GCS
 - Patients with mild TBI, GCS of 13 to 15, have minimal chance (3%) of deteriorating into coma and developing elevated ICP

- Patients with moderate TBI, GCS from 9 to 12, have moderate chance (10%–20%) of deteriorating into coma and developing elevated ICP
- Patients with a GCS of 8 or less, severe TBI, have highest chance of developing elevated ICP and also have worst outcome
- Patients with severe TBI more likely to develop increased ICP if they have abnormal head CT or if they meet two of the three criteria of:
 - Age older than 40 years
 - Unilateral or bilateral motor posturing
 - Systolic blood pressure <90 mm Hg
- No study clearly demonstrates that monitoring and treating ICP improves neurologic outcome
 - There are strong associations between intracranial hypertension and poor outcome.
 - Development of refractory intracranial hypertension has a very high mortality rate.
 - In a randomized trial of pentobarbital coma for refractory intracranial hypertension, control of the elevated ICP determined outcome.
- 92% of patients where ICP was controlled survived
- 83% of patients where ICP was not controlled died
- Historically, institution of treatment protocols aimed at controlling elevated ICP significantly improved outcome in TBI.
 - 1977 mortality rate of 50% in comatose patients (GCS <8) in cohort treated without ICP monitoring
 - Significantly lower mortality of 30% in similar patient cohort using ICP monitoring
 - Mortality rates at 30 days for patients with severe TBI slowly declining
 - Mortality of patients in Traumatic Coma Data Bank reduced from 39% in 1984 to 27% in 1996
- Availability of multiple monitoring modalities provided more information on which patients have poor outcomes and provided treatment goals
- Treatment strategies now aimed at:
 - Maintaining ICP <20 to 25 mm Hg
 - Maintaining CPP >60 mm Hg
 - Maintaining PbtO₂ >10 mm Hg
 - Still, TBI associated with significant morbidity and mortality in short and long term

CHAPTER 103 ■ NEUROLOGIC MONITORING

- Neurologic monitoring in intensive care unit (ICU) used:
 - In general sense as part of systems-based approach to assess one of major bodily systems
 - Or with specific intent to guide therapy and/or assess prognosis
 - Imaging studies of central nervous system (CNS) play a central role in assessment by establishing diagnoses and quantifying extent of pathology
- Many interventions in ICU aimed at restoring or maintaining recovery of patient affect results of neurologic monitoring
 - Understanding parameters affecting the state of brain contextually necessary for interpreting results of neurologic monitoring
- Questions of contraindications to MRI need to be considered:
 - Metal implants (see www.mrisafety.com)
 - Morbid obesity
 - Claustrophobia
 - Use of contrast agents, require special consideration
- Quality of CT images simply degraded by patient movement
 - MRI images acquired in uncooperative, moving patient may contain “spurious pathology” because of “misregistration” of anatomic structures
- Radiologist needs adequate details of clinical history so imaging protocol can be designed to maximize information
- CT provides a map of degree of radiographic absorption of intracranial structures
 - Test of choice for localizing blood and imaging bone
 - Newer helical CT scanners make image acquisition comparatively fast
 - Allows two- and three-dimensional reconstruction of arterial anatomy during first pass of radiocontrast administration to obtain a CT arteriogram
- MRI provides a map of response of hydrogen nuclei to external magnetic fields
 - More versatile than CT
 - Provides better imaging of posterior fossa contents
 - Considerably more time consuming
 - T1 weighting enhances detection of lipids, methemoglobin (as subacute residua of hemorrhage), and concentrated protein (in a colloid cyst)

NEURORADIOLOGIC IMAGING

- Routine imaging studies important in repeated assessment of neurologic status
 - Objective information about structural abnormalities essential for clinical diagnosis
 - Neuroradiologic imaging studies typically are CT or MRI
 - Although not “monitoring” per se, repeated studies or critically timed studies provide clues about time course of pathologic process.
 - Typical imaging workup for various clinical diagnoses presented in Table 103.1
- To maximize utility of imaging study one needs to be aware of strengths and weaknesses of imaging modality

TABLE 103.1

TYPICAL IMAGING PROCEDURES FOR NEUROLOGIC DISEASES IN THEIR ACUTE PHASE

Neurologic disease	Initial imaging	Further workup/alternatives
Stroke	CT to rule out hemorrhage	Diffusion- and perfusion-weighted MRI to identify ischemic core and penumbra, respectively
Arteriovenous malformation	CT for hemorrhage	MR angiography or angiography as soon as possible
Intracerebral aneurysm	CT for subarachnoid hemorrhage	CT angiography or angiography to identify aneurysm; TCD for vasospasm
Brain tumor	MRI without and with contrast	MRI as indicated later
Traumatic brain injury	CT	
Multiple sclerosis	MRI without and with contrast	MRI without and with contrast after initial treatment
Meningitis/encephalitis	CT without and with contrast	
Intracranial abscess	CT without and with contrast	
Granuloma	MRI without and with contrast	MRI without and with contrast even initially, if patient is stable

CT, computed tomography; MRI, magnetic resonance imaging; TCD, transcranial Doppler ultrasonography. Modified from Gilman S. Imaging the brain. First of two parts. *N Engl J Med*. 1998;338:812–820.

- Radiofrequency pulse prior to T1 image acquisition suppresses enhancement of lipids (“fat suppression”)
- An example of protocol change affecting resulting image
- T2 weighting enhances detection of unbound water such as in cerebrospinal fluid (CSF) (Fig. 103.1)
- Radiofrequency pulse prior to T2 image acquisition (fluid attenuation inversion recovery [FLAIR] imaging) suppresses enhancement of CSF and improves edema detection (see Fig. 103.1)
- MRI can also be focused to detect moving elements:
 - MR arteriography or venography
 - CSF flow studies
 - Axoplasmic motion of bulk water imaged with MRI to obtain a diffusion image (apparent diffusion coefficient [ADC] map)
 - Axoplasmic motion stops shortly after brain ischemia
 - Diffusion images provide earliest radiographic evidence for core zone of an ischemic stroke
- Contrast media distribute with blood flow and accentuate areas of increased vascularity as in:
 - Inflamed tissue
 - Areas of tumor-induced angiogenesis
- Contrast media also distribute into and highlight brain structures missing blood–brain barrier:
 - As pineal gland or pituitary stalk
 - Brain areas where blood–brain barrier has been disrupted

- Perfusion imaged during bolus administration of contrast medium by MRI or by CT
- Resulting map of time to peak concentration of contrast medium provides qualitative information on cerebral blood flow (CBF)
- Qualitative differences in CBF used to identify ischemic penumbra of stroke

CEREBRAL METABOLISM: FLOW–METABOLISM COUPLING

- Cerebral metabolic rate of oxygen (CMRO₂) of the brain averages 3.0 to 3.8 mL O₂/minute/100 g
 - Only 2% of body weight, human adult brain accounts for:
 - 15% to 20% of resting oxygen consumption
 - 25% to 30% of the glucose consumption of the body
 - To meet high demand for oxygen and glucose brain requires perfusion (CBF) of 40 to 60 mL/minute/100 g of brain tissue
 - CBF regulated by four primary factors:
 - Metabolic stimuli
 - Chemical stimuli
 - Perfusion pressure
 - Neural stimuli
- In normal brain increased cerebral metabolism rapidly matched by local increases in CBF

FIGURE 103.1. Magnetic resonance images from a patient with a glioblastoma multiforme. The axial, gadolinium-enhanced T1-weighted image demonstrates the enhancing tumor margin with its nonenhancing central necrosis. The axial, T2-weighted image shows water as a bright signal in peritumoral edema and the central tumor necrosis, as well as in the cerebrospinal fluid, while the fluid attenuation inversion recovery image highlights only the edema around the tumor and suppresses the cerebrospinal fluid signal and the tumor necrosis. (Images courtesy of Ilona Schmalfuss, MD.)

FIGURE 103.2. Flow–metabolism coupling in the central nervous system. As the metabolic needs of the brain—expressed as the cerebral metabolic requirement for oxygen (CMRO₂)—increases, cerebral blood flow (CBF) increases in parallel.

- Referred to as regional flow–metabolism coupling or cerebral metabolic autoregulation
- CBF thus linked to brain function and metabolism so that CBF varies in parallel with CMRO₂ (Fig. 103.2)
- Two compensatory responses to acute reductions in CBF established:
 - Autoregulation
 - Increased oxygen extraction
 - Oxygen extraction is able to vary within a narrow range
 - “Misery” perfusion occurs when oxygen extraction is increased in response to increased CMRO₂, either when autoregulatory CBF compensation has been exceeded or uncoupling has occurred
 - As cerebral perfusion pressure (CPP) falls, CBF maintained initially by resistance arteriole vasodilation
- Several vasoactive metabolic mediators proposed for cerebral regulation:
 - Hydrogen ion
 - Potassium
 - CO₂
 - Adenosine
 - Glycolytic intermediates
 - Phospholipid metabolites
 - Nitric oxide
- Global relationship between CBF and CMRO₂ expressed by:
 - Fick equation where DajO_2 is the arteriojugular difference in oxygen content:

$$\text{CMRO}_2 = \text{DajO}_2 \times \text{CBF} \text{ or } \text{DajO}_2 = \text{CMRO}_2 / \text{CBF}$$

- CBF measured within first 6 hours after traumatic brain injury (TBI) was <18 mL/minute/100 g (the threshold for cerebral ischemia) in 33% of patients
 - Arterial vasospasm an independent predictor of poor outcome
 - Secondary ischemic neurologic damage worsened outcome and was associated with:
 - Systemic factors such as hypotension or hypoxemia
 - Local factors, such as intracranial hypertension
 - Disruption of normal homeostatic mechanisms such as autoregulation may also aggravate cerebral ischemia

- Hyperventilation to reduce intracranial pressure (ICP) may be deleterious by decreasing CBF, thus leading to ischemia

Hypothermia

- Cerebral protection by hypothermia attributed to cerebral metabolic suppression
 - Temperature coefficient (Q_{10}) is factor by which CMRO₂ is decreased by 10°C decrease in temperature
 - Between 37°C and 27°C Q_{10} is 2.23
 - Between 27°C and 17°C, temperature range where electroencephalogram (EEG) activity ceases, Q_{10} doubles to 4.53
 - Below 17°C, the Q_{10} returns to near 2.0
 - Absent EEG activity (during barbiturate coma) Q_{10} remains near 2.0 over entire temperature range
 - With moderate hypothermia (above 27°C) CO₂ reactivity and autoregulation are intact and CBF and CMRO₂ remain coupled
 - There is a change in coupling of CBF and CMRO₂ during deep cerebral hypothermia (below 25°C).
 - Nonetheless, metabolic regulation remains the main determinant of CBF even during deep cerebral hypothermia.

Anesthetics

- Except for ketamine, most intravenous (IV) and inhalational anesthetics depress cerebral metabolism with consequent reductions in CMRO₂, CBF, and ICP.
 - As CMRO₂ decreases, CBF is reduced proportionately because of flow–metabolism coupling.
 - After administration of propofol and thiopental, coupling usually remains intact and SjvO₂ remains unaltered or improves.
 - Etomidate can produce rapid reduction in CBF with slower reduction in CMRO₂.
 - This mismatching of coupling may induce significant—albeit transient—SjvO₂ desaturation.
 - Benzodiazepines and opiates have limited intrinsic effects on CBF, CMRO₂, and CBF–CMRO₂ coupling.
 - They cause decreased CBF and ICP that parallels sedation-induced decrease in CMRO₂.
 - Decreased sympathetic tone caused by sedation risks a decrease in mean arterial pressure that may diminish cerebral perfusion.

Arterial Blood Gases: Carbon Dioxide and Oxygen

- CO₂ a potent cerebral vasodilator and a major determinant of CBF
 - At normotension, CBF increases almost linearly when PaCO₂ increases 25 to 80 mm Hg
 - Global CBF varies 2% to 4% for each mm Hg change in PaCO₂
 - Effects of PaCO₂ on cerebral circulation regulated by complex, interrelated system of mediators:

- Initial stimulus of CO₂-induced vasodilation is decreased by brain extracellular pH
- Further mediated by nitric oxide, prostanoids, cyclic nucleotides, potassium channels, and decreased intracellular calcium concentration as final common pathway
- Arteriolar tone an important influence on how PaCO₂ affects CBF
 - Moderate hypotension impairs response of cerebral circulation to PaCO₂ changes
 - Severe hypotension abolishes it altogether
- PaCO₂ modifies pressure autoregulation
 - From hypercapnia to hypocapnia, there is widening of autoregulation plateau
- Moderate changes in PaO₂ do not significantly alter CBF
 - When PaO₂ falls below 50 mm Hg CBF increases so cerebral DO₂ remains constant.
 - Hypoxia acts directly on cerebral tissue to release lactic acid, adenosine, and prostaglandins, which contribute to cerebral vasodilation.
 - Hypoxia acts directly on cerebrovascular smooth muscle to produce hyperpolarization and reduce calcium uptake, enhancing vasodilation.

Pressure Autoregulation

- Refers to ability of brain to maintain total and regional CBF nearly constant despite large changes in systemic arterial blood pressure, independently of flow–metabolism coupling
- Generally expressed as the relationship between CBF and arterial blood pressure when cerebral venous and CSF pressures are low
- Can be more precisely defined using relationship between CBF and CPP that represents difference between systemic MAP and cerebral outflow pressure
 - Because cerebral venous system is compressible and may act as “Starling resistor” or waterfall phenomenon, outflow resistance governed by whichever pressure is higher: ICP or venous outflow pressure (jugular bulb pressure)
- The cerebral vascular resistance (R) can be expressed as:

$$R = CPP/CBF = (8/\pi) \times h \times (l/r^4)$$

where $(8/\pi)$ is a constant, h is blood viscosity, l is length, and r is radius of vessel

- Importantly, the radius enters to the fourth power in the equation, making it a most efficient means of controlling vascular resistance.
- In adults under normal conditions, CBF constant between a CPP of roughly 60 and 150 mm Hg
 - Autoregulation curve shifted to the right in hypertensive patients and to the left in neonates
- At lower limit of autoregulation, cerebral vasodilation maximal
 - Below this level, CBF falls passively with CPP
 - Beyond upper limit where vasoconstriction is maximal elevated intraluminal pressure may force vessels to dilate, leading to increased CBF and damage to blood–brain barrier.
- Metabolic mediators, such as adenosine, also involved in low-pressure range of autoregulation

Neurogenic Regulation

- Major difference between other systemic circulations and cerebral circulation is relative lack of humoral and autonomic control on normal cerebrovascular tone
 - Maximal stimulation of sympathetic or parasympathetic nerves alters CBF only slightly
- Is considerable evidence indicating existence of age-related differences in cerebral resistance vessels to neural stimuli
 - Both *in vivo* and *in vitro*, cerebrovascular constrictor responses to noradrenaline or electrical transmural stimuli greater in fetal and neonatal than in adult animals

Other Factors Regulating Cerebral Blood Flow

- CO hardly influences CBF normally, it may significantly influence flow to ischemic regions
- Improving cerebral perfusion by volume loading is indirectly accomplished by improving blood rheology and directly accomplished by increasing systemic arterial pressure, and preventing occult decreases in systemic pressure in hypovolemic patients.
 - Blood viscosity a major determinant of vascular resistance
 - CBF is inversely related with hematocrit
 - Some have claimed viscosity directly participates in cerebral hemodynamic autoregulation, termed *viscosity autoregulation*

CEREBRAL FUNCTION

Clinical Examination

- Cerebral function can be monitored with instrumentation or assessed clinically
 - Each monitor offers only a small window into the state of the CNS
 - Even in combination, current monitors have limitations in spatial and/or temporal resolution
 - A neurologic examination of an alert patient, contrariwise, can comprehensively assess function of CNS
 - Can be repeated as often as needed
 - Requires neither expensive technical equipment nor specialized technologists
- Clinically the neurologic examination has important limitations
 - First, patient’s clinical status or underlying disease may limit amount of information obtainable by a clinical examination
 - Second, results and utility of neurologic examination may be constrained by therapeutic interventions frequently used in ICU
 - For example, an intubated patient who is treated with neuromuscular blocking agents
 - Finally, neurologic evaluations performed intermittently by examiners of variable skill, raising problems of reliability
- Two aspects of examination that are particularly pertinent to ICU environment will be discussed:

TABLE 103.2**GLASGOW COMA SCALE**

Category	Grading		Comments
Eye opening	Spontaneous	4	Swelling may interfere with testing.
	To voice	3	
	To pain	2	
	None	1	
Motor response	Follows commands	6	Avoid description of flexion as decorticate and extension as decerebrate, because those terms denote an anatomic location of a lesion.
	Localizes pain	5	
	Withdraws to pain	4	
	Flexion to pain	3	
	Extension to pain	2	
	Flaccid	1	
Verbal response	Oriented	5	Impossible to assess in intubated patients. Some centers determine the response by inference and designate the final score with the subscript "T."
	Confused	4	
	Inappropriate	3	
	Incomprehensible	2	
	None	1	

The GCS score is the sum of the best attainable subscores in the categories of eye opening (E), motor (M), and verbal (V) responses. It ranges from 15 ($E_4 + M_6 + V_5$) to 3 ($E_1 + M_1 + V_1$).

- Assessment of level of consciousness, because of its ties to patient outcome for many different neurologic diseases
- Examination for assessing brain death
 - Because it is a graded assessment of brainstem function
 - Because it illustrates sources of error impacting results of clinical neurologic examination in ICU environment

Level of Consciousness (LOC): Glasgow Coma Scale (GCS)

- LOC typically assessed by GCS
 - Numerical scores assigned for best responses in categories of eye opening, motor response, and verbal response (Table 103.2)
 - For the GCS association of lower scores with worsened outcome has been shown for:
 - Traumatic brain injury
 - Subarachnoid hemorrhage
 - Brain abscess
 - Survival after cardiac arrest
 - Septic encephalopathy
 - GCS has several important limitations even if applied correctly
 - First, information loss inherent in reducing a graded assessment of three responses into a single number
 - Second, mechanical problems, such as swelling and endotracheal intubation, may prevent proper assessment of eye opening and verbal response.
 - In this setting, some assign lowest component score, others try to infer "true" score from related neurologic findings, still others add subscript "T" to indicate intubated patient.
 - Third, sedatives and neuromuscular blocking agents affect GCS score
 - Finally, GCS provides limited information about brainstem function
- as a guide to neurologic examination of comatose patient (Fig. 103.3)
- Given the gravity of diagnosis of brain death, prerequisite to determination is clinical picture, typically supported by imaging studies, that is consistent with occurrence of brain death
 - First step is determination of coma (i.e., lack of responsiveness to external stimuli due to unconsciousness)
 - Motor responses *elicited by examination* need differentiation from spontaneous movements *during examination*
 - Latter typically brief, slow movements originating from spinal cord and do not become integrated into decerebrate or decorticate responses
 - Rarely reproducible upon repeat testing
 - Reproducible partial eye opening failing to reveal iris described in response to peripheral painful stimulus in patient fulfilling clinical criteria of brain death
 - Conditions confounding clinical diagnosis of brain death are noted (Table 103.3)
 - In addition to confounding conditions, diagnosis of brain death should be consistent with imaging studies and/or overall clinical picture before formal determination of brain death considered
 - Next step in neurologic examination is assessment of brainstem function
 - Typical tests, afferent and efferent pathways, and potentially interfering clinical conditions summarized (Table 103.4)
 - To complete diagnosis of brain death, an apnea test is performed
 - To test response to an acute decrease in pH of CSF due to hypercarbia
 - Hypercarbia induced by disconnecting mechanical ventilation
 - Continued oxygenation is ensured by both preoxygenation and apneic oxygenation
 - Absence of respiratory movements at PaCO_2 of 60 mm Hg or after increase in PaCO_2 of 20 mm Hg consistent with brain death

Determination of Brain Death

- Because clinical determination of brain death requires comprehensive and methodical assessment of patient, steps serve

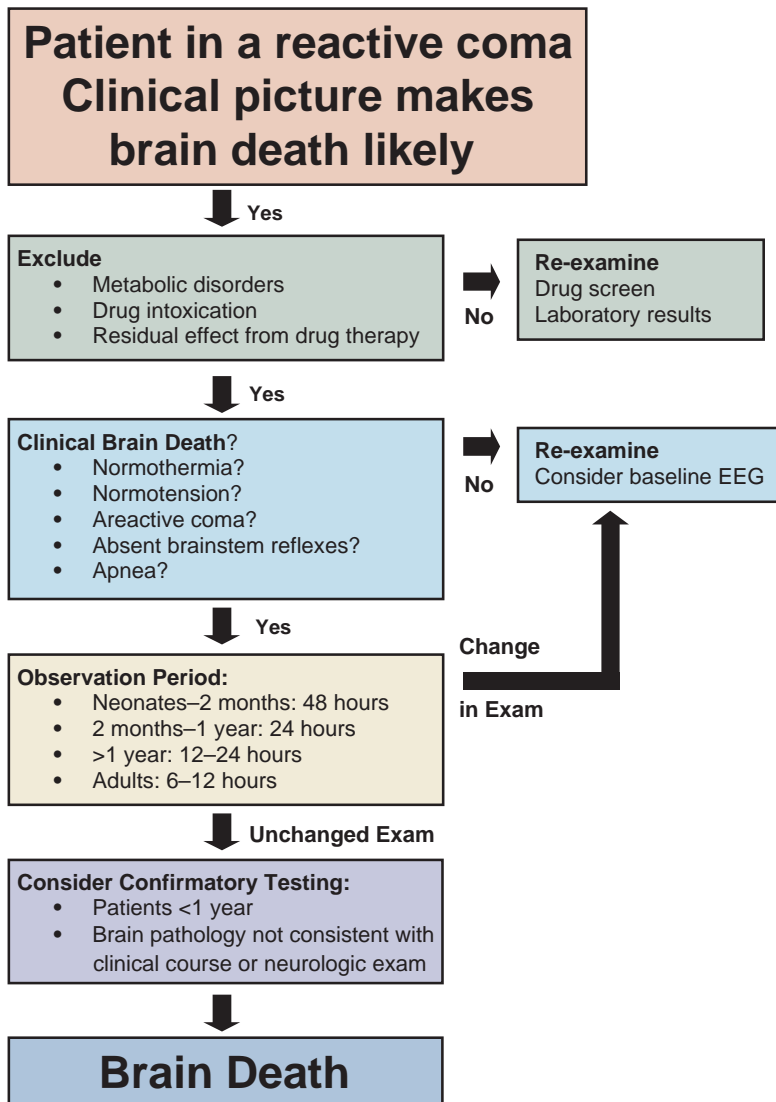

FIGURE 103.3. Algorithm for the determination of brain death.

- Testing may be complicated by arterial hypotension due to loss of arterial and autonomic tone
 - Such hypotension corroborates diagnosis of brain death but makes hemodynamic stability required for apnea testing difficult to attain
 - Apnea test may trigger movement responses, which reflect residual spinal activity
- Once criteria for brain death are met, either an observation period followed by repeat assessment or a confirmatory test is used to reach a final diagnosis
 - Cerebral angiography is the gold standard among confirmatory tests
 - Contrast media injected into aortic arch and distributes to external carotid circulation, whereas internal carotid and vertebral arteries fill only to level of skull base and atlanto-occipital junction, respectively
 - Similar findings obtained with:
 - Magnetic resonance angiography (MRA)
 - Single photon emission computed tomography 99mTc-HMPAO (SPECT)
 - EEG and transcranial Doppler also frequently used as confirmatory tests

Electrophysiologic Techniques

Diagnostic Electroencephalography: Clinical Utility in the ICU

- Diagnostic EEG studies/EEG monitoring in ICU done primarily for one of three purposes:
 - Brain death determination
 - Monitoring for evidence of seizure activity or cerebral ischemia
 - Determination of drug effect to titrate sedative/anesthetic drugs or control ICP
- Criteria for brain death vary from state to state
 - Some require a 16- to 32-channel isoelectric EEG on two consecutive recordings at least 24 hours apart to provide corroborating evidence for cessation of brain function.
 - Other factors affecting EEG can produce isoelectric EEG absent brain death.
 - Thus EEG cannot be used as sole evaluation for brain death.
 - Drug levels (Table 103.5) decline significantly over 24-hour period.

TABLE 103.3

NEUROLOGIC STATES RESEMBLING BRAIN DEATH

Disease state	Diagnostic aids	Comments
Hypothermia	Core temperature <32°C Osborne waves on ECG Drug screening	May cause central nervous system depression up to clinical brain death
Acute poisoning	Serum concentration measurements	In differentiating from brain death, consider antidote and/or document subtherapeutic drug concentration and/or wait for four elimination half-lives Direct central nervous system depressants may confound confirmatory testing of brain death because of CMRO ₂ –CBF coupling
Metabolic encephalopathy	Laboratory testing Intact lower brainstem function	Imaging studies should document structural central nervous system changes Imaging studies should document structural central nervous system changes
Akinetic mutism	Intact sleep–wake cycle	Imaging study shows frontal or mesencephalic brain lesion
Locked-in syndrome	Clinical course and imaging studies	Central locked-in syndrome: Corticobulbar and corticospinal tracts are interrupted at the level of the base of the pons; vertical eye movements are intact Peripheral locked-in syndrome: Guillain-Barré syndrome, advanced amyotrophic lateral sclerosis, neuromuscular blocking agents, organophosphate poisoning

ECG, electrocardiogram; CMRO₂, cerebral metabolic requirement for oxygen; CBF, cerebral blood flow.

- Patients with massive drug overdose or impaired metabolic pathways may show an isoelectric EEG for longer than 24 or 48 hours.
- Other diagnostic testing methods, including other electrophysiologic and nonelectrophysiologic methods, may be helpful.
 - Evoked potentials (see below) are more resistant to drug effects than EEG
 - Frequently used to demonstrate brainstem and cortical function even in face of an isoelectric EEG
 - Additionally, an EEG recorded immediately after cardiac arrest may show isoelectric pattern that subsequently recovers
 - Cortical evoked potentials demonstrated more reliable in assessing neurologic function immediately after ischemic or anoxic insult
- Continuous EEG monitoring or sequential diagnostic EEG studies described for:
 - Detection of nonconvulsive seizure (NCS) activity or
 - Seizure activity in the pharmacologically paralyzed patient
 - Detection of cerebral ischemia
 - Processed EEG algorithms developed to facilitate detection of ischemia, epileptiform, and frank seizure activity during continuous EEG monitoring
 - Technology not yet evolved to eliminate need for on-site technologist with monitoring experience
 - Continuous EEG monitoring in ICU demonstrated that NCSs much more common than previously thought
 - Reported following:
 - Neurosurgical procedures
 - Subarachnoid hemorrhage

TABLE 103.4

CLINICAL EXAMINATION OF THE BRAINSTEM DURING EVALUATION FOR BRAIN DEATH

Brainstem reflex	Afferent path	Efferent path	Caveats
Pupillary light reaction	II	III	Not confounded by systemic drugs; absence may be caused by prolonged administration of neuromuscular blocking agents
Ocular movements (oculocephalic reflex or caloric nystagmus)	VIII	III, VI	Confounded by damage from ototoxic drugs; cervical spine trauma may preclude testing of the oculocephalic reflex; voluntary ocular movements are sometimes the only finding that differentiates a “locked-in” syndrome from brain death
Corneal reflex/pressure on supraorbital nerve	V	VII	
Gag	IX	IX, X	May be difficult to assess in orotracheally intubated patient
Cough	X	X, cervical roots	Best tested by assessing the response to tracheal suctioning

TABLE 103.5

SEDATIVE-HYPNOTIC AND ANALGESIC DRUGS AND THE ELECTROENCEPHALOGRAM (EEG)

Drug		Effect on EEG dominant frequency	Effect on EEG amplitude	Burst suppression
Barbiturates	Low dose	Fast frontal β activity	Slight \uparrow	Yes, with high doses
	Moderate dose	Frontal α frequency spindles	\uparrow	
	High dose	Diffuse $\delta \rightarrow$ burst suppression \rightarrow silence	$\uparrow\uparrow\uparrow \rightarrow 0$	
Etomidate	Low dose	Fast frontal β activity	\uparrow	Yes, with high doses
	Moderate dose	Frontal α frequency spindles	\uparrow	
	High dose	Diffuse $\delta \rightarrow$ burst suppression \rightarrow silence	$\uparrow\uparrow \rightarrow 0$	
Propofol	Low dose	Loss of α , \uparrow frontal β	\uparrow	Yes, with high doses
	Moderate dose	Frontal δ , waxing/waning α	\uparrow	
	High dose	Diffuse $\delta \rightarrow$ burst suppression \rightarrow silence	$\uparrow\uparrow \rightarrow 0$	
Dexmedetomidine		Early appearance of high-amplitude δ frequency that increases with dose, similar to opiates	\uparrow	No
Ketamine	Low dose	Loss of α , \uparrow variability	$\uparrow\downarrow$	No
	Moderate dose	Frontal rhythmic delta	\uparrow	
	High dose	Polymorphic δ , some β	$\uparrow\uparrow$ (β is low amplitude)	
Benzodiazepines	Low dose	Loss of α , increased frontal β activity	\uparrow	No
	High dose	Frontally dominant δ and θ	\uparrow	
Opiates	Low dose	Loss of β , α slows	\uparrow	No
	Moderate dose	Diffuse θ , some δ	\uparrow	
	High dose	δ , often synchronized	$\uparrow\uparrow$	

δ , < 3-Hz frequency; θ , 3.5- to 7.5-Hz frequency; α , 8- to 13-Hz frequency; β , > 13-Hz frequency.

- CNS infection
- Head injury
- Evidence using neuron-specific enolase as a marker of neurologic injury that NCSs may produce neurologic damage
- Seizure duration and time to diagnosis significantly related to extent of damage and long-term outcome
- Without continuous EEG monitoring, NCSs cannot be detected
 - Not consistently and specifically associated with other findings such as hypertension and tachycardia

Processed Electroencephalogram: Monitoring of Sedation

- EEG to monitor depth of sedation in patients in ICU described extensively:
 - Nearly all techniques utilize processed EEG rather than unprocessed analog signal
 - Generally accomplished using one or two channels of EEG information
 - Recorded over frontopolar region of cerebral cortex
 - Location chosen because application of surface recording electrodes easy
 - Most devices designed for this purpose have been validated using frontopolar recording locations
 - Smaller number of channels used based on assumption that drug effect similar in all areas of brain
 - Generally valid except in case of patient with focal brain damage
- None of commercially available devices for monitoring drug effects on the EEG calibrated or validated for monitoring drug effects in patients with abnormal EEG
- Relatively limited information available on use of EEG to monitor drug effects in neurologically damaged patients
- Most commonly used for titrating sedative drugs
 - Particularly in pharmacologically paralyzed patient
 - Also for titration of barbiturate drugs used to control ICP
- Devices used to monitor the drug effect utilize either:
 - Unprocessed, raw analog EEG similar to electrocardiogram monitoring in ICU
 - One of three signal processing techniques:
 - Power spectrum analysis
 - Bispectral analysis
 - EEG entropy analysis
 - Bispectral Index (BIS, Aspect Medical Systems, Inc., Natick, MA) monitoring processes EEG signals that are recorded from a self-adhesive electrode strip placed on forehead.
 - Calculates and displays a BIS value
 - Dimensionless number ranging from 0 to 100 derived from highly processed EEG data that includes:
 - EEG power
 - EEG frequency
 - Bicoherence
 - Low BIS numbers indicate strong relationships among EEG frequencies and reflect condition consistent with deep hypnotic state (Table 103.6)
 - Relationship valid despite effects of age and infirmity on sensitivity to sedation

TABLE 103.6**CLINICAL CONDITION EXPECTED WITH BISPECTRAL INDEX VALUES**

100	Awake patient, amnesia unlikely
80	Sedated responsive patient, amnesia prominent unless significant event
70	Heavily sedated or unconscious patient, amnesia probable
60	General anesthesia, unresponsive to verbal stimuli
40	Deep hypnotic state
20	Burst suppression
0	Isoelectric electroencephalogram

- Aspects of imperfect performance of BIS monitor well known
 - BIS can decrease to numbers (20–50) consistent with deep general anesthesia during natural sleep
 - Memory less likely to form at lower BIS values but has been demonstrated even at BIS in range of 40–60, associated with general anesthesia
 - Artifact from electromyogram, electro-oculographic, or pacemaker generators can produce significant but spurious BIS increases (from 50s to 80s)
 - Makes possible overdosing nonrelaxed or paced patients when attempting to maintain a given BIS range
 - Can be driven higher by medications that are CNS stimulants
 - Ketamine
 - Methylphenidate
 - Dexmedetomidine
 - Cannot differentiate deep sedation from cerebral ischemia
 - Both cause loss of higher-frequency EEG waves (α and β slowing and δ and θ wave intrusion)
 - In extreme states, both can produce burst suppression or isoelectric EEG patterns with a low BIS
 - When O_2 delivery decreases below a level sufficient to meet $CMRO_2$, electrical function fails and BIS decreases
 - May partly explain improved ICU outcomes when the BIS is maintained >60

Evoked Potentials (EP)

- Recordings of electrical activity from different parts of the nervous system produced by either sensory or motor stimuli applied to activated portions of sensory and motor systems, respectively

- Except for motor-evoked responses recorded from muscle, EPs much smaller than background EEG or muscle electrical activity
- Responses from repetitive stimuli must be averaged to discern responses from background biologic signals or environmental noise
 - Auditory EPs very small (generally $<0.5 \mu V$) and require as many as 1,000 to 2,000 averaged responses to clarify signal
 - Somatosensory EPs larger ($0.5\text{--}10 \mu V$) and require fewer averages to clarify
- EPs described in terms of:
 - Latency (time [msec] from stimulus application to onset or peak of response)
 - Amplitude (μV)
 - Amplitude more important parameter for ICU studies because voltage mainly related to amount of functional neural tissue generating response
 - Latency related to conduction time from stimulus site to generating site
 - Assumption not always the case since a peripheral or cranial nerve injury may produce a nerve with fibers conducting at many different velocities
- Compared to EEG, EPs much less susceptible to effects of IV sedative-hypnotic drugs and not significantly affected by IV analgesics
- Table 103.7 summarizes different types of evoked potentials monitored in ICU

Peripheral Nerve Stimulation

- Rate of recovery from neuromuscular blocking (NMB) agents depends on:
 - NMB agent chosen
 - Dosing pattern (intermittent or continuous infusion)
 - Numerous patient factors (e.g., pseudocholinesterase deficiency, hepatic or renal dysfunction, induced cytochrome P450 enzyme, organophosphate toxicity, among many others)
- Suitability for extubation following prolonged neuromuscular blockade traditionally relied on functional strength testing
 - Ability to produce a negative inspiratory force
 - Ability to sustain a head lift
 - Incomplete patient cooperation due to sedation or confusion can adversely affect tests
- Peripheral nerve stimulation (PNS) used for “muscle twitch” testing, or acceleromyography, complements such functional assessments by objectively revealing condition of neuromuscular junction, independent of patient participation

TABLE 103.7**EVOKED POTENTIALS (EPS) IN THE ICU**

Type of EPs	Stimulus type and site	Recording sites
Somatosensory	Electrical, peripheral nerve	Peripheral nerve, spinal cord, head
Brainstem auditory	Loud click, ear	Ear, head
Magnetic motor	Magnetic pulse, head	Spinal column, peripheral nerve, muscle
Electrical motor	Electrical, head	Spinal column, peripheral nerve, muscle

TABLE 103.8

PERCENTAGE NEUROMUSCULAR JUNCTION BLOCKADE WITH NONDEPOLARIZING NEUROMUSCULAR BLOCKING AGENTS AND CORRESPONDING TRAIN-OF-FOUR AND CLINICAL RESPONSES

Response	Blockade (%)
Train-of-four 0/4	95
Train-of-four 1/4	90
Train-of-four 2/4	85
Train-of-four 3/4	80
Train-of-four 4/4	75
Sustained (≥ 5 s) tetanus	50
Sustained (≥ 5 s) head lift	25

- Reliable interpretation of nerve stimulation requires uniform stimulation and placement parameters
 - Conventional PNS delivers current—adjustable up to 80 mA:
 - In a train-of-four (TOF) series at 2 Hz as double-burst stimulation (DBS)
 - As single shocks at 1.0 or 0.1 Hz
 - By tetanic stimuli of 50 or 100 Hz
 - Maximal current settings ensure best chance of delivering suprathreshold stimuli and activation of greatest percentage of motor fibers despite changes of impedance or proximity
 - Occur with electrode separation or desiccation, skin cooling, or peripheral edema
 - TOF and DBS patterns do not require comparison to earlier responses for interpretation
 - Well suited for use in ICU setting where recovery of neuromuscular function may take hours to days and may involve assessments by multiple providers
- Muscle twitch testing measures the force of muscle contractions in response to PNS
 - Ratio of force between last and first stimuli in a series (TOF or DBS) best defines percentage of acetylcholine receptors occupied by *nondepolarizing* NMB agents in the neuromuscular junction
 - Counting loss of twitches in a TOF simpler method for assessing block level (Table 103.8)
 - TOF ratio does not change following administration of *depolarizing* NMB agent such as succinylcholine
 - When depolarizing NMB agents used, force of contraction diminishes equally across all stimuli and disappears altogether with sufficient dose
 - Excessive depolarizing NMB agent dose results in prolonged phase II block
 - TOF responses during a phase II block behave similarly to responses obtained following nondepolarizing NMB agents
- Peripheral nerve stimulator is attached to patient using two pregelled electrocardiogram electrodes; needle electrodes can also be used
- Electrodes placed closely (without the gels touching) to one another over a site where motor nerve lies relatively superficial to skin
- Antegrade nerve conduction improved if positive lead applied to proximal electrode
- Current path between electrodes should not contain muscle whose movement is monitored
- Separation of electrodes beyond several centimeters increases probability that PNS current may depolarize muscle directly
 - Causing movement unrelated to conduction through neuromuscular junction
 - Misinterpretation of the level of neuromuscular blockade
- Common sites for electrode placement are:
 - Over course of ulnar nerve at medial aspect of the wrist or over ulnar groove at elbow
 - Stimulation of ulnar nerve activates the m. adductor pollicis and twitches thumb
 - Placement of electrodes anterior to tragus will stimulate facial nerve
 - Innervates the m. corrugator supercilii and furrows the eyebrow
 - Stimulation of posterior tibial nerve posterior to the medial malleolus
 - Causes the m. flexor hallucis brevis and great toe to move
- Cold weakens muscle strength even absent NMB agents
 - Making PNS testing valuable in patients recovering from hypothermia
- Patients who have had a stroke will experience up-regulation of acetylcholine receptor density on muscle membrane as affected muscles denervate
 - PNS on affected limb will produce a TOF response exceeding the response seen from same site PNS on normal limb
 - To avoid overdosing or prematurely extubating patient based on TOF testing
 - PNS should be performed on sites unaffected by prior nerve injury
- PNS particularly helpful for monitoring level of relaxation achieved during infusion of NMB agents
 - PNS monitoring helps direct rate of infusion and avoid excessive administration
 - Pharmacokinetic and pharmacodynamic models illustrating TOF response to PNS with succinylcholine and rocuronium NMB infusions are at <http://vam.anest.ufl.edu/simulations/simulationportfolio.php>

CEREBRAL PERFUSION

- Most common clinical measure aimed at ensuring adequate CBF is to maintain cerebral perfusion pressure (CPP) above lower limit of cerebral autoregulation
- In cases of intracranial disease, relevant pressure opposing adequate perfusion is ICP

Monitoring of Intracranial Pressure

- ICP reflects dynamic interaction of tissues and fluids within a fixed-volume, hard cranial shell of approximately 1,400 mL in an adult
- Contents divided into:
 - Cerebral parenchyma
 - Arterial and venous blood
 - CSF components

FIGURE 103.4. Pressure–volume relationship of the intracranial vault. Volume in milliliters (abscissa) of water added to a supratentorial extradural balloon in a monkey, 1 mL/hour. Pressure in millimeters of mercury (ordinate). (With permission from Langfitt TW. Increased intracranial pressure. *Clin Neurosurg.* 1969;16:43–71.)

- Cerebral parenchyma accounts for 80% to 90% of contents
 - Includes both intra- and extracellular fluid as well as cellular membranes
- Volume of blood together with CSF makes up the remaining 10% to 20%
- **Monro-Kellie doctrine:**
 - Any increase in volume of one intracranial component occurs at the expense of another
 - Normal adult ICP is 8 to 15 mm Hg; in babies pressure is 10 to 20 mm Hg
 - Compensation in ICP may be achieved by:
 - Changes in volume of CSF
 - The slight distention of dura
 - Changes in intravascular volume, particularly in the venous channels
 - Compression or swelling of brain
 - Rate of change in volume of intracranial contents of importance
 - Rapid increase in volume produced by an epidural hematoma may overwhelm compensatory mechanisms and produce a rapid increase in ICP (Fig. 103.4)
 - Slowly growing brain tumor may produce a gradual displacement of structures within the cranial vault without a significant increase in ICP
- ICP is not static
 - Pressure fluctuations occur with cardiac systole due to distention of the intracranial arteriolar tree and respiration (ICP falling with inspiration and rising with expiration)
 - Straining or compression of neck veins can also cause a rise in pressure
 - Value in excess of 18 to 20 mm Hg is abnormal and must be treated
- As ICP increases cerebral venous pressure increases in parallel
 - Remaining 2 to 5 mm Hg higher, or else the venous system would collapse

- Because of relationship, CPP satisfactorily estimated as:

$$\text{CPP} = \text{MAP} - \text{ICP}$$

- Cerebral arterial circulation maintains constant CBF for a CPP 60 to 150 mm Hg
- Clinical deterioration in neurologic status widely considered a sign of increased ICP
- Bradycardia, increased pulse pressure, and pupillary dilation are signs of increased ICP
- Five methods most commonly used to monitor ICP are:
 - An intraventricular catheter
 - Considered the gold standard
 - A subarachnoid or subdural bolt
 - A subdural catheter
 - An intraparenchymal fiberoptic filament sensor
 - An extradural fiberoptic sensor
- All ICP monitors are invasive and share a risk of infection of about 5%
- Patients requiring ICP monitoring are generally those:
 - With a closed head injury and a GCS ≤ 8
 - In whom CT scan shows significant brain distortion
 - With worsening neurologic status
 - In whom there is need to sedate, paralyze, or operate in context of an abnormal brain
 - With postoperative complications
 - Who are unconscious or in shock

Interpretation of Intracranial Pressure Waveforms

- Normal ICP waveform has three characteristic peaks (P1, P2, and P3) of decreasing height correlating with arterial pulse waveform (Fig. 103.5)
- P1 (percussion) wave originates from arterial systole
 - Has sharp peak and constant amplitude
- P2 (tidal) wave more variable and ends on dicrotic notch
 - Elevation of P2 reflects decreased intracranial adaptive capacity and impaired autoregulation
 - However, sustained increases in ICP can occur without P2 elevation
- P3 (dicrotic) wave follows the dicrotic notch and is venous in origin
- Consecutive ICP waveforms observed over time show three distinct patterns observed:
 - A waves, now more commonly referred to as plateau waves, are pathologic (Fig. 103.6)
 - Rapid rise in ICP to 50 to 100 mm Hg, with variable period in which ICP remains elevated (“plateau”), followed by rapid fall to baseline

FIGURE 103.5. Intracranial pressure waveform showing the percussion wave (P1), tidal wave (P2), and dicrotic wave (P3). The timing of the peaks corresponds to the arterial pressure waveform. (Image courtesy of Integra Neurosciences, Inc.)

FIGURE 103.6. Lundberg plateau waves. The tracing of the intracranial pressure shows several pathologic increases of intracranial pressure, with plateaus lasting from 20 to 60 minutes. (Image courtesy Integra Neurosciences, Inc.)

- Plateau waves typically last from 5 to 20 minutes
- Generally seen in patients with already elevated ICP
- During a series of plateau waves, both amplitude and duration may increase
 - Leading to “terminal” wave in which ICP may rise to impede CBF
 - “Truncated” or atypical plateau waves not exceeding 50 mm Hg early indicators of neurologic deterioration
- B and C waves are smaller fluctuations in ICP related to respiration and autonomic fluctuations in blood pressure (Traube-Hering-Mayer waves), respectively
 - Of little clinical significance
- Markedly decreased or elevated CPP may lead to ischemia or spontaneous hemorrhage, respectively
- Normal CPP by no means ensures normal CBF
 - Increased cerebrovascular resistance (e.g., because of carotid stenosis, cerebral vasospasm, or microcirculatory compromise) may cause ischemia despite normal CPP
 - Similarly, normal CPP may coexist with abnormally increased CBF in settings such as posttraumatic vasoparalysis or normal perfusion pressure breakthrough after resection of an arteriovenous malformation

Direct Cerebral Blood Flow Measurement

- Ideal clinical method for CBF measurement in patients with intracranial pathology would be:
 - Noninvasive, inexpensive bedside procedure
 - Continuous or at least frequently repeatable
 - Provides good spatial resolution for superficial and deep structures of all vascular territories
 - No currently available method comes close to having characteristics (Table 103.9)
- Direct measurement of CBF possible by determining kinetics of wash-in or wash-out of inert tracer compound
 - Widely used measurement uses radioactive isotope of ^{133}Xe per inhalation or IV
 - Followed by measurement of radioactivity wash-out, with γ detectors placed over specific areas of brain
 - Method provides spatial resolution of 3 to 4 cm, depending on number of detectors
 - In normal brain, flow at different depths may be inferred from the early wash-out
 - Should reflect high-perfusion cortical gray matter and low-perfusion deeper white matter

TABLE 103.9

TECHNIQUES FOR MEASURING CEREBRAL BLOOD FLOW

Category	Technique	Resolution		Invasiveness	Cost
		Temporal	Spatial		
Bedside	Kety-Schmidt ^{133}Xe wash-out	15 min 3–15 min	Hemispheric 3–4 cm	Jugular catheter Jugular catheter, radiation	+ +
	Arteriovenous difference in oxygen content (AVDO ₂), jugular venous oxygen saturation (SjvO ₂)	<1 min	Global	Jugular catheter	+
	Double indicator dilution	3 min	Global	Jugular catheter, descending thoracic aortic catheter	+
	Near-infrared spectroscopy	<1 min	Local, bifrontal	No	+
	Thermal clearance probe	<1 min	Local, 1–2 cm	Exposed cortex	+
	Laser Doppler flow probe	<1 min	Local, 1–2 cm	Exposed cortex	+
	Positron emission tomography (PET)	4–6 min/section	<1 cm	Radiation from positron emitter	+++++
Tomographic	Stable Xenon computed tomography (CT)	4–6 min/section	<1 cm	Radiation from CT scan	+++
	Single photon emission tomography (SPECT)	4–6 min/section	<1 cm	Radiation from γ emitter	+++
	Magnetic resonance imaging (MRI)	4–6 min/section	<1 cm	No	+++

- Important disadvantage of technique is lack of sensitivity for focal areas of hypoperfusion
 - Obscured by adjacent areas of adequate flow
 - Phenomenon described as “look-through”
- Methods like SPECT, PET, xenon-enhanced CT or perfusion CT, or MRI provide excellent spatial resolution
- Not available at the bedside
- Some used clinically as confirmatory tests in determination of brain death
 - SPECT and MRA show a “hollow skull phenomenon” and absent intracranial flow, respectively
- Xenon-enhanced CT, which can be combined with standard CT scanning
 - Used to obtain prognostic information and withhold unnecessarily aggressive therapy by assessing severity of decreased CBF during stroke
 - Perfusion imaging allows detection of viable penumbra around areas of ischemia
 - May be restored to normal function if relative ischemia reversed

Transcranial Doppler (TCD)

Theoretical Basis

- Ultrasound waves used to measure velocity of blood flow in basal arteries of brain and extracranial portion of internal carotid artery
- Waves transmitted through relatively thin temporal bone, orbit, or foramen magnum
- When they contact moving red blood cells, they are reflected at changed frequency through brain and skull back to detector
- Change in frequency as blood cells move toward or away from ultrasound transmitter and detector an example of Doppler effect, related to velocity and direction of flow
 - Velocity increases during systole and decreases during diastole
 - Blood in lumen center moves faster than near the vessel wall, producing a spectrum of flow velocities
 - Spectrum resembles shape of waveform produced by intra-arterial pressure transducer
- TCD measurements most commonly made in middle cerebral and internal carotid arteries
 - Also measured in other vessels, including anterior cerebral, anterior communicating, posterior cerebral, posterior communicating, and basilar arteries
 - In approximately 10% of patients, particularly elderly females, technically satisfactory recordings cannot be obtained because of increased skull thickness
 - TCD cannot provide a simple assessment of global or hemispheric CBF
- Beyond question of vessel patency
 - Link between TCD measurements and CBF is indirect and subject to one technical limitation and two principal assumptions inherent in the link
 - Technical limitation is:
 - Accuracy with which the flow velocity can be determined depends on the angle of insonation
 - Variability of repeated measurements can be minimized either by:
 - Using a single examiner
 - Rigidly mounting TCD probe on patient’s head with a headset, provided shift in brain structures caused by mass lesion does not displace artery
 - Two principal assumptions that have to be met for TCD-measured blood flow velocity to correspond to CBF are:
 - Flow and flow velocity are directly related only if arterial diameter remains constant
 - Blood flow in basal arteries of brain must be directly related to cortical CBF
 - Assumptions likely represent oversimplification and have not been supported adequately by evidence

Detection of Cerebral Vasospasm

- TCD helpful in identifying vasospasm following aneurysmal subarachnoid hemorrhage
 - As diameter of arterial lumen decreases with vasospasm velocity of blood flowing through the narrowed vessel must increase if flow is to be maintained
 - With absolute flow velocity alone, detection and documentation of severity and duration of vasospasm possible
 - Specificity approaches 100% but with limited sensitivity
- TCD has contributed much to understanding of natural history of vasospasm following aneurysmal subarachnoid hemorrhage (SAH)
 - But most studies predate current therapeutic approach of:
 - Early exclusion of aneurysm
 - Therapy with hypertensive-hypervolemic hemodilution and nimodipine
 - Recent advance in treatment of vasospasm that highlights one limitation of TCD is therapeutic dilation of stenotic arteries
 - TCD flow velocities may remain elevated despite successful dilation as a result of impaired autoregulation in the poststenotic vascular bed.
 - Likewise, TCD cannot assess isolated distal vasospasm.
 - May account for as much as a third of all cases of vasospasm
 - Because of limitations TCD not universally used to assess aneurysmal SAH patients

Assessment of Intracranial Pressure and Confirmation of Brain Death

- TCD-generated waveforms exhibit sequential characteristic changes as ICP increases
 - As ICP increases systolic waveform becomes more peaked
 - As ICP nears diastolic blood pressure, diastolic flow diminishes and subsequently ceases
 - Once ICP exceeds diastolic blood pressure, TCD shows a pattern of to-and-fro movement of blood, indicating imminent intracranial circulatory arrest
 - Change in waveforms used to calculate pulsatility index
 - Relating difference between peak-systolic and end-diastolic velocity either to mean or to systolic velocity
 - Such waveform analyses correlate well with ICP but cannot replace ICP monitoring
 - Autoregulation, vasospasm, or proximal arterial stenosis may alter TCD signal independent of ICP
- Clinical brain death demonstrates a characteristic blood flow velocity pattern
 - Short systolic inflow of blood

- Followed by an exit of blood (flow direction reverses) from cranium during diastole
- TCD a validated confirmatory test in diagnosis of brain death
 - Sensitivity exceeds 90%, specificity of 100%
- TCD can ascertain diagnosis in most patients at the bedside
 - Large craniotomy or inadequate bone window may preclude complete examination necessary to confirm brain death

Jugular Venous Oxygen Saturation Monitoring (SjvO₂)

- SjvO₂ monitoring touted as an indicator of cerebral oxygen homeostasis
 - Changes in SjvO₂ from normal range (60%–70%) provide:
 - Indirect information on state of CMRO₂
 - Because blood flow normally linked to CMRO₂, indirect information on CBF
 - Approximately 50% to 70% of patients with severe head trauma (GCS ≤ 8) will have an episode of desaturation (SjvO₂ < 50%)
 - Ischemic threshold widely accepted to be SjvO₂ < 50% during early hyperemic conditions following head injury
 - Clinical utility of SjvO₂ monitoring remains unsettled
- Complexity of catheter placement, sample collection, and results interpretation may contribute to 20% utilization of SjvO₂ monitoring in victims of moderate to severe head injury
- SjvO₂ preferentially measured from flow-dominant internal jugular (IJ) vein
 - Right 60%, left 25%, equal 15%
 - To provide best estimate of *whole* brain CMRO₂ conditions
- Hemispheric dominance established by which side will, in response to unilateral compression of IJ vein, produce greater rise of ICP
 - Alternatively, IJ vein size seen by ultrasound a reasonable estimate of dominance
 - As is relative size of jugular foramina on head CT scan
- Cannulation of the jugular bulb for intermittent or continuous monitoring similar to IJ catheterization for CVL placement
 - However needle, wire, and catheter are advanced in cephalad direction
 - Risk of causing an intracranial vascular injury reduced if wire is not pushed into jugular bulb
 - Catheter advanced slowly until resistance indicates it has reached roof of the bulb
 - Catheter then withdrawn 1 cm so that head movement cannot cause catheter-related vessel injury or thrombosis
 - Recommended not to power-flush or administer infusions through catheter
- Increase in SjvO₂ indicates either:
 - Lowered CMRO₂ (less extraction) and/or increased or hyperemic CBF
- Decrease in SjvO₂ (greater extraction) indicates:
 - Increased CMRO₂, hypoxia/anemia, or oligemia
 - Observed changes in SjvO₂ might then help guide therapeutic interventions
- Experience validates association of desaturation (SjvO₂ < 50%) with worsened neurologic outcome
- Mortality reduced 66% when monitoring or managing cerebral extraction of oxygen with SjvO₂ in conjunction with CPP than when CPP alone managed
- CMRO₂ increased in patients with ICP ≥ 20 mm Hg and normal to decreased cerebral extraction (“luxury perfusion”) of oxygen with hyperventilation therapy
- Elevated ICP associated with normal to increased cerebral extraction of oxygen was treated with mannitol, resulting in improved ICP and cerebral oxygenation
- Profound neurologic deterioration occurs with SjvO₂ ≤ 30%
 - As cerebral circulatory arrest develops, external carotid artery provides blood sampled at jugular bulb
 - SjvO₂ then increases
 - In clinical setting where brain death is expected
 - Ratio of mixed venous blood saturation to SjvO₂ < 1:
 - Highly sensitive (95%), specific (100%), and predictive (92%) for cerebral circulatory arrest
- Limitations with SjvO₂ monitoring may explain low utilization
 - Admixture of extracranial blood through collateral venous drainage into superior sagittal, sigmoid, and cavernous sinuses directly into jugular bulb occurs even when catheter correctly placed
 - If samples are drawn faster than 2 mL/minute or catheter tip lies too short of jugular bulb, extracranial blood may further contaminate specimen
 - Spuriously elevate SjvO₂
 - “Clean” SjvO₂ sample does not distinguish between:
 - Lateralizing differences in flow
 - Metabolism
 - Brain injury
 - Because SjvO₂ reflects global average from variety of brain regions
 - Marked regional hypoperfusion may not be reflected by change in SjvO₂
 - SjvO₂ and brain tissue oxygen pressure (PbtO₂), measure of regional ischemia, usually track in same direction
 - But maintaining SjvO₂ above conventional thresholds did not reliably protect against occurrence of regional ischemic insults
 - SjvO₂ cannot be used alone to:
 - Direct hyperventilation
 - Or to alert clinicians to evolving hypocapnia-induced regional cerebral ischemia
 - “Acceptable” hyperventilation may cause harm clinically undetected by SjvO₂
- SjvO₂ monitoring most useful as trend monitor in:
 - Patients with diffuse global brain injury
 - When it identifies saturations below ischemic threshold
- Normal-range SjvO₂ can represent false-negative measurement
 - Insofar as areas of regional ischemia may be present
- Currently, best technique for guiding therapy to regional area of concern is PbtO₂

Near-infrared Spectroscopy (NIRS)

- NIRS utilizes minimal absorption and greater penetration of wavelengths in this portion of electromagnetic spectrum to evaluate changes in CBF and cerebral oxygenation

- Similar to pulse oximetry, NIRS compares differences in absorption of Hgb (670–760 nm) to O₂-Hgb (830 nm)
- NIRS used for noninvasive assessment of brain oxygenation through intact skull by detecting changes in oxyhemoglobin concentrations associated with neural activity
- NIRS offers advantage of continuous, noninvasive monitoring of cerebral cortex
 - Typically done with one sensor each for right and left hemispheres of brain
 - Originally developed for monitoring neonates
 - Penetration in adults significantly less compared to neonates
 - Extracranial changes in blood flow and oxygenation affect absorption values
 - May be as sensitive in detecting progressive cerebral hypoxia as EEG
 - But spatial resolution limited by number of detectors
 - Together with transcranial Doppler evaluation provides useful information in hemodynamic evaluation of carotid artery occlusion
 - Clinical utility in adults remains limited

Brain Oxygenation (PbtO₂)/Microdialysis

- In contrast to most other techniques for evaluating brain oxygenation
 - Tissue monitoring/microdialysis offers advantages and disadvantages of monitoring very discrete regions of tissue
 - Continuous PbtO₂ monitoring measures oxygen delivery and identifies cerebral hypoxia and ischemia in patients with:
 - Brain injury
 - Aneurysmal SAH
 - Malignant stroke
 - Other patients at risk for secondary brain injury
- 2007 Guidelines for the Management of Severe Head Injury brain tissue oxygenation threshold of <15 mm Hg adopted as level III recommendation
 - Subthreshold levels of PbtO₂ associated with increased morbidity and mortality in patients with severe brain injury
 - Increased FiO₂ has little effect on PbtO₂ in normal tissue
 - In injured brain, PbtO₂ increased as long as blood flow is present
- Management strategy in severe TBI includes PbtO₂ monitoring and therapy directed at maintaining brain oxygenation >25 mm Hg
 - Multimodal approach results in reduced patient mortality compared to CPP-directed therapy
- In 101 comatose, nonpenetrating head injury patients, whose GCS score was >8
 - Despite aggressive management of both ICP and CPP brain tissue hypoxia frequently occurred
 - Depth and duration of tissue hypoxia associated with unfavorable outcome and death at 6 months after injury
- In patients with severe injury in whom hyperventilation considered
 - Monitoring of brain oxygenation may be considered
 - Significance of local partial pressure of brain tissue oxygen debated
 - However, evidence for inclusion in multimodal monitoring is increasing
- Microdialysis technique can be combined with PbtO₂ monitoring using same highly localized probe
 - Microdialysis catheter consists of fluid path surrounded by semipermeable membrane
 - Fluid path perfused with balanced salt solution equilibrating with brain interstitial fluid
 - Fluid returned from path contains brain substances:
 - In proportion to local concentration
 - Specific membrane permeability
 - Perfusate flow rate
 - Concentration of substances of interest can be followed over time
- In research technique used to study the role of excitotoxicity or proteomics of brain ischemia in stroke
 - Monitoring application closest to clinical utility aims to determine state of aerobic glucose utilization by following ratio of metabolic intermediary products such as the pyruvate-to-lactate ratio
 - Ratiometric determinations of chemically similar molecules obviate the need to calibrate the probe based on the permeability of the substance(s) of interest
 - Decrease in pyruvate-to-lactate ratio indicates increase in anaerobic metabolism and/or mitochondrial dysfunction consistent with ischemia

CHAPTER 104 ■ BEHAVIORAL DISTURBANCES IN THE ICU

- Advances in critical care have led to improved survival rates among those admitted to intensive care units (ICUs)
 - In the United States approximately 55,000 patients are treated in ICUs each day.
 - At least 40% of adult ICU patients require mechanical ventilation (MV).
- Patients requiring long-term MV (> 3 days) represent 4% to 10% of critical care admissions and consume 30% to 50% of critical care resources.
- Incidence of neurologic dysfunction or injury has been underestimated, underreported, and only recently studied in critically ill patients

- Higher severity of initial neurologic dysfunction (lower Glasgow Coma Scale [GCS]) was associated with higher 30-day mortality
- No change or worsening of severity of GCS from first to third ICU day was also associated with higher 30-day mortality
- Neurologic morbidities include polyneuropathy, encephalopathy, delirium, and cognitive impairments
- Medical and surgical management of critical illnesses can, and frequently does, result in *de novo* behavioral disturbances, including delirium and cognitive impairments

DELIRIUM: AN ACUTE BEHAVIORAL DISTURBANCE

- A neurobehavioral syndrome characterized by:
 - Acute confusion
 - Inattention
 - Disorganized thinking
 - Fluctuating course of mental status changes
 - Motoric subtypes of delirium are:
 - Hypoactive
 - Hyperactive
 - Mixed
 - *Hypoactive* or “quiet” delirium is characterized by reduced mental and physical activity and inattention
 - *Hyperactively* delirious patients are agitated, combative, and at risk for self-extubation, reintubation, pulling out central lines, and falls
 - Delirium is a dynamic condition and often fluctuates between the hypoactive or hyperactive.
 - In ICU mixed clinical picture is common
 - Given multiple possible presentations not uncommon for clinicians to miss diagnosis
 - Delirium underdiagnosed by 80% of physicians
 - Standardized ICU examinations using reliable, sensitive, and specific CAM (Confusion Assessment Method)-ICU allows for accurate detection and analysis of delirium
- Delirium may be most common psychiatric condition experienced by hospitalized elderly
 - Affecting between:
 - 15% and 20% of hospitalized medical patients
 - 25% to 65% of surgical patients
 - As many as 80% of ICU patients
 - Once considered benign recent evidence links delirium with adverse outcomes:
 - Prolonged hospitalization
 - Poor surgical recovery
 - Increased morbidity and mortality
 - Also associated with adverse cognitive outcomes in critically ill patients (see below)
 - Delirium is not simply a marker of preexisting subclinical or early dementia.

CHRONIC COGNITIVE IMPAIRMENTS

- Cognitive processes or functions defined as ways of experiencing and thinking about the world and include:
 - Intelligence
 - Attention

- Learning
- Memory
- Language
- Visual spatial abilities
- Executive function (reasoning, decision making, planning, problem solving, working memory, sequencing, and executive control)
- In ICU survivors, one-third or more will develop chronic cognitive impairment
- Current data suggest cognitive impairments common in survivors of critical illness

NATURE OF COGNITIVE IMPAIRMENTS

- There are 10 cohorts totaling approximately 455 patients assessing long-term cognitive impairments following critical illness
- Evidence suggests that 25% to 78% of ICU survivors experience cognitive impairments
 - Among patients with acute respiratory distress syndrome (ARDS), prevalence of cognitive impairments is as high as:
 - 70% to 78% at hospital discharge
 - 45% to 46% at 1 year
 - 47% at 2 years
 - 25% at 6 years
- Cognitive impairments occur in various cognitive domains (Table 104.1)

TABLE 104.1

COGNITIVE IMPAIRMENTS OBSERVED FOLLOWING CRITICAL ILLNESS

Cognitive domains	Specific cognitive impairments
Attention	Divided attention Focused attention Sustained attention
Memory	Explicit or declarative Recall (verbal and nonverbal) Recognition (verbal and nonverbal) Short-term memory
Intelligence	Verbal intelligence Performance intelligence Full-scale (general) intelligence
Language	Verbal fluency
Visual spatial	Apraxia Visuoconstruction
Executive function	Decision making Executive control Impulsivity Perseveration Planning Problem solving Shifting sets Working memory
Mental processing speed	Slow mental processing speed
Motor	Grip strength

- Cognitive impairments in critically ill patients similar to those reported in other populations such as carbon monoxide poisoning and following elective coronary artery bypass graft surgery
- In general, memory the most frequently observed deficit
 - Followed by impaired executive function and attention
- Memory questionnaire administered to prospective cohort of 87 ARDS survivors found 20% of patients rated memory as poor 18 months after ICU discharge
- Evaluation of executive function in general ICU survivors at 3 and 9 months found that 35% of patients were impaired
- Similar findings seen in MV, nondelirious patients who had impaired memory and problem-solving abilities (i.e., executive dysfunction) during ICU treatment, during hospital treatment, and at 2-month follow-up
 - While in ICU, 100% of patients had impaired executive function
 - 67% had impaired memory
 - At 2-month follow-up, 50% had impaired executive function and 31% had impaired memory
- Acute respiratory distress syndrome (ARDS) patients had significantly lower measured IQ compared to their premorbid estimated IQ at hospital discharge
 - Measured IQ returned to premorbid level at 1-year follow-up
 - No additional improvement in IQ at 2 years
 - Does not necessarily suggest comparable recovery in all cognitive domains
 - Data from traumatic and anoxic brain injury literature suggest some cognitive abilities more likely to improve than others
- Cognitive impairments not associated with:
 - ICU length of stay (LOS)
 - Acute Physiology and Chronic Health Evaluation II (APACHE II) scores
 - Tidal volume
 - Number of days receiving sedative, narcotic, or paralytic medications
- Impaired executive function measured *during* ICU treatment was associated with ICU and hospital LOS
- Impaired memory measured during ICU and hospital treatment was associated with admission APACHE II scores
- These relationships were not present by 2-month follow-up.
- Age has not been associated with cognitive impairments.
- Most patients in 10 cohorts studied were young or middle-aged adults (mean age, 54 years)

DELIRIUM AND ITS RELATION TO ADVERSE COGNITIVE OUTCOMES

- Studies of association between delirium and adverse cognitive outcomes generally carried out in non-ICU populations
- Data from these investigations likely apply to ICU cohorts
- Important difference between delirium and cognitive impairments is delirium fluctuates but cognitive impairments do not
- Table 104.2 shows comparison of characteristics of delirium, dementia, and cognitive impairments
- Higher incidence of dementia in hospitalized elderly patients with a history of delirium at follow-up evaluation
 - Patients 85 years or older, excluding those with dementia, with an episode of delirium during hospitalization were significantly more likely to be diagnosed with dementia at 3-year follow-up compared to patients without delirium
 - Over 3-year period, 60% of geriatric medical patients with delirium at hospital admission (after evaluating for dementia at baseline) developed dementia compared to only 18.5% of patients without delirium

INDICATORS OF COGNITIVE IMPAIRMENTS

- Consistent finding is lack of association between some indicators of illness severity and development of cognitive impairments

TABLE 104.2

COMPARISONS BETWEEN COMPONENTS OF DELIRIUM, DEMENTIA, AND COGNITIVE IMPAIRMENTS

	Delirium	Dementia	Cognitive impairments
Mental status	Marked fluctuation	Chronically impaired—appears stable but deteriorates over time	Normal
Cognitive function	Sudden onset Acute cognitive impairment characterized by disorientation and confusion	Insidious onset Chronic cognitive impairment Often memory is the first observed cognitive impairment Progressive loss of cognitive functions (impaired judgment, executive function, etc.) Progressive decline over time Interferes with daily functioning and work May include changes in personality, mood, and behavior	Sudden onset Chronic cognitive impairment May affect one or multiple cognitive domains, with memory, executive function, and information processing most commonly affected Initially there may be some recovery or improvement of cognitive function Stable over time May interfere with daily functioning and work
Duration	Temporary	Permanent	Permanent

- In critically ill patients, one in three patients with delirium had cognitive impairments at 6-month follow-up
 - Patients were not primarily geriatric (mean age of 53 years)
 - Findings suggest that presence of delirium may be critical in predicting adverse long-term cognitive outcome

LACK OF RECOGNITION OF COGNITIVE IMPAIRMENTS

- In non-ICU clinical settings, physicians fail to recognize (or assess) cognitive impairment in 35% to 90% of patients
- Cognitive impairments rarely evaluated in critically ill patients
 - May be overlooked in one of every two cases
- In 42% of ARDS survivors who underwent rehabilitation therapy, most were not evaluated for cognitive impairments, and only 12% of patients were identified as having cognitive impairments by clinical rehabilitation team
- Consequences of cognitive impairments far reaching and may contribute to decreased ability to perform activities of daily living and inability to return to work
 - Two years after hospital discharge:
 - 34% of ARDS survivors returned to full-time work or were full-time students
 - 34% were receiving disability payments started after hospital discharge for ARDS
 - 32% (20 of 62) were not working or were retired

POTENTIAL MECHANISMS OF DELIRIUM AND LONG-TERM COGNITIVE IMPAIRMENTS

- Many physiologic and pharmacologic perturbations affect the central nervous system in critically ill patients
- Precise mechanisms contributing to delirium and cognitive impairment or both are unknown, various theories proposed, including:
 - Potentially adverse effects of medical illness on cognition
 - Pathologic processes underlying delirium and cognitive impairments
 - The impact of psychoactive medications, including sedatives and analgesics
- Delirium and cognitive impairments rarely have one causal mechanism
 - They are thought to be multifactorial
 - Pathogenesis likely due to interactions between patient vulnerability and precipitating factors or insults, including critical illness and its treatment

Psychoactive Medications

- Many medications used for sedation or pain control—including those used in ICU setting—known to cause or worsen delirium
- Association exists between high delirium prevalence rates in surgical and critically ill populations and use of sedatives and narcotics

- Data on impact of anesthetics and sedatives on long-term cognitive functioning conflicting
 - Reports suggest they may have neurotoxic effects, particularly for high-risk groups such as the very old (>75 years) and/or those with a recent history of cognitive impairment
- In some, effects of medications on cognition may be mediated by genetic factors
 - Apolipoprotein E4 (APOE4) allele is one probable genetic factor that may affect individual sensitivity to drug effects
 - Allele a significant risk factor for:
 - Development of certain forms of Alzheimer disease
 - Hippocampal atrophy
 - Worse recovery of neurologic function following traumatic brain injury (TBI)
 - Cognitive decline following cardiopulmonary bypass surgery
 - Delirium
- More research is needed but appears that certain anticholinergic agents may have particularly adverse effects on cognition when administered to patients possessing the APOE4 allele.
 - Lorazepam increases susceptibility to impaired verbal learning and related cognitive deficits in patients with the APOE4 allele compared to patients without this polymorphism.

DELIRIUM AS A MECHANISM OF COGNITIVE IMPAIRMENTS

- Some researchers have speculated that delirium is a marker of subclinical dementia or cognitive impairment.
 - Which might not otherwise develop for years or decades
- Data suggest common pathogenic mechanisms might underlie both Alzheimer disease and delirium.
 - Although, from a clinical standpoint, there are similarities and differences

COGNITIVE REHABILITATION

- Cognitive rehabilitation used widely with patients following TBI, stroke, and other neurologic insults
 - Evidence suggests cognitive rehabilitation can be highly effective
- May be mediated by factors such as cause of brain injury and cognitive domain (i.e., memory, executive functioning, etc.) of focus
 - For example, patients with hypoxic brain injuries may be less responsive to cognitive rehabilitation than those with TBI or stroke

EMOTIONAL DISORDERS

- Psychiatric morbidity following critical illness common and includes depression, anxiety, and posttraumatic stress disorder (PTSD)
- Unclear whether emotional disorders are a psychological reaction to extraordinary emotional and physiologic stress, sequelae of brain injury sustained due to critical illness and its treatment, or all of the above

- Combination of medications, physiological changes, pain, altered sensory inputs, and an unfamiliar environment may contribute to emotional changes

Posttraumatic Stress Disorder

- Estimates of PTSD prevalence in critically ill cohorts as high as 63%
- Generally exceed those of other high-risk populations
- General medical ICU cohorts shown to have both lowest and highest rates of PTSD compared to more specialized populations
 - Reported prevalence rates of PTSD range from 9.7% to 63%
 - Rates of PTSD in specialized populations range from 18.5% to 43%
- Risk factors for development of PTSD and related symptoms not been systematically studied

- Several probable risk factors have been identified:
 - Delusional memories
 - Younger age
 - Existence of prior mental health history
 - Anxiety
 - Female gender

Depression and Anxiety

- Depression common among medically ill cohorts due both to the specific physical effects of certain illnesses and/or effects of illness on quality of life, independence, employment, and other factors
 - Occurs in 25% to over 50% of ARDS survivors
- Regarding anxiety, with the exception of PTSD, less is known
 - Anxiety occurs in 4% to 41% of ARDS survivors
 - Reported in 24% of ARDS survivors at 1 and 2 years
 - Smoking and alcohol abuse may be related to symptoms of depression and anxiety in ARDS survivors

SECTION XV ■ GASTROINTESTINAL (GI) BLEEDING

CHAPTER 105 ■ UPPER GASTROINTESTINAL BLEEDING

Acute gastrointestinal (GI) bleeding is a common indication for admission to the intensive care unit (ICU) in the United States, with over 300,000 admissions per year. Most (75%) of these arise from the upper GI tract. Despite advances in critical care medicine, the mortality associated with upper GI bleeding has not changed and remains about 10%, likely due to aging of the population and increasing comorbidities.

EPIDEMIOLOGY

- The annual incidence of hospital admission for upper GI bleeding in the United States is approximately 100 per 100,000.
- Peptic ulcer disease (PUD) is the most common cause of upper GI bleeding, accounting for half of cases (Table 105.1).
- Upper GI bleeding is twice more common in males than females and increases with age.
- Mortality for patients younger than 60 years in the absence of malignancy or organ failure is <1%.
- Patients rarely die from blood loss; rather, death is due to decompensation of other underlying conditions.
- Four major risk factors for PUD are nonsteroidal anti-inflammatory drugs (NSAIDs), *Helicobacter pylori* infection, stress, and gastric acid.
- Duodenal ulcers are more common than gastric ulcers.
- Recent data showed a decline in the proportion of cases caused by PUD—down to 21%—with nonspecific mucosal abnormalities being the most common cause (42%).
- Mallory-Weiss tears account for 5% to 15% of cases, while the proportion of patients bleeding from varices varies widely, depending on the population, from about 5% to 30%.
- Hemorrhagic or erosive gastropathy (usually from NSAIDs or alcohol) and erosive esophagitis often cause mild upper GI bleeding, but major hemorrhage does not usually occur from erosions (Fig. 105.1).
- Esophagogastric varices are also a common cause of upper GI bleeding and usually develop as a consequence of systemic or segmental portal hypertension.
- The outcome of an episode of active variceal hemorrhage depends on the control of active bleeding and the avoidance of complications associated with bleeding and its treatment.

CLINICAL PRESENTATION

- Upper GI bleeding commonly presents with hematemesis and/or melena.
- Hematemesis or coffee-ground emesis indicates an upper GI source of bleeding, which is above the ligament of Treitz, at the junction of the duodenum and jejunum.

- Melena suggests a minimum blood loss of 200 mL. The presence of melena is indicative of blood being present in the digestive tract for at least 12 to 14 hours.
- Although the more proximal the bleeding site in the upper GI tract, the more likely the patient will have melena, a significant percentage of patients with ascending colon sources of bleeding may also present with melena.
- Hematochezia is usually a presentation of lower GI bleeding, but an upper GI source that bleeds rapidly may also present with hematochezia.

TABLE 105.1

ETIOLOGY OF UPPER GASTROINTESTINAL BLEEDING

MUCOSAL (EROSIVE OR ULCERATIVE)

1. Peptic ulcer disease
 - a. Idiopathic
 - b. Aspirin- or NSAID-induced
 - c. Infectious (*Helicobacter pylori*, cytomegalovirus, *Herpes simplex virus*)
2. Stress-related mucosal disease
3. Zollinger-Ellison
4. Esophagitis
 - a. Peptic
 - b. Infectious (*Candida albicans*, *H. simplex virus*, cytomegalovirus)
 - c. Medication-related (aspirin, NSAIDs, alendronate)

VASCULAR

1. Dieulafoy lesion
2. Idiopathic angiomas
3. Osler-Weber-Rendu syndrome
4. Watermelon stomach
5. Radiation-induced telangiectasia
6. Blue rubber bleb nevus syndrome

PORTAL HYPERTENSION

1. Esophageal varices
2. Gastric varices
3. Portal hypertensive gastropathy

TUMORS

1. Benign (leiomyoma, polyp, lipoma)
2. Malignant

TRAUMATIC

1. Mallory-Weiss tear
2. Nasogastric tube (usually while in the intensive care unit)
3. Foreign body ingestion

OTHER

1. Hemobilia
2. Hemosuccus pancreaticus

FIGURE 105.1. Severe esophagitis. Endoscopic view of severe esophagitis.

- Patients with upper GI bleeding who have hematochezia usually have hemodynamic instability and rapidly dropping hemoglobin.
- Vomiting, retching, or coughing preceding hematemesis—especially in an alcoholic patient—should increase suspicion for a Mallory-Weiss tear.
- In addition to symptoms, a detailed history should include use of aspirin or other NSAID intake, alcohol consumption, presence of liver disease or variceal bleeding, history of PUD, weight loss, dysphagia, reflux, aortic aneurysm, or abdominal aortic vascular graft.

DIAGNOSTIC EVALUATION

Gastric Lavage

- Nasogastric lavage is important for confirmation of the diagnosis and may be predictive of a high-risk lesion if bright red blood is present in the lavaged.
- A nasogastric tube may also decrease the risk of aspiration in patients with active hematemesis.
- A nonbloody nasogastric aspirate may be seen in up to 16% of patients with upper GI bleeding, usually if bleeding has ceased or if from a duodenal source, particularly if the pylorus is closed.
- The presence of bile in the aspirate is often misleading and does not necessarily rule out a postpyloric source of bleeding in 50% of cases.
- Testing of gastric contents for blood can frequently be misleading because of nasogastric tube-related trauma. In addition, the low pH of gastric contents may interfere with the guaiac test's design for occult blood testing in stool, giving false results.
- An elevated blood urea nitrogen (BUN)-to-creatinine ratio usually indicates an upper GI source as well as major blood loss.
- Patients without renal disease who have a BUN >25 mg/dL have lost a minimum of 1 L of blood.

TABLE 105.2

CLINICAL AND LABORATORY DETERMINANTS OF SIGNIFICANT BLOOD LOSS

CLINICAL

1. Resting tachycardia (>100 beats/min or 20 beat increase from baseline if baseline heart rate >100 beats/min)
2. Orthostasis:
 - a. Pulse increase >20 beat/min
 - b. Systolic BP decrease >20 mm Hg
 - c. Diastolic BP decrease >10 mm Hg
3. Hematochezia
4. Failure to clear bright red blood from gastric lavage

LABORATORY

1. High transfusion requirement (more than 1 unit every 8 h)
2. Lactic acidosis
3. Azotemia

BP, blood pressure.

- Persistent azotemia (for more than 24 hours) is an indication of hypovolemia because volume loss contributes quantitatively more than the digestion of blood in raising BUN and is the sole determinant of azotemia 24 hours after cessation of bleeding.

Amount of Blood Loss

- Determination of estimated blood loss is the single most important aspect of care in patients with upper GI bleeding. This estimation helps with the aggressiveness of volume resuscitation and triage to an appropriate level of care (i.e., transfer to ICU).
- Estimation of blood loss is often incorrect and requires an accurate assessment of vital signs, central venous pressure, hemoglobin and hematocrit, and a degree of clinical experience. Some indicators of clinically significant blood loss are summarized in Table 105.2.
- Most complications associated with blood loss result from the adverse effects of hypovolemia and hemorrhagic shock on organs and are compounded by limited or poor baseline physiologic reserve.
- Initial hematocrit may be misleading due to loss of whole blood, which results in equal loss of plasma and erythrocytes.
- Redistribution of plasma from the extracellular to intravascular space, within 24 to 48 hours of the initial hemorrhage, results in dilution of red cell mass and a fall in hematocrit. The hematocrit fall may occur even more rapidly with volume replacement with crystalloid or nonheme colloid.
- *Acute* responses to blood loss represent a spectrum of changes, including resting tachycardia, orthostasis, peripheral vasoconstriction (cold, clammy skin), and acute end-organ dysfunction (mental status changes, oliguria).
- *Chronic* blood loss is usually associated with stable hemodynamic responses, retention of hypotonic fluid, and an absence of impaired organ function due to compensatory changes in the cardiovascular system.

Diagnostic Workup

- Upper GI endoscopy is the diagnostic modality of choice for further evaluation of upper GI bleeding.
- Endoscopy helps in localization and identification of the bleeding lesion in the upper GI tract and can be therapeutic in establishing hemostasis and preventing recurrent bleeding.
- Upper GI studies with radiocontrast material such as barium are contraindicated in the setting of acute upper GI bleeding due to interference with subsequent endoscopic intervention, angiography, and surgery.
- Angiographic diagnosis of the source of upper GI bleeding is made by extravasation of contrast material. The bleeding must be brisk, with a rate of about **0.5 to 1 mL/minute**. Angiography can be helpful in establishing the diagnosis in 75% of patients; about 85% of bleeding originates from a branch of the left gastric artery.
- Nuclear medicine studies using ^{99m}Tc -pertechnetate-labeled red blood cell scan may also aid in localization of the bleeding site and has the ability to detect bleeding at lower rates (**<0.5 mL/minute**) than contrast angiography.
- Endoscopy is the diagnostic method of choice for esophagogastric varices. In cases where endoscopy is nondiagnostic and gastric variceal bleeding is suspected, studies such as endoscopic ultrasound, portal venography, or computed tomography (CT) angiography can be used.
- Cirrhotic patients with upper GI bleeding should be administered a prophylactic antibiotic—usually a fluoroquinolone—preferably prior to endoscopy.

PREDICTORS OF OUTCOME AND RISK STRATIFICATION

- Three clinical parameters that are independent predictors of death and rebleeding are (1) hemodynamic instability, (2) older age, and (3) presence of comorbidities (Table 105.3).
- Early therapeutic endoscopic intervention plays an important role in achieving hemostasis, reducing the rebleeding rate, and improving morbidity and mortality in high-risk peptic ulcer-related upper GI bleeding.
- On the contrary, early endoscopy increases costs without a change in outcomes in patients with low-risk clinical and endoscopic features.

TABLE 105.3

CLINICAL INDICATORS OF SIGNIFICANT UPPER GI BLEEDING

PATIENT CHARACTERISTICS

Older age (>60 y)
Severe comorbidities (i.e., cardiopulmonary disease)
Onset of hemorrhage after hospitalization

RELATED TO AMOUNT OF BLEEDING

Hematemesis of bright red blood
Hematochezia
Gastric lavage with bright red blood
Hemorrhagic shock
High transfusion requirement

TABLE 105.4

ENDOSCOPIC FINDINGS THAT PREDICT RECURRENT UPPER GI BLEEDING

Endoscopic stigmata of bleeding	Prevalence (%)	Risk of bleeding (%)
Clean ulcer base	35	3–5
Flat spot	10	7–10
Oozing without visible vessel	10	10–20
Adherent clot	10	25–30
Nonbleeding visible vessel	25	50
Active arterial bleeding	10	90

- Risk stratification of patients with upper GI bleeding can be done using clinical and laboratory data and endoscopic findings. Endoscopic risk stratification depends on findings that predict the risk of rebleeding (Table 105.4).

MANAGEMENT

- The initial evaluation of a patient with upper GI bleeding includes the assessment of hemodynamic stability and need for aggressive resuscitation, if necessary.
- Table 105.5 summarizes the general principles of management.

TABLE 105.5

PRINCIPLES OF TREATMENT FOR UPPER GASTROINTESTINAL BLEEDING

GENERAL

1. Close monitoring in the ICU if bleeding is significant
2. Place a large nasogastric tube
3. Large bore IV access
 - a. At least two 14- or 16-gauge peripheral IVs
 - b. Or a 12 Fr double lumen catheter or a 9 Fr introducer
4. Volume resuscitation with crystalloids to maintain hemodynamic stability
5. Transfuse PRBCs to maintain hemoglobin
 - a. >7 g/dL in healthy, young individuals
 - b. >10 g/dL in elderly with comorbidities such as ischemic heart disease
6. Correct coagulopathy
7. Consult gastroenterology and surgery if bleeding severe

SPECIFIC (BASED ON THE CAUSE/LESION)

1. Acid suppression
2. Splanchnic vasoconstrictors for variceal bleeding
 - a. Octreotide
 - b. Vasopressin analogues
3. Antibiotics (fluoroquinolones) for variceal bleeding
4. Upper GI endoscopy
5. Angiography (as indicated)
6. Surgery

ICU, intensive care unit; IV, intravenous; Fr, French; PRBCs, packed red blood cells; GI, gastrointestinal.

Hemodynamic Resuscitation

- The initial management of upper GI bleeding should be directed at restoring blood volume to maintain hemodynamic stability. Hemodynamic stabilization with adequate volume and blood resuscitation also helps to minimize treatment-associated complications.
- Intravenous (IV) access with two large-bore (14- to 16-gauge) catheters should be maintained at all times.
- In cases where peripheral IV catheters cannot be placed, a large-bore central line (9 to 12 French) should be inserted; triple-lumen catheters have one 16- and two 18-gauge ports and are long and should therefore be avoided due to unacceptably high resistance to flow.
- Hypovolemia and hypotension from GI blood loss should be treated promptly with fluid resuscitation using crystalloid and packed red blood cells (PRBCs).
- All patients with hemodynamic instability or a hematocrit drop of more than 6%, a transfusion requirement greater than two units of PRBCs or significant active bleeding as evidenced by continued hematemesis with bright red blood from gastric lavage or hematochezia should be admitted to ICU for close observation and resuscitation.
- High-risk patients, including the elderly or those with severe comorbidities such as ischemic **heart disease** or congestive heart failure, should be transfused to maintain **their hemoglobin >10 g/dL**.
- On the contrary, unnecessary transfusion should be avoided in young, healthy individuals in whom maintenance of hemoglobin >7 g/dL may be sufficient.
- In hemorrhagic shock, close monitoring of end-organ perfusion (coronary, central nervous system, and renal) and preventing ischemic organ injury improves survival.
- In addition to a baseline electrocardiogram (ECG) and telemetry monitoring, urine output should be monitored continuously.
- In patients with massive hemorrhage or variceal bleeding, monitoring of preload via a central venous or pulmonary artery catheter may be useful; less invasive monitoring, including those devices using pulse-wave form variability (LidCO, PICCO, Flow Track) to evaluate preload, may also be useful in these situations.
- Coagulopathy should be corrected as needed to maintain **platelet count >50,000 cells/ μ L** and **prothrombin time within 2 seconds** of the upper level of normal.
- After replacement of factors and platelets, recombinant activated **factor VII** can rapidly correct severe coagulopathy in hepatic failure.
- Elective intubation should be considered in patients with ongoing hematemesis or altered mental status to facilitate endoscopy and decrease the risk of aspiration. Gastroenterology and, in cases of severe bleeding, surgery consultations should be requested.

Pharmacologic Treatment

Gastric Acid Suppression

- Acid-suppressive therapy with **proton pump inhibitors (PPI)** is an essential adjunct to therapeutic endoscopy for management of patients with PUD-related upper GI bleeding.

- Other acid-suppressing agents, including H_2 -receptor antagonists (H_2RA), have not been shown to reduce the rate of rebleeding or transfusion requirement in PUD.
- High-dose PPI infusion following a bolus injection significantly reduces the rate of rebleeding compared to standard therapy in patients with bleeding from PUD.
- Current recommended doses of IV PPI therapy are lansoprazole, 90- to 120-mg bolus followed by 6 to 9 mg/hour infusion, and pantoprazole, 80 mg bolus followed by 8 mg/hour infusion. The infusion is usually continued for 48 to 72 hours and, if there is no further bleeding, switched to a twice-daily dose.
- The superiority of PPI over H_2RA s has been attributed to better maintenance of **gastric pH above 6.0**, which may lead to clot stabilization by prevention of fibrinolysis, and thus rebleeding.

Other Therapies

- Splanchnic vasoconstrictors are important adjunct therapies to variceal hemorrhage. The current agent of choice in the United States is the somatostatin analogue octreotide.
- Somatostatin and its analogues inhibit the release of vasodilator hormones such as glucagon, thereby indirectly causing splanchnic vasoconstriction and decreased portal inflow.
- For octreotide, the recommended dose is a 50- μ g IV bolus followed by an infusion of 50 μ g/hour for 5 days.
- Additionally, a longer-acting analogue of vasopressin, terlipressin, may also be used. Its efficacy is similar to octreotide and endoscopic sclerotherapy.
- Octreotide may also be considered as an adjunct therapy in the management of nonvariceal bleeding.
- If a vasopressor is needed temporarily for the maintenance of blood pressure, medications that have β_2 -adrenergic activity, such as dopamine or albuterol, should be avoided due to potential risk of splanchnic vasodilation.

Endoscopic Treatment

- Identification and hemostasis of the source of upper GI bleeding is critical in the patient's outcome.
- Emergent endoscopy with therapeutic intervention is needed in patients who remain hemodynamically unstable and continue to bleed.
- In cases for which hemodynamic stability can be established quickly with volume resuscitation, endoscopy can be performed within 24 hours.
- The two most commonly used hemostasis techniques in the United States are injection therapy with epinephrine (1:10,000) and contact thermal devices.
- Combination therapy with injection and thermal coagulation are superior to monotherapy in patients with major endoscopic stigmata such as active bleeding or adherent clot.
- Visible vessels should be treated with thermal coagulation, whereas endoscopic intervention is not required for low-risk lesions such as a clean-base ulcer or a flat spot.
- Upper GI endoscopy is associated with potential complications, including aspiration, adverse reactions to conscious sedation, viscus perforation, and increased hemorrhage during therapeutic intervention.

- Contraindications to endoscopy include suspected GI perforation, unstable angina, severe coagulopathy, and severe agitation.
- In patients with recent ischemic cardiac events, the risks of endoscopy may outweigh its benefits, and it should therefore be used judiciously.
- Complications of endoscopic therapy include mucosal ulceration, motility abnormalities, stricture formation, esophageal perforation, and mediastinitis, as well as portal hypertensive gastropathy due to shunting of blood to the gastric mucosa.

Nonvariceal Bleeding

- Early therapeutic endoscopic intervention is important in achieving hemostasis, reducing rebleeding rates, and improving morbidity and mortality in PUD-related upper GI bleeding.
- One-third of patients with active bleeding or a nonbleeding visible vessel require urgent surgery; further bleeding is possible if treated conservatively.
- Patients with recurrent bleeding after endoscopic therapy benefit from repeat endoscopic therapy.
- Treatment of adherent clots is controversial. Double-blind trials of PPI therapy without endoscopic therapy showed extremely low rates of recurrent bleeding. In contrast, two small endoscopic trials showed better results with endoscopic therapy than conservative therapy.
- Bleeding from Mallory-Weiss tear stops spontaneously in 80% to 90% of patients and recurs only in up to 5% of patients. Endoscopic intervention is effective in actively bleeding Mallory-Weiss tears but is not necessary if active bleeding is not present.
- Rarely, surgery may be required to repair the tear. Massive bleeding can be seen if the Mallory-Weiss tear occurs in a patient with portal hypertension.

Variceal Bleeding

- Compared to nonvariceal causes of upper GI bleeding, which stop spontaneously in 90% of cases, variceal bleeding subsides spontaneously in only 50% of patients.
- The development of massive bleeding from gastroesophageal varices is indicative of advanced liver disease.
- Isolated gastric varices can occur due to segmental portal hypertension or as a consequence of obliteration of esophageal varices with endoscopic intervention.
- Active variceal bleeding occurs in about 50% of patients with decompensated cirrhosis, accounting for about one-third of all cirrhosis-related deaths.
- The mortality is very high, ranging between 70% and 80% in patients with continued variceal bleeding or rebleeding; each episode of bleeding is associated with a 30% risk of mortality.
- Variceal hemorrhage can predispose patients to hepatic encephalopathy, hepatorenal syndrome, and systemic infection, all of which increase the mortality in these patients.
- The risk of rebleeding remains high, ranging between 60% and 70%, unless endoscopic intervention is instituted to obliterate the varices.
- The greatest risk of rebleeding is within the first 48 to 72 hours, although it can occur as late as 6 weeks. Table 105.6 summarizes the risk factors for rebleeding from esophageal varices.

TABLE 105.6

RISK FACTORS FOR EARLY (<6 WEEKS) RECURRENT VARICEAL BLEEDING

CLINICAL

Age >60 years
Severity of initial bleed
Severity of chronic liver disease
Presence of ascites
Renal failure

ENDOSCOPIC

Active bleeding during endoscopy
Clot on varices
Red color signs (i.e., cherry red spot)
Increasing size of varices

- Esophageal variceal bleeding is usually amenable to endoscopic therapy via the obliteration of varices by either sclerotherapy or band ligation.
- Endoscopic band ligation is superior to sclerotherapy in initial hemostasis, rate of recurrent bleeding, complications, and mortality.
- **Sclerotherapy** may be indicated in cases where visualization is poor, but is usually followed by band ligation.
- Unlike esophageal varices, endoscopic management of gastric varices is less effective due to deeper localization of varices in the submucosa.
- Injection of cyanoacrylate tissue glue and thrombin are promising therapies in the endoscopic management of gastric varices.
- The transjugular intrahepatic portosystemic shunt (TIPS) procedure is done as salvage therapy to artificially create a portosystemic shunt to decompress the portal venous system and, consequently, variceal vasculature. It is recommended in patients with variceal bleeding refractory to pharmacologic and endoscopic therapy, regardless of the severity of cirrhosis.

Angiographic Treatment

- In a few patients with nonvariceal upper GI bleeding, angiographic localization may be necessary, with the option of hemostasis using a vasoconstrictor (i.e., intra-arterial vasopressin) or embolization (i.e., gelatin sponge).
- Embolization carries the risk of bowel ischemia, infarction, and necrosis, which is seen less in the duodenum than in the stomach due to the dual circulation from celiac and superior mesenteric arteries.

Surgery

- Surgical indications for the management of nonvariceal hemorrhage are life-threatening hemorrhage refractory to pharmacologic and endoscopic intervention, failure of medical therapy to resolve or prevent the recurrence of PUD, and related complications such as bleeding.
- The surgical procedure depends on the location of the ulcer and the clinical status of the patient. Mortality from surgical intervention for PUD can be as high as 30%.

TABLE 105.7**RISK FACTORS FOR STRESS ULCER BLEEDING**

1. Respiratory failure requiring mechanical ventilation for more than 48 h
2. Coagulopathy
 - a. Thrombocytopenia ($<50,000$ cells/ μL)
 - b. INR (>1.5)
 - c. PTT (greater than two times the upper limit of normal)
3. Other risk factors
 - Severe sepsis syndrome
 - Shock
 - Liver failure
 - Renal failure
 - Major trauma
 - Extensive burns
 - Intracranial hypertension

INR, international normalized ratio; PTT, partial thromboplastin time.

- The TIPS procedure has decreased the need for surgical shunt, which is indicated for patients with variceal hemorrhage and preserved hepatic synthetic function.
- Distal esophageal transaction, with or without devascularization, is another surgical option in patients with massive, refractory variceal hemorrhage, but is associated with high mortality.

STRESS-RELATED MUCOSAL DAMAGE

- Splanchnic hypoperfusion plays a pivotal role in the pathogenesis of stress-related mucosal damage. Stress-related mucosa damage (SRMD), also known as stress ulcers, occurs as a consequence of critical illness and is the most common cause of GI bleeding in the ICU. Table 105.7 summarizes the risk factors for bleeding from stress ulcers.
- SRMD occurs within a few hours of critical illness and can present as lesions ranging from subepithelial petechiae to superficial erosions that can progress into true ulcers. These lesions are usually multiple and occur predominantly in the fundus of the stomach, typically sparing the antrum.
- Acute respiratory failure requiring mechanical ventilation for longer than 48 hours and coagulopathy are the two strongest independent risk factors for clinically significant GI bleeding due to SRMD.
- Most SRMD lesions are asymptomatic and clinically insignificant, although some patients may develop clinically evident bleeding, presenting with hematemesis, coffee-ground emesis, melena, and hematochezia.
- Clinically evident bleeding due to SRMD occurs in up to 25% of critically ill patients who do not receive prophylactic therapy, with approximately 20% of these patients having clinically significant bleeding.
- Clinically significant, SRMD-related bleeding is associated with an increased length of ICU stay and morbidity and mortality.

Treatment

- The treatment of stress ulcer bleeding is supportive. Efforts should be focused on reversing the precipitating factors.
- Acid suppression with H_2RA or PPIs is routinely used as adjunct therapy, given that luminal acidity is an essential factor in the pathogenesis of SRMD.
- Bleeding from SRMD is usually not amenable to endoscopic intervention because the lesions are diffuse. However, in cases of severe bleeding, endoscopy may be indicated and successful if hemorrhage is from one or several lesions.
- Since the gastric mucosa has a rich collateral blood supply, angiographic treatment—including embolization or intra-arterial vasopressin—may be considered for bleeding refractory to endoscopic therapy.

Prophylaxis

- The incidence of stress ulcer bleeding has been decreasing as a result of more aggressive fluid resuscitation and prophylactic therapy.
- Most deaths in patients with stress ulcer bleeding are not due to GI hemorrhage. Therefore, the contribution of stress ulcer bleeding to overall ICU mortality does not appear to be significant in unselected ICU populations.
- Although gastric acid production is not increased in the most critically ill patients, it is essential in the pathogenesis of SRMD, and thus, therapies targeting gastric acid have been the mainstay of prophylaxis.
- Medications that suppress gastric acid, such as H_2RAs and PPIs, prevent SRMD by raising the gastric fluid pH, ideally above 4.0.
- Gastric pH-altering agents, as well as sucralfate, decrease the incidence of clinically significant bleeding by approximately 50%. However, a more recent study showed the superiority of H_2RAs over sucralfate in the prevention of SRMD-related bleeding.
- A major concern about using pH-altering medications is an increased risk of ventilator-associated pneumonia due to gastric colonization with the Enterobacteriaceae secondary to increased gastric pH and subsequent retrograde gastro-oropharyngeal contamination.
- Based on available data, the risk of pneumonia attributable to pH-altering drugs can be minimized via the implementation of preventive measures such as maintenance of the semirecumbent position, avoidance of high gastric residuals, and the administration of tube feeds into the small bowel whenever possible.
- Enteral feeding also decreases the risk of clinically evident GI bleeding. The beneficial effects of enteral feeding are probably multifactorial.
- Due to limited data, the use of enteral nutrition as the sole “therapy” for stress ulcer prophylaxis should be discouraged.

CHAPTER 106 ■ APPROACH TO LOWER GASTROINTESTINAL BLEEDING

IMMEDIATE CONCERNS

- Lower gastrointestinal (LGI) bleeding (LGIB) may be the primary cause of admission to the intensive care unit (ICU) or occurs during the course of ICU care for disorders other than LGIB. The initial approach to patients with LGIB, whether occult or acutely overt, is resuscitation to maintain organ perfusion.
- ICU physicians must maintain adequacy of airway and circulation, including ensuring an open airway and adequate intravenous access.
- Thereafter, the severity of bleeding should be graded to determine whether urgent diagnostic and interventional procedures need to be initiated immediately.
- The consequences of LGIB should be prevented or treated, just as would an acute myocardial infarction (AMI) induced by anemia or unstable hemodynamic status. A summary approach to ICU patients is noted in Table 106.1.

Essential Diagnostic Tests and Procedures

- History taking, including previous operative interventions and medications
- Physical examination, including digital examination
- Stool guaiac for anemic patients with suspicious gastrointestinal (GI) blood loss
- Complete blood count
- Endoscopic procedures: sigmoidoscopy, colonoscopy, enteroscopy, and capsule endoscopy
- Barium study
- Radiologic procedures: angiography

TABLE 106.1

SUMMARY OF AN APPROACH TO ICU PATIENT'S WITH LOWER GASTROINTESTINAL BLEEDING

1. Immediately assess and stabilize the patient's hemodynamic status
The ABCs of resuscitation
2. Determine presence of lower gastrointestinal bleeding
By history, physical examination, and sometimes nasogastric aspiration
3. Arrange appropriate diagnostic and therapeutic interventions to stop any active bleeding
4. Treat any underlying lesions, and monitor and manage the comorbid illness

ICU, intensive care unit.

- Nuclear scintigraphy: technetium-labeled red blood cell scan
- Other examinations for affected organs due to unstable hemodynamics, such as electrocardiogram (ECG) for AMI

Treatment

- Ensure stable hemodynamic status, using fluids and transfusion of blood components.
- Endoscopic therapies include local injection, electrocoagulation, hemoclippping, argon plasma coagulation, and elastic banding according to the nature of the bleeding.
- Radiologic interventions include angiography with intra-arterial vasopressin infusion, embolization, and glue.
- The adverse events caused by treatment modalities, such as perforation caused by endoscopic thermocoagulation or bowel infarction due to angiographic embolization, should be monitored and managed.
- Surgical consultation is warranted for severe LGIB in which the patient cannot be resuscitated or if all available therapeutic modalities fail.

OVERVIEW

- LGIB is defined as a bleeding source distal to the ligament of Treitz, thus involving the small bowel and colon, and accounts for an estimated 20% to 24% of all major GI bleeding.
- The annual incidence of LGIB is approximately 0.03% in the adult population and the annual incidence of hospitalization for LGIB to be 20 to 30 cases per 100,000 persons.
- LGIB is more common in men than women, and the incidence increases with age, with a >200-fold increase from the third to ninth decades of life.
- Patient age is an important factor in the differential diagnosis of GI bleeding. Patients <40 years are more likely to suffer from small bowel tumors, whereas patients >40 years are more prone to bleeding from vascular lesions and neoplasm.
- LGIB is approximately 20% to 33% as common as upper GI bleeding (UGIB) but has a lower mortality rate than does UGIB. Two to 15% of patients with presumed LGIB will have UGIB.
- Patients who develop LGIB while hospitalized for another disease process have a higher risk of death than those admitted with LGIB. Similarly, LGIB patients with comorbid illness have a higher mortality than those without.
- Most deaths are not the direct result of uncontrolled bleeding, but rather exacerbation of an underlying disorder or development of a nosocomial complication.

TABLE 106.2**CAUSES OF LOWER GASTROINTESTINAL BLEEDING****COLONIC SOURCES**

- Vascular ectasia
- Diverticulosis
- Ischemic colitis
- Acute hemorrhagic rectal ulcer syndrome
- Neoplasia
- Postpolypectomy
- Inflammatory bowel disease
- Infectious colitis and ulcer
- NSAID-induced colopathy
- Radiation colitis
- Hemorrhoids
- Dieulafoy lesions
- Colon varices
- Aortoenteric fistula

SMALL BOWEL SOURCES

- Vascular ectasia
- Focal active bleeding small bowel tumor:
 - Lymphoma
 - Adenocarcinoma
 - GIST
 - Other tumors
- NSAID-induced enteropathy
- Crohn disease
- Meckel diverticulum
- Vasculitis: SLE, Behçet disease, Schönlein-Henoch purpura
- Infection related ulcer: CMV, and so forth
- Small bowel varices
- Aortoenteric fistula

NSAID, nonsteroidal anti-inflammatory drugs; GIST, gastrointestinal stromal tumor; SLE, systemic lupus erythematosus; CMV, cytomegalovirus.

- LGIB remains a difficult diagnostic and treatment problem for several reasons:
 - Bleeding can originate from any part of the lower GI tract.
 - Blood loss is often intermittent in nature, and it is difficult to identify the source in the absence of active bleeding, especially angiographically.
 - The colon preparation before urgent colonoscopy is, obviously, needed but often incomplete.
 - Recurrent bleeding due to angiodysplasia or diverticula may be seen with LGIB.
 - Unlike UGIB, there are no evidence-based and effective pharmacologic therapies for LGIB.
- Among the many causes of LGIB (Table 106.2), diverticular bleeding, angiodysplasia, colitis, and neoplasm have been reported to be the most frequent.
- In ICU acute hemorrhagic rectal ulcers and ischemic colitis are the most frequent causes of LGIB, followed by colitis, angiodysplasia, and diverticular bleeding (Table 106.3)

Presentation

- LGIB may present in multiple ways, including occult fecal blood; iron deficiency anemia; melena; intermittent scant hematochezia; or acute, massive, and overt bleeding.

TABLE 106.3**CAUSES OF LOWER GASTROINTESTINAL BLEEDING IN SURGICAL, TRAUMA, AND MEDICAL ICUS**

Causes	Percent
Acute hemorrhagic rectal ulcer syndrome (AHRUS)	26.7
Ischemic colitis	17.1
Colitis other than ischemia	8.6
Vascular ectasia (angiodysplasia)	6.7
Diverticular bleeding	5.7
Malignancy	5.7
Colonic polyp	3.8
Solitary ulcer	3.8
Hemorrhoid	2.9
Dieulafoy lesions	1.9
Radiation colitis	1.0
Small bowel bleeding	6.7
Undetermined	9.4

ICU, intensive care unit.

From Wang HP. Unpublished data.

- Patients with chronic LGIB may only present with anemia, whereas those with acute LGIB may complain of passing bright red blood per rectum, dark blood with clots, or, less commonly, melena.
- Patients with brown or infrequent stools are unlikely to have brisk bleeding, and those with frequent passage of red or maroon stool may have aggressive ongoing bleeding.
- **Pallor, fatigue, chest pain, palpitations, dyspnea, tachypnea, tachycardia, posture-related dizziness, and syncope** are suggestive of hemodynamic compromise and demand aggressive care.
- The severity of LGIB may be underestimated due to compensatory mechanisms that delay the onset of hypotension. Careful history taking and physical examination are essential to the care of LGIB patients.
- The approach to LGIB patients is initially aimed at immediate assessment and stabilization of the hemodynamic status, followed by identifying the source of bleeding, stopping any active bleeding, treating any underlying lesions, monitoring and managing comorbid illness, and preventing recurrent bleeding.
- Even with the advances in localization studies, approximately 10% of patients still require surgical intervention without having their bleeding source identified.

ANATOMIC CONSIDERATIONS OF LOWER GASTROINTESTINAL BLEEDING (LGIB)

- LGIB is anatomically defined as bleeding located from the ligament of Treitz to the anus, and may include the jejunum, ileum, ileocecal valve, colon (ascending, transverse, descending, sigmoid, rectum), and anus.
- Given the length of lower GI tract (the small bowel averages 6.7 meters), as well as the special anatomic problem for the small bowel, such as its free intraperitoneal location, multiple overlying loops, and active contractility, there are several management issues for LGIB; these include choice of tests

for fecal occult blood, the necessity of nasogastric (NG) tube placement, and the application of endoscopy, radiologic procedures, and ultrasound.

Fecal Occult Blood

- This is the most common form of GI bleeding. In the ICU, patients suspected of having GI blood loss, secondary to findings of persistent anemia, will have a fecal occult blood study as the first investigative step. Although there are numerous types of fecal occult blood tests, the test used determines the location in the GI tract where blood is likely to be detected.

Guaiac-based Tests

- Guaiac-based tests, the classic fecal occult blood study, utilizes hemoglobin's pseudoperoxidase activity. Guaiac turns blue after oxidation by oxidants or peroxidases in the presence of an oxygen donor such as hydrogen peroxide. Because hemoglobin is degraded in the GI tract, guaiac-based tests are more sensitive for detecting bleeding in the lower than upper GI tract.

Immunochemical Fecal Occult Blood Tests

- Immunochemical fecal occult blood tests detect human globin epitopes and are highly sensitive for the detection of stool blood. These tests do not detect upper GI blood because globin molecules are degraded by upper GI tract enzymes.

Heme-porphyrin Test

- The heme-porphyrin test is the most sensitive method of detecting occult blood loss of either the upper or lower GI tract. However, it cannot discriminate between UGIB and LGIB.

Nasogastric Tube Placement

- The necessity of NG tube placement and gastric lavage for acute LGIB to exclude an upper GI source has not been studied prospectively. Routine use of the NG tube to exclude the possibility of an upper GI bleed is controversial and, overall, nasogastric aspiration localizes bleeding accurately only in 66% of attempts. Nonetheless, approximately 2% to 15% of patients presenting with acute severe hematochezia have an upper GI source of bleeding identified on upper GI endoscopy.
- In the American Society for Gastrointestinal Endoscopy (ASGE) guideline, NG tube placement to rule out an upper GI source of bleeding may be considered if a source is not identified on colonoscopy, particularly if there is a history of upper GI symptoms or anemia.
- Patients with hemodynamic compromise and hematochezia should have an NG tube placed.
- The absence of blood in NG aspirate is not sufficient to exclude UGI bleeding—16% of patients with bleeding secondary to a duodenal ulcer have a negative NG tube lavage.

APPROACH TO LOWER GASTROINTESTINAL BLEEDING

Resuscitation

- Approximately 85% of GI bleeding episodes stop spontaneously, whereas the remainder require aggressive resuscitation, diagnostic modalities, and often intense medical and/or surgical management.
- The first management step for a patient presenting with overt LGIB is the ABCs of resuscitation. Resuscitation is imperative to restore euvolemia and prevent complications of blood loss in the cardiac, pulmonary, renal, or neurologic systems.
- Resuscitation takes place in parallel with the initial evaluation of the patient; resuscitation must not be withheld or delayed for diagnostic procedures.
- The patient's respiratory and heart rates, and blood pressure, including orthostatic measurements, should be assessed.
- Attention to the airway is important when the LGIB is caused by an obstructive lesion, which may lead to vomiting with the consequent high risk of aspiration.
- Postural hemodynamic changes, chest pain, palpitations, syncope, pallor, dyspnea, and tachycardia suggest hemodynamic compromise; the severity of bleeding is easy to underestimate due to compensatory mechanisms.
- An **orthostatic decrease** in systolic blood pressure >10 mm Hg or an increase in **heart rate** >10 beats/minute indicates an **acute loss of at least 15%** of blood volume.
- With hemodynamic compromise, two 16-gauge or larger intravenous (IV) catheters should be secured immediately; central venous access can be established in unstable patients.
- Packed red blood cells should be utilized in hemodynamically unstable patients, with the goal of maintaining a hematocrit of approximately 30% in the elderly and in those with heart disease or who are otherwise compromised physiologically and 20% to 25% in younger patients.
- The initial hematocrit may not be the true value, requiring up to **72 hours for equilibration** with the intravascular space.
- The presence of coagulopathy (international normalized ratio [INR] >1.5) or **thrombocytopenia** ($<50,000$ cells/ μ L) should be corrected with fresh frozen plasma or platelet transfusions, respectively.
- Oxygen should be administered to keep the SpO₂ between 93% and 95% at a minimum, and vital signs and urine output should be closely monitored. In the elderly or those with a history of cardiac disease, an ECG and cardiac enzyme analysis should be considered.

Determination of Bleeding Site: Noninstrumental

History

- Careful history taking is helpful for determining the level of bleeding from the GI tract and to work out a differential diagnosis of the LGIB.
- Included should be the duration, frequency, and color of the stool; related symptoms of the GI tract such as constipation, fever, or location of pain; medical or surgical history; and history of medications.

- Except for asymptomatic patients with only anemia due to GI bleeding, the *color of the stool* is always queried. Blood that has been in the GI tract for < 5 hours is usually red, whereas blood present for > 20 hours is usually melanic.
- **Massive UGIB** can occasionally masquerade as lower GI bleeding in 10% to 15% of patients presenting with severe hematochezia.
- Upper GI, small bowel bleeding, or slow oozing from the right colon usually produces melena, whereas patients with hematochezia typically have left colonic or rectal lesions.
- If the blood coats the surface of stool, the left colon—especially the rectum and anus—is more likely to be the bleeding source. If the stool is mixed with blood, the source may be in the right colon.
- Blood dripping into the toilet may occur with hemorrhoidal bleeding.
- The duration and frequency of bleeding may help in determining the severity of the problem.
- Related GI tract symptoms may lead to the diagnosis of LGIB. Severe constipation should prompt an investigation for colon cancer or a stercoral ulcer; diarrhea may indicate enterocolitis; and fever or local pain may indicate an inflammation-related bleeding source, such as infectious colitis or inflammatory bowel disease.
- A previous history of colonic polyps, diverticulosis, or colonic tumor should be considered as a possible source of LGIB during the initial evaluation.
- Renal failure is a well-known risk factor for angiodysplasia or arteriovenous malformation (AVM), as is aortic stenosis.
- Note should be made of patients with renal impairment or who are being dialyzed, as these patients may have platelet abnormalities, resulting in a tendency to bleed if a lesion is present.
- Ischemic bowel may be present when severe abdominal pain and bloody stool occur in patients with severe atherosclerotic vascular disease, atrial fibrillation, or hypotension.
- Radiation therapy for prostate or pelvic cancer induces inflammatory changes of the rectum and can produce radiation proctitis, presenting months or even years after the radiation exposure.
- A history of recent colonoscopy with polypectomy indicates postpolypectomy bleeding as the likely source.
- In patients who have undergone aortoiliac reconstructive surgery, the frequency of significant postoperative colonic ischemia ranges between 1% and 7%.
- Medication history is also important. Medications that can damage the GI mucosa or exacerbate bleeding include nonsteroidal anti-inflammatory drugs (NSAIDs), alendronate, potassium chloride, and anticoagulants.
- A family history of colon cancer increases the likelihood of a colorectal neoplasm and generally calls for a complete colonic examination in patients with hematochezia.

Physical Examination

- A thorough physical examination is essential to assess loss of blood volume, a possible bleeding source, and comorbid conditions. The physical examination should also include complete vital signs and heart, lung, and abdominal assessment, as well as an examination of the conjunctiva and skin.
- Orthostatic vital signs are an important complement to standard monitoring in a patient with severe bleeding but without overt hemodynamic instability.

- Abdominal tenderness on examination may indicate an inflammatory process, such as ischemic colitis or inflammatory bowel disease.
- The rectal examination serves to identify anorectal lesions and confirm the stool color described by the patient. In addition, approximately 40% of rectal carcinomas are palpable during a digital rectal examination.

Laboratory Examination

- Initial laboratory studies should include a complete blood count, serum urea nitrogen, creatinine, coagulation profile (prothrombin time, INR, and partial thromboplastin time), liver tests, blood type and cross-match, and electrolytes.
- The **blood urea nitrogen-to-creatinine ratio** has been used as a noninvasive test to help distinguish UGIB from colonic sources of bleeding; a **ratio of 33 or higher** has a sensitivity of 96% for UGIB.

Determination of the Bleeding Site: Diagnostic Approach

Endoscopic Approach: General

- **Safety of Endoscopic Procedures for Critically Ill Patients.** Colonoscopy remains the procedure of choice for evaluating patients with acute LGIB, and enteroscopy is considered for proximal small bowel bleeding. However, for ICU patients with acquired bleeding and hemodynamic instability, questions remain due to the possibility of severe comorbid illness.
- Colonoscopy complication rates in LGIB of the general population or patients admitted to the ICU primarily for hemorrhage are low and with acceptable diagnostic rate of 67% for ICU patients.
- The complication risk increases in patients with comorbid disease, and in particular, in patients with underlying cardiac disease.
- **Preparation before Endoscopic Procedures.** Good bowel preparation is important for an adequate and sensitive colonoscopy. Studies of urgent colonoscopies performed in an unprepared colon to evaluate for LGIB revealed completion rates as low as 35%.
- In patients with severe diverticular hemorrhage, completion rates may reach up to 100% if aggressive bowel preparation is performed before urgent colonoscopy.
- Bowel preparation regimens may be less effective for LGIB in ICU patients.
- Rapid colon preparation regimens are better suited for those in the ICU or with active LGIB. However, the physician should be aware that hyperosmotic preparations draw plasma water into the bowel lumen to promote evacuation.
- For the critically ill patient with LGIB, there are no data on the “proper timing” of colon preparation. Further, preparation may be incomplete due to poor motility or ileus. Some have suggested that polyethylene glycol electrolyte lavage solution (PEG-ELS) on the day of procedure may be adequate.
- The safety of colon preparation is important for critically ill patients with comorbid illness. PEG-ELS causes no significant change in weight, vital signs, serum electrolytes, or complete blood count and is relatively safe for patients with

electrolyte imbalance, advanced liver disease, poorly compensated congestive heart failure, or renal failure.

- Monobasic and dibasic sodium phosphate (NaP) is a hyperosmotic preparation and may cause alterations in serum electrolytes and extracellular fluid status.

Colonoscopy for Critically Ill Patients

- Advances in endoscopic technology have brought colonoscopy to the forefront of the management of LGIB. However, colonoscopy as the first diagnostic maneuver for brisk LGIB or LGIB with hemodynamic compromise is controversial.
- In hemodynamically unstable patients with ongoing bleeding, angiography in conjunction with surgical consultation may be a more appropriate option.
- Colonoscopy in patients with severe hematochezia is impractical because of inadequate visualization caused by brisk blood loss.
- For acute LGIB colonoscopy can provide a rapid diagnosis and specific therapy if bleeding is found.
- Rapid endoscopic identification of a bleeding source, regardless of whether therapy is administered, may contribute to the clinical management of recurrent bleeding.
- Compared with angiography, urgent colonoscopy has a higher diagnostic yield (80% to 90% vs. 12% to 48%) and a lower complication rate.
- Most patients undergoing radiographic evaluation for LGIB—regardless of findings and interventions—will subsequently require a colonoscopy to establish the cause of bleeding.
- Although most episodes of LGIB will stop spontaneously, 10% to 15% of patients undergoing urgent colonoscopy received endoscopic therapy.
- The lesions most amenable to colonoscopic treatment of LGIB, in most studies, are usually angiodysplasia or diverticulosis.
- In a study of ICU patients with nonprimary LGIB, spontaneous cessation occurred in 53% of patients; 29% achieved hemostasis with endoscopy, but had a higher rate (19%) of recurrent bleeding.

Timing of Colonoscopy

- The use of colonoscopy is controversial for critically ill patients with LGIB. However, evidence suggests that earlier intervention leads to more diagnostic and therapeutic opportunities.
- Urgent colonoscopy after bowel preparation with endoscopic treatment of patients with active diverticular bleeding or stigmata of bleeding has been shown to be highly effective in decreasing the need for surgical intervention.

Sigmoidoscopy or Colonoscopy?

- In studies of the general population with LGIB, diverticular and angiodysplastic bleeding are the most frequent events with bleeding most often occurring in the right colon.
- Flexible sigmoidoscopy can be performed in the initial evaluation of patients with LGIB, but the diagnostic yield of flexible sigmoidoscopy in LGIB is low, ranging from 9% to 58%.
- However, in ICU patients with acquired bleeding, 78% of responsible lesions were in the left colon.
- If the critical situation precludes use of total colonoscopy, sigmoidoscopy as the first maneuver may be acceptable for this patient group.

- If a definite and compatible bleeding source is not identified with flexible sigmoidoscopy, the study should proceed to a full colonoscopy in most patients.

Enteroscopy and Capsule Endoscopy for Critically Ill Patients

- The small bowel is a problematic area to evaluate because of the limitations of standard upper GI endoscopy and colonoscopy. It is estimated that 10% to 25% of LGIB originates in the small bowel.
- Some clinicians have utilized peroral intubation with a standard colonoscope, reaching a point 20- to 60-cm distal to the ligament of Treitz to increase the diagnostic yield of GI bleeding of obscure origin by 17% to 46%.
- Small bowel enteroscopy is currently the best endoscopic investigative modality. Current tools for ruling out small bowel diseases include push-type enteroscopy (PE), double-balloon enteroscopy (DBE), intraoperative enteroscopy, and capsule endoscopy.
- Push-type enteroscopy allows endoscopic evaluation of the proximal 60 cm of the jejunum or 150-cm distal to the pylorus.
- The diagnostic yield of PE is between 38% and 65% of patients in whom upper and lower endoscopy are negative.
- Complications of PE are infrequent, occurring in <1% of cases. Most complications, including bleeding and perforation, are related to the use of an overtube.
- The data on effectiveness and safety of PE for ICU patients are limited.
- Total enteroscopy with DBE can be achieved in 60% to 86% of cases.
- The diagnostic yield of DBE is between 52% and 76%.
- Oral DBE requires no specific preparation other than a 6- to 8-hour fast before the procedure. If a retrograde (anal) approach is undertaken, standard colonic preparation is necessary.
- Complications of DBE are noted in 1.1% to 8.5%, and include aspiration pneumonia, abdominal pain, perforation, and acute pancreatitis.
- The effectiveness and safety of DBE for critically ill patients are unknown.
- Before the advent of capsule endoscopy and DBE, intraoperative endoscopy was the only way to detect and treat lesions beyond the reach of push enteroscopy.
- Diagnostic intraoperative enteroscopy is likely to decrease with introduction of the less invasive capsule endoscopy and DBE; however, it still plays a role in specific clinical situations.
- The yield in detecting bleeding lesions reaches 70% to 100%, making intraoperative endoscopy the most sensitive method of diagnosing small bowel disorders.
- Lesions can be treated endoscopically or marked with a tattoo for surgical resection. The terminal ileum is reached in more than 90% of patients.
- The high sensitivity, however, comes at the cost of extreme invasiveness, making it a procedure of last resort.
- The complication rate is estimated at about 3%, including mucosal tears and bleeding of the mesentery due to traction.
- Capsule endoscopy is a safe and promising diagnostic tool for GI bleeding of unknown origin, focusing especially on the small bowel; it may obviate the need for angiography in some difficult patients.
- Studies comparing capsule endoscopy with other diagnostic procedures, including enteroclysis, PE, computed

tomography (CT) scan, and intraoperative enteroscopy, showed that capsule endoscopy was clearly superior in the diagnosis of occult/obscure/overt small bowel bleeding.

- The overall diagnostic yield rate of capsule endoscopy in patients with GI bleeding ranges from 45% to 66%.
- To increase the diagnostic yield of capsule endoscopy, prokinetic agents, oral bowel preparation (oral sodium phosphate and polyethylene glycol), simethicone, and erythromycin have been recommended.
- Despite the higher diagnostic yield, capsule endoscopy limitations are evident: biopsy specimens cannot be obtained, therapeutic intervention cannot be performed, and localization of some lesions is imprecise.
- The primary risk with capsule endoscopy is capsule entrapment within the GI tract; this occurs in 0.75% to 5% of cases.
- Absolute contraindications to its use include GI obstruction and ileus.
- The use of capsule endoscopy in critically ill patients has been limited and the use of capsule endoscopy for small bowel or obscure bleeding must be made on a case-by-case basis.

Nonendoscopic Approach

Nuclear Medicine

- The two techniques of radionuclide scanning commonly use either ^{99m}Tc -labeled red blood cells or ^{99m}Tc technetium sulfur colloid.
- A ^{99m}Tc -labeled red blood cell scan is the preferred technique, with images that can be detected for up to 12 to 24 hours after injection, whereas the half-life of ^{99m}Tc technetium sulfur colloid is only 2 to 3 minutes.
- This technique can detect bleeding at a rate as low as **0.1 to 0.5 mL/minute** and is thought to be a sensitive diagnostic tool for LGIB.
- The sensitivity of a radionuclide scan for active bleeding has been noted to be $>90\%$ and is superior to that of angiography.
- Another role for radionuclide scanning is in the evaluation for Meckel diverticulum, especially in young patients presenting with LGIB with a sensitivity as high as 81% to 90%.
- **Timing the Use of Radionuclide Scanning.** Radionuclide scanning, often performed repeatedly during a hospital course, may be used as the screening test, followed by angiography, small bowel enteroscopy, or surgery to definitively localize and treat the bleeding lesion.
 - Because of its high sensitivity, radionuclide scanning has been utilized as a guide for surgical resection. However, radionuclide scanning is normally not used as a definitive study before surgical therapy.
 - The literature suggests that the localization accuracy of radionuclide scanning is quite variable, ranging from **24% to 94%**. Thus, most clinicians use radionuclide scanning as a guide for further diagnostic studies, such as enteroscopy or colonoscopy, rather than for surgical intervention.

Angiography

- Mesenteric angiography is more invasive than technetium-labeled red blood cell scanning, and requires a bleeding rate of at least **0.5 to 1.0 mL/minute** to detect bleeding.
- Angiography is usually undertaken when patients have clinical indicators of severe bleeding (e.g., tachycardia and/or syncope).

- Although colonoscopy is the diagnostic modality of first choice for LGIB, many endoscopists are reluctant to perform colonoscopy in hemodynamically unstable patients with ongoing bleeding and these patients usually undergo radiographic studies.
- Angiography will localize the site of bleeding in 40% to 86% of patients with LGIB.
- Occasionally, the bleeding of colonic lesions, such as vascular abnormalities, can be too massive for colonoscopic visualization, thus precluding the procedure.
- In some centers, a radionuclide scan is requested before mesenteric angiography, because a negative radionuclide scan is unlikely to have a positive angiogram.
- Even if a bleeding site is identified on angiography, localizing the site intraoperatively can be difficult; angiography has a specificity of 100% but a sensitivity of only 30% to 47%.
- Complications include hematoma or bleeding at the catheter site; access site thrombosis; contrast reactions; injury to the target vessels, including dissection and distal embolization; and renal failure. The injured vessels usually involve the SMA, IMA, and celiac artery.
- Angiography also offers therapeutic possibilities via pharmacologic vasoconstriction or selective embolization (transcatheter arterial embolization [TAE]).
- Pharmacologic vasoconstriction is achieved with intra-arterial vasopressin infusion.
- TAE may be a more definitive means of controlling bleeding, but is associated with a risk of **intestinal infarction**. The bowel infarction or colonic necrosis rate from embolization ranges from 10% to 20%.
- Selective embolization initially controls bleeding in up to 100% of patients, but rebleeding rates have been reported to be 15% to 40%.
- Superselective TAE may decrease the incidence of ischemia and rebleeding beyond that of selective embolization. With advances in superselective embolization techniques, clinically significant bowel ischemia has become an uncommon complication.
- The major complication rate was 10% to 20% and included dysrhythmias, pulmonary edema, hypertension, and ischemia.
- Although the efficacies of vasopressin and embolization are reasonably comparable, embolization allows more rapid completion of therapy and a decreased likelihood of systemic complications.
- Embolization should be considered a primary option for LGIB with vasopressin reserved for diffuse lesions or cases in which superselective catheterization is not technically possible.
- **Vasopressin** should not be used in patients with significant coronary artery disease or peripheral vascular disease; mesenteric thrombosis, intestinal infarction, and death have been reported with its use.
- Nitroglycerin reverses the vasopressin-induced coronary vasoconstriction without affecting the therapeutic vasoconstriction of the mesenteric artery.

Computed Tomography Scan and Magnetic Resonance Imaging

- CT scans are not usually considered diagnostic tools for LGIB, except in the context of bleeding bowel tumors. Additionally, there is no current role for the use of magnetic resonance imaging (MRI) in the evaluation of LGIB.

- In the evaluation of colonic vascular lesions, helical CT has a sensitivity of 70% and specificity of 100% compared to colonoscopy and conventional angiography.

Other Modalities

- Data regarding the use of ultrasound for LGIB have been limited. Ultrasound may be considered as a screening tool for LGIB or applied when the bleeding source cannot be identified by other modalities
- Small bowel follow through (SBFT) is of little use in evaluating obscure GI bleeding, with a diagnostic yield that may be as low as 0%.
- Enteroclysis is superior to SBFT for evaluation of the small bowel. However, with the advent of capsule endoscopy, the use of SBFT or enteroclysis for GI bleeding has declined.
- Barium enema cannot detect superficial lesions or confirm a definitive bleeding source of the colon. Furthermore, it may complicate subsequent colonoscopy or angiography and is less useful for critically ill patients with LGIB.

TREATMENT OF LOWER GASTROINTESTINAL BLEEDING

Pharmacologic Therapy

- Unlike pharmacologic therapies for UGIB, there are no medications with a strong evidence base for LGIB.
- The medications for the different causes of LGIB include estrogen/progesterone compounds, octreotide, aminocaproic acid (an antifibrinolytic), and tranexamic acid.
- Estrogen/progesterone compound use is controversial for diffuse ectasias or angiodysplasia refractory to endoscopic therapy and has been noted to be ineffective in recent studies.
- Octreotide at a dose of 0.05 to 1 mg/day may lead to decreased transfusion requirements, but, unfortunately, carefully controlled trials are not available.
- Aminocaproic acid and tranexamic acid may be helpful, but studies with controlled data are not forthcoming.

Endoscopic Procedures

- Endoscopic therapy for LGIB includes injection therapy (epinephrine, saline, or ethanol), heater probe, monopolar

TABLE 106.4

ENDOSCOPIC PROCEDURES FOR BLEEDING

LGIB lesions	Endoscopic procedures
Ulcer	Injection therapy Heater probe Electrocoagulation Hemoclips Band ligation ^a APC ^b
Angiodysplasia	APC Heater probe Electrocoagulation
Diverticulum	Hemoclips APC Injection therapy Heater probe Electrocoagulation
Radiation proctitis	APC Topical formalin
Postpolypectomy bleeding	Hemoclips Band ligation APC Injection therapy Heater probe

LGIB, lower gastrointestinal bleeding.

^aEspecially for Dieulafoy lesions.

^bAPC, argon plasma coagulation. Not recommended for ulcers with big exposed vessels.

and multipolar electrocoagulation, argon plasma coagulation, hemoclips, and band ligation (Table 106.4).

- An alternative treatment for hemorrhagic radiation-induced proctitis, by topical application of formalin, can be performed with or without endoscopy in the operating room.

Radiologic Interventions (See Also Angiography)

- In addition to its diagnostic role, angiography offers therapeutic possibilities via pharmacologic vasoconstriction with vasopressin or selective embolization.
- Comparison between embolization and intra-arterial vasopressin infusion is listed in Table 106.5.

TABLE 106.5

COMPARISON BETWEEN TAE AND INTRA-ARTERIAL VASOPRESSIN INFUSION FOR LGIB

	TAE	Vasopressin infusion
Completion of Tx	Quick	Slow
Definite Tx	Yes	No
Diffuse lesions	Discouraged	Favored
Complications	Bowel infarct	Myocardial ischemia, bowel ischemia, peripheral ischemia, hypertension, arrhythmias, hyponatremia

TAE, transcatheter arterial embolization; LGIB, lower gastrointestinal bleeding; Tx, therapy.

Surgery

- Surgery should be considered in patients in whom a bleeding source has clearly been identified. An emergency procedure is suggested for patients who require more than six units of blood within 24 hours, or a total of 10 units.
- Blind segmental resection is contraindicated, as it is associated with a rebleeding rate of 42% and excessive rates of morbidity and mortality as high as 83% and 57%, respectively.
- If the bleeder cannot be clearly identified, intraoperative enteroscopy may be a management option.
- Recurrent bleeding from colon diverticula occurs in 20% to 40% of patients and is generally considered an indication for surgery.
- Surgery is usually not recommended on the basis of nuclear red blood cell scans alone because of variable accuracy of nuclear red blood cell scans.

LOWER GASTROINTESTINAL BLEEDING AND ACUTE MYOCARDIAL INFARCTION

- Whether LGIB occurs before or after the AMI, selecting an endoscopic procedure is a dilemma.
- The risks versus benefits of endoscopy must be carefully considered in patients with a recent MI because of the potential for cardiopulmonary complications, including myocardial ischemia, hypotension, cardiac arrhythmias, and hypoxia.
- Underlying heart disease, lower blood pressure on arrival in the emergency department, lower hemoglobin level on

arrival, and persistent shock before endoscopic examination are all associated with higher risk of MI after emergency endoscopy.

- Establishment of stable hemodynamics and oxygen delivery before emergency endoscopy may reduce the risk of procedure-related MI, especially in patients with known heart disease.
- Colonoscopy in patients with a recent MI is associated with a higher rate of minor, transient cardiovascular complications compared with control patients but is relatively infrequently associated with major complications.
- Colonoscopy may be beneficial after an MI, despite a higher risk in certain circumstances.

Acute Hemorrhagic Rectal Ulcer Syndrome

- Acute hemorrhagic rectal ulcer syndrome (AHRUS) has been reported as one of the most frequent causes of LGIB in the ICU.
- Lesions of AHRUS locate at the lower rectum and account for 26.7% of massive LGIB in the ICU.
- AHRUS characteristically occurs suddenly, with painless, massive, fresh rectal bleeding in elderly, bedridden patients with severe comorbid illness. It is prone to occur in patients with diabetes mellitus who are using anticoagulant or antiplatelet agents.
- Therapies for AHRUS include injection therapy, heater probe, hemoclips, and per anal suturing.
- The prognosis of AHRUS depends on the state of the underlying diseases and achievement of hemostasis.

CHAPTER 107 ■ LIVER FAILURE: ACUTE AND CHRONIC

ACUTE LIVER FAILURE

Definitions and Immediate Concerns

- Acute liver failure (ALF) may be defined as the development of hepatic encephalopathy (HE) and coagulopathy in a patient with no history of previous liver disease, with the onset HE within 26 weeks of jaundice. It should be stressed that ALF is not a disease, but rather a clinical syndrome triggered by numerous etiologic agents.

Overview

- There are three possible outcomes after ALF: spontaneous survival without orthotopic liver transplantation (OLT), OLT, or death.

- In the U.S. Acute Liver Failure Study Group (ALFSG) cohort, one-third of patients died, one-quarter underwent OLT, and the remainder (42%) recovered spontaneously.
- The dismal overall survival of patients with ALF, 25% in the 1970s, has improved to ~65% with the advent of OLT and improvements in intensive care management.

Etiology, Prevalence, and Initial Testing

- In the United States, acetaminophen (APAP) accounts for ~45% of cases, half of those due to ingestion of a single large dose with suicidal intent and the other half as “therapeutic misadventures.”
- The second most common cause of ALF remains indeterminate even after extensive serologic and historical evaluation (15% of cases).

TABLE 107.1

CAUSE, PREVALENCE, AND EVALUATION OF ACUTE LIVER FAILURE

Cause	Prevalence ^a (%)	Evaluation
APAP	45	History; APAP level
HBV	7	anti-HBc (IgM and total), HBsAg, anti-HBs, HBV DNA, anti-HDV
AIH	5	ANA, ASMA, anti-LKM, immunoglobulins
HAV	4	anti-HAV (IgM and total)
Shock liver	4	Echocardiogram, brain natriuretic peptide
Wilson disease	3	Serum ceruloplasmin and copper; urine copper; slit-lamp eye examination
BCS	2	Doppler ultrasound of liver
Malignancy	1	Contrast-enhanced CT; MRI (preferred)
AFLP/HELLP	1	Pregnancy test
HSV	0.5	Anti-HSV 1/2, HSV DNA
Other	4	Anti-HCV/HCV RNA, anti-CMV/CMV DNA, anti-EBV/EBV DNA, toxicology screen
Indeterminate	14	All of above negative
Idiosyncratic drug	13	History; all of above negative

APAP, acetaminophen; HBV, hepatitis B virus; HDV, hepatitis D virus; AIH, autoimmune hepatitis; ANA, anti-nuclear antibody; ASMA, anti-smooth muscle antibody; anti-LKM, anti-liver kidney microsomal antibody; HAV, hepatitis A virus; BCS, Budd-Chiari syndrome; CT, computed tomography; MRI, magnetic resonance imaging; AFLP/HELLP, acute fatty liver of pregnancy/hemolysis-elevated liver enzymes–low platelet syndrome; HSV, herpes simplex virus; HCV, hepatitis C virus; CMV, cytomegalovirus; EBV, Epstein-Barr virus.

N = approximately 1,000 at the time of publication. (W.M. Lee, personal communication.)

Suggested evaluation of patients with idiosyncratic drug hepatotoxicity and indeterminate ALF should include all of the tests listed, since these are diagnoses of exclusion.

^aPrevalence of causes are estimates based on the U.S. Acute Liver Failure Study Group Cohort (personal communication).

- Additional causes of ALF are idiosyncratic drug reactions (13%) and acute hepatitis B (7%).
- The remaining causes of ALF are autoimmune hepatitis, acute hepatitis A, hepatic vein thrombosis (Budd-Chiari syndrome), hypotension (“shock liver”), fulminant Wilson disease, malignant infiltration of the liver, and pregnancy-associated ALF (acute fatty liver and HELLP [hemolysis, elevated liver enzymes, and low platelets] syndrome), all constituting fewer than 5% of cases each.
- The initial laboratory and procedural evaluation of patients with ALF to determine cause is indicated in Table 107.1.

Assessment of Prognosis

Outcomes of ALF

- The **cause** of ALF is the single most important prognostic factor.
- The second prognostic factor is the **interval between jaundice and the development of HE**; the shorter the above interval, the higher the likelihood of spontaneous survival.
- In patients with APAP overdose, spontaneous recovery is the rule (63% in the ALFSG cohort).
- Patients with acute hepatitis A, shock liver, and pregnancy-related ALF—assuming prompt delivery of the fetus—also have >50% spontaneous survival. Patients with ALF from all other causes have very poor rates of recovery without OLT.
- Patients with APAP overdose and acute hepatitis A usually have hyperacute progression (jaundice-HE interval within 7 days) and have a relatively good prognosis, whereas most idiosyncratic drug reactions have a more subacute presentation (jaundice-HE interval of more than 28 days) and dismal prognosis without OLT.

Prognostication Schemes

- The most time-honored scheme is the King’s College Criteria.
- For patients with APAP-induced ALF, predictors of death included arterial pH <7.30, or azotemia, severe coagulopathy, and high-grade HE (grade 3 or 4).
- In patients with ALF due to other causes, severe coagulopathy or any three of the criteria listed in Table 107.2 also predicted death.

Complications and Treatment

General Management

- ALF commonly causes multiorgan dysfunction, such that management requires close collaboration between intensivists, hepatologists, transplant surgeons, and other specialists.
- Since the progression of complications can be rapid, patients should be transferred to a liver transplant center; in general, higher-volume centers have superior outcomes.
- Sedation should initially be minimized to avoid confusing the effects of drugs with deteriorating mental status.
- Worsening HE is a clear indication for admission to the intensive care unit (ICU); the likelihood of spontaneous survival decreases with a worsening coma grade at admission.

Cause-specific Management

Treatment of Acetaminophen ALF

- The administration of *N*-acetylcysteine (NAC) has become widely applied to patients with ALF due to APAP.
- Although nomograms to determine whether NAC should be administered are available, the time of ingestion frequently cannot be determined accurately, and ingestions are multiple.
- NAC should be given in cases where the timing, dose ingested, or plasma concentration is in question as the potential benefit outweighs the adverse effects.

TABLE 107.2

SCHEMES FOR PREDICTING POOR PROGNOSIS AND THE NEED FOR ORTHOTOPIC LIVER TRANSPLANTATION IN PATIENTS WITH ACUTE LIVER FAILURE (ALF)

Scheme	Cause of ALF	Criteria for liver transplantation
King's College criteria	APAP	Arterial pH <7.30 Or all of the following: 1. PT >100 s 2. Creatinine >3.4 mg/dL 3. Grade 3/4 encephalopathy
	Non-APAP	PT >100 s (INR >6.5) Or any 3 of the following: 1. NANB/drug/halothane etiology, 2. Jaundice to encephalopathy >7 d 3. Age <10 or >40 y 4. PT >50 s 5. Bilirubin >17.4 mg/dL
Factor V	Viral	Age <30 y: factor V <20% Or Any age: Factor V <30% and grade 3/4 encephalopathy
Factor VIII/V ratio	APAP	Factor VIII/V ratio >30
Liver biopsy	Mixed	Hepatocyte necrosis >70%
Arterial phosphate	APAP	>1.2 mmol/L
Arterial lactate	APAP	>3.5 mmol/L
Arterial ammonia	Mixed	>150–200 μ mol/L
APACHE II/III score	APAP	>15
MELD score	Non-APAP	>30

Abbreviations per legend of Table 107.1, as well as: PT, prothrombin time; INR, international normalized ratio; NANB, non-A, non-B viral hepatitis; APACHE, Acute Physiology and Chronic Health Evaluation; MELD, model for end-stage liver disease.

Modified from Sanyal AJ, Stravitz RT. Acute liver failure. In: Boyer TD, Wright T, Manns MP, eds. *Hepatology—A Textbook of Liver Disease*. 5th ed. Philadelphia, PA: Elsevier; 2006:383–415; and Stravitz RT, Kramer AH, Davern T, et al., and the Adult Acute Liver Failure Study Group. Management of acute liver failure: recommendations of the Acute Liver Failure Study Group. *Crit Care Med*. 2007;35:2498–2508.

- Intravenous NAC should be administered when a patient has higher than grade 1 HE or in patients who cannot tolerate oral dosing.
- The administration of NAC, even late after ingestion, appears to confer survival benefit. Thus, dosing should continue until evidence of severe liver injury resolves (international normalized ratio [INR] <1.5 and resolution of HE), rather than by completion of a set number of doses.

Other Cause-specific Treatments

- Specific medications that should be considered in patients with ALF due to other causes are outlined in Table 107.3.
- It should be emphasized that randomized, controlled studies to support these therapies do not exist, and most of these recommendations are made only on the basis of case reports, expert opinion, and a high therapeutic threshold.

Management of Specific Complications of ALF

Neurologic Complications: Pathophysiology

- By definition, patients with ALF develop varying degrees of HE (Table 107.4).

- Worsening mental status may be a consequence of progression to cerebral edema, which is present in 38% to 81% of cases of grade 3 or 4 encephalopathy.
- Patients who develop cerebral herniation have substantially higher serum ammonia levels—usually more than 200 μ mol/L—and greater cerebral ammonia uptake. Conversely, herniation rarely occurs when serum ammonia levels remain below 150 μ mol/L.
- Ammonia also interferes with cerebral energy metabolism, leading to the accumulation of lactate.
- Increased cerebral blood flow (CBF) remains an important factor in the formation of cerebral edema.
- CBF rises with the accumulation of ammonia and is frequently excessive relative to energy expenditure.
- Although excessive CBF contributes to worsening cerebral edema, patients are also especially vulnerable to ischemia if hypotension occurs. Thus, it is important that cerebral perfusion pressure be carefully controlled and extremes avoided.

Management of HE

- Therapies are aimed at lowering serum ammonia levels in patients with ALF due to the central role of ammonia in the pathogenesis of hepatic encephalopathy.

TABLE 107.3

CAUSE-SPECIFIC THERAPY OF PATIENTS WITH ACUTE LIVER FAILURE

Cause	Therapy
APAP	NAC Oral: 140 mg/kg load, then 70 mg/kg every 4 h NAC IV: 150 mg/kg load, then 12.5 mg/kg/h × 4 hr, then 6.25 mg/kg/h
<i>Amanita</i>	Penicillin G: 1 g/kg/d IV & NAC (as in APAP overdose)
HSV	Acyclovir: 30 mg/kg/d IV
AIH	Methylprednisolone 60 mg/d IV
HBV	Lamivudine 100–150 mg/d PO
Wilson disease	? Plasmapheresis, D-penicillamine
AFLP/HELLP	Delivery of fetus

APAP, acetaminophen; NAC, N-acetylcysteine; *Amanita* refers to mushroom intoxication; HSV, herpes simplex virus; AIH, autoimmune hepatitis; HBV, hepatitis B virus; AFLP/HELLP, acute fatty liver of pregnancy/hemolysis-elevated liver enzymes–low platelet syndrome.

- Nonabsorbable disaccharides (e.g., lactulose) and oral antibiotics (neomycin, rifaximin, or metronidazole) have not been adequately studied in patients with ALF and appear to have little effect on outcome.
- If lactulose is administered, the dose should be adjusted to achieve no more than three to four bowel movements per day, and care must be taken to avoid excessive abdominal distention, volume depletion, and hypernatremia.
- Oral neomycin is minimally absorbed from the gastrointestinal tract but has been reported to cause acute renal failure and is therefore not recommended.
- A computed tomography (CT) scan of the head should be considered early in the course of ALF to exclude other causes of altered mental status.

Management of Cerebral Edema

- A head CT may be used to detect cerebral edema. However, a normal scan does not rule out clinically important intracranial hypertension.

- Many experts advocate intracranial pressure (ICP) monitor placement in OLT candidates with stage III or IV HE.
- The coagulopathy in patients with ALF increases the bleeding risk of ICP monitor placement, with bleeding complications in up to 20%. Recent series have found lower bleeding rates with the use of recombinant factor VIIa (rFVIIa) shortly before insertion of the device.
- The specific management of cerebral edema in patients with ALF resembles that of other causes of intracranial hypertension, with the important caveat that hyperemia plays an important additional pathogenic role in the former.
- Patients should be cared for in a calm, quiet environment, with limited stimulation. Chest physiotherapy and suctioning should be temporarily minimized.
- The head of the bed should be elevated to at least 30 degrees, as this reduces ICP and decreases the risk of hospital-acquired pneumonia. Additionally, the duration of time that a patient is placed supine or in Trendelenburg position for procedures should be minimized.

TABLE 107.4

HEPATIC ENCEPHALOPATHY GRADES AND RELATIONSHIP TO CEREBRAL EDEMA AND PROGNOSIS IN ACUTE LIVER FAILURE

Stage	Mental status	Cerebral edema	Spontaneous recovery without liver transplantation
I	Euphoria, mild confusion, dysarthria, abnormal sleep rhythm	Rare	52% overall 87% APAP 35% drug reaction 18% indeterminate cause 38% other cause
II	Accentuation of stage I, lethargy, moderate confusion, incontinence		
III	Stupor, severe confusion, incoherent speech	40%–80%	33% overall 50% APAP 12% drug reaction 16% indeterminate cause 27% other cause
IV	Coma or near coma		

APAP, acetaminophen.

Data modified from Trey C, Davidson C. The management of fulminant hepatic failure. *Prog Liver Dis.* 1970;3:282–298; Gazzard BG, Portmann B, Murray-Lyon IM, et al. Causes of death in fulminant hepatic failure and relationship to quantitative histological assessment of parenchymal damage. *Q J Med.* 1975;44(176):615–626; and Ostapowicz G, Fontana RJ, Schiodt FV, et al. Results of a prospective study of acute liver failure at 17 tertiary care centers in the United States. *Ann Intern Med.* 2002;137(12):947–954.

- Endotracheal intubation and mechanical ventilation must be implemented in a timely fashion to avoid the potentially injurious effects of hypoxemia and hypercapnia, while also reducing aspiration risk and facilitating management of intracranial hypertension.
- Propofol is preferred over benzodiazepines by some. However, if used over several days, the dose of propofol should be limited to <5 mg/kg/hour to decrease the risk of the potentially fatal propofol infusion syndrome.
- Hyperventilation can be used therapeutically to reduce ICP. Patients with hepatic encephalopathy often spontaneously hyperventilate, with resultant respiratory alkalosis.
- The major concern with using hyperventilation as a means to lower ICP is that vasoconstriction may be severe enough to cause cerebral ischemia.
- If the PaCO_2 suddenly normalizes, rebound vasodilatation may occur with consequent elevation in ICP. Thus, sudden changes in PaCO_2 should be avoided and arterial blood gases or end-tidal CO_2 should be closely monitored.
- Jugular venous oximetry may be useful to guide therapy, with a high jugular venous oxygen saturation used as evidence that hyperventilation is safe.
- Osmotic agents, including mannitol and hypertonic saline (HTS), lower ICP most effectively in the setting of global cerebral edema with an intact blood–brain barrier.
- A general indication for the administration of mannitol includes persistently (>10 minutes) elevated ICP (>20 mm Hg) after ensuring proper calibration of the ICP monitor.
- A serum osmolality limit of 320 mOsm/L is arbitrary. A more useful surrogate is the osmolar gap, which more reliably predicts the risk of renal failure and should be allowed to normalize (e.g., <15 – 20) between doses.
- Theoretical advantages of HTS over mannitol include the following: (1) the blood–brain barrier is less permeable to HTS (making it a more effective osmotic agent); (2) it is a volume expander rather than a diuretic; and (3) there is no proven nephrotoxicity.
- Great caution must be taken when HTS is weaned or discontinued to ensure that the serum sodium falls very slowly to avoid precipitating rebound cerebral edema.
- High-dose barbiturates (pentobarbital [3–5 mg/kg intravenous [IV] loading bolus followed by 1–3 mg/kg/hour IV infusion], or thiopental [5–10 mg/kg loading bolus followed by 3–5 mg/kg/hour]) can be used as rescue therapy when other interventions have been maximized but the ICP remains more than 20 mm Hg.
- Electroencephalography (EEG) should be performed to guide dosing, with the goal being to achieve a burst-suppression pattern.
- Corticosteroids are of no value in treating intracranial hypertension in ALF and should not be used for this purpose.
- Fever increases ICP and is an independent predictor of worse outcome in brain-injured patients, such that euthermia should be maintained.
- Temperatures of 32°C to 33°C have been used to control intracranial hypertension in patients with ALF refractory to standard care. Important potential adverse effects of hypothermia in the setting of ALF include interference with coagulation and an increased risk of infection.

Management of Seizures

- Nonconvulsive seizures are a potential cause of worsening cerebral edema and secondary brain injury.

- In general, routinely obtaining an EEG in patients with hepatic encephalopathy, particularly when there is a clinical change in neurologic status, may be useful.
- There is currently insufficient evidence to justify the routine use of prophylactic phenytoin. Sedation with propofol or benzodiazepines is likely to provide more effective antiseizure prophylaxis than phenytoin.

Cardiopulmonary Complications

- Patients with ALF frequently develop **systemic inflammatory response syndrome (SIRS)**, regardless of whether or not their course is complicated by infection.
- Hypotension is typical of patients with ALF and can be ascribed to low systemic vascular resistance, the use of sedatives, mechanical ventilation, and relative adrenal insufficiency.
- Lactic acidosis is an important prognostic marker in ALF, but the mechanism is not primarily dysoxia, but rather impaired hepatic clearance and increased splanchnic production.
- Most patients with severe ALF will require an arterial catheter, and various tools are available to optimize volume status and cardiac output.
- The goal mean arterial pressure (MAP) should be individualized to optimize organ perfusion, rather than choosing an arbitrary number, but is generally kept above 60 to 65 mm Hg.
- In patients with relative adrenal insufficiency, treatment with low-dose corticosteroids (e.g., hydrocortisone 50–100 mg IV every 6–8 hours, or 8–10 mg/hour as a continuous IV infusion) reduces vasopressor requirements, although the impact on outcome is uncertain.
- As many as 37% of patients with ALF develop **acute lung injury (ALI)** or acute respiratory distress syndrome (ARDS).
- With established ALI or ARDS, tidal volumes should be limited to 6 mL/kg of predicted body weight, although increases in PaCO_2 cannot be tolerated in the setting of cerebral edema and intracranial hypertension.
- Positive end-expiratory pressure settings should be sufficient to achieve adequate oxygenation, while concomitantly ensuring that ICP, blood pressure, and cardiac output are not compromised.

Renal Failure

- Acute renal failure complicates **up to 50%** of cases of ALF and is even more frequent when the cause of ALF is acetaminophen intoxication.
- Hypovolemia, hypotension, and the use of nephrotoxins—including aminoglycosides, nonsteroidal anti-inflammatory drugs, and intravenous contrast—should be minimized.
- Patients with ALF can develop hepatorenal syndrome (HRS) as a consequence of intense renal vasoconstriction.
- The decision to initiate renal replacement therapy (RRT) must consider the magnitude of renal dysfunction, metabolic derangements, and volume overload.
- Continuous renal replacement therapy (CRRT) is preferred over intermittent hemodialysis (IHD) by many clinicians, largely because of more stable volume management and greater time-averaged dialysis dose.
- Transient hypotension is poorly tolerated in patients with cerebral edema; not only does the cerebral perfusion pressure decrease, but cerebral vasodilatation may increase, with further increases in CBF and ICP.

- Excessively rapid correction of metabolic acidosis with bicarbonate-based dialysate may transiently increase cerebrospinal fluid CO₂, reduce central nervous system (CNS) pH, and promote more cerebral vasodilatation.
- Regardless of the mode of RRT, an adequate hemofiltration or dialysis dose should be used, while blood pressure—and preferably ICP—are carefully monitored and maintained.
- With CRRT, regional, rather than systemic, anticoagulation is most often used to improve filter longevity, most often with citrate. Since citrate accumulates with poor hepatic function, ionized calcium levels must be regularly monitored.

Infections

- ALF patients are at high risk of nosocomial infections with both bacterial and fungal pathogens, which occur in almost 40% of these patients.
- Early diagnosis can be difficult since patients often have subtle manifestations of infection but is vital because of the high associated morbidity and mortality.
- Daily surveillance cultures (urine, blood, sputum) and chest radiography should be considered, as they may improve early diagnosis of infection and guide selection of antimicrobial agents.
- Prophylactic antibiotics have not been shown to improve survival and may promote infection with resistant pathogens.
- Empiric broad-spectrum antibiotics (including vancomycin and an antifungal agent, as indicated) should be administered to any patient with ALF who develops significant isolates on surveillance cultures, unexplained progression of HE, or signs of SIRS, as these frequently predict sepsis in patients with ALF.

Coagulopathy

- Despite a deficiency of clotting factors, low fibrinogen, thrombocytopenia, and platelet dysfunction, clinically important spontaneous bleeding is seen in <10% of patients.
- The routine use of blood products to correct these abnormalities is not justified since they are unnecessary, ineffective, and interfere with the prognostic utility of the INR.
- Correction of coagulopathy should be performed in the setting of significant hemorrhage or in anticipation of invasive procedures.
- Vitamin K deficiency has been reported to contribute to the coagulopathy of ALF and should be repleted parenterally (10 mg subcutaneously [SC] or slow [over 30 minutes] IV).
- rFVIIa (40 µg/kg) may be considered in patients with life-threatening bleeding and prior to placement of an ICP monitor or performance of a liver biopsy. However, the risk of thrombosis with rFVIIa is increasingly being documented, even among patients with ALF.
- If fibrinogen levels are low (<100 mg/dL), cryoprecipitate should be given prior to rFVIIa.
- Coagulopathy and mechanical ventilation are well-established indications for gastrointestinal (GI) stress ulcer prophylaxis.
- Mechanical methods of deep venous thrombosis prophylaxis are recommended in place of low-dose unfractionated heparin or low-molecular-weight heparin.

Metabolic Derangements

- ALF is a catabolic state, with increased energy requirements and negative nitrogen balance, which may in turn contribute to immunosuppression.

- Higher-than-usual caloric intake is recommended, with 35 to 40 kcal/kg/day and 0.8 to 1 g/kg/day of protein, preferably provided via the enteral route.
- Reduced hepatic glycogen stores and impaired gluconeogenesis are responsible for the frequent development of hypoglycemia.
- Conversely, hyperglycemia may contribute to increases in ICP and other complications. Thus, blood glucose values must be closely monitored and maintained within the normal range with intravenous short-acting insulin.

Liver Transplantation for ALF

- OLT remains the treatment of last resort for ALF. The decision to list a patient with ALF for OLT requires careful clinical and psychosocial assessment.
- Since OLT candidates with ALF are generally younger and healthier than their counterparts with chronic liver disease, the pretransplant evaluation can usually be abbreviated to include echocardiography, duplex ultrasonography of the liver, and routine pretransplant laboratories (e.g., total anti-cytomegalovirus, human immunodeficiency virus antibody).
- Criteria for listing a patient with ALF for OLT change and current criteria may be found on the United Network for Organ Sharing website (in Policy 3.6). Presently, patients with ALF are given priority to receive a cadaveric organ over all patients with chronic liver disease (status 1).
- Early (3-month) mortality after OLT for ALF is higher than for patients transplanted for all causes of chronic liver disease—about 20% versus 10%, respectively. Thereafter, however, 5- and 10-year survival after OLT for ALF approximates 70% and 65%, respectively.

CHRONIC LIVER FAILURE

Definitions and Immediate Concerns

- Almost all patients with chronic liver failure have underlying cirrhosis, the fibroinflammatory alteration of hepatic architecture that results from numerous chronic insults to the liver. Immediate concerns regarding every patient with chronic liver failure on presentation to the ICU include assessment for possible infection and upper GI bleeding, which precipitate most admissions.

Overview

- Patients with chronic liver disease develop liver failure (decompensation) as a result of portal hypertension and hepatocellular insufficiency.
- Complications of portal hypertension include hemodynamic alterations, functional renal failure, ascites, and GI bleeding, most commonly from variceal hemorrhage.
- Complications of hepatocellular insufficiency include coagulopathy and hepatic encephalopathy, with the latter occurring also as a result of portosystemic shunting.
- ICU use is increasing for patients admitted to the hospital for decompensated cirrhosis (from 18% to 28% of hospitalizations in one major center over 10 years).

Etiology

- The most common cause of end-stage liver disease in the United States is **chronic hepatitis C**, with or without a contribution from alcohol abuse (about 40% of cases).
- Patients with alcoholic cirrhosis and indeterminate (**cryptogenic**) causes occupy the second and third most frequent causes, respectively.
- Other less common causes include chronic hepatitis B, immune-mediated liver diseases (autoimmune hepatitis, primary biliary cirrhosis, primary sclerosing cholangitis), and hereditary liver diseases (hemochromatosis, alpha-1-antitrypsin deficiency).

Assessment of Prognosis in Cirrhotic Patients Admitted to the ICU

- Several prognostic schemes have been assessed (Table 107.5), and those using general organ system assessments, such as the Sequential Organ Failure Assessment (SOFA) score, appear to be more accurate than liver-specific schemes.
- The number of organ systems (cardiovascular, respiratory, hepatic, renal, coagulation, and neurologic) failing 24 hours after ICU admission strongly predicts in-hospital mortality, from 33% in patients with single organ failure to 97% in those with failure of three or more organs.
- In the absence of OLT as a therapeutic option, cirrhotic patients admitted to the ICU have a very poor long-term prognosis, with 69% 1-year mortality and median survival of only 1 month.

Management of Complications of Chronic Liver Failure in the ICU

Evaluation of Abdominal Pain

- The development of abdominal pain in a patient with end-stage liver disease often denotes a life-threatening complication of cirrhosis or portal hypertension (Table 107.6).

- A diagnostic **paracentesis** should be performed immediately in any patient with ascites and abdominal pain to diagnose spontaneous bacterial peritonitis (SBP) or to look for evidence of GI tract perforation into ascites.
- The latter may be distinguished from SBP by its higher total protein and lactate dehydrogenase concentration, the isolation of more than one organism (including anaerobes and *Candida*), lower glucose, and higher white blood cell (WBC) and polymorphonuclear (PMN) leucocyte counts.
- **Hemoperitoneum** from spontaneous rupture of a mesenteric varix or hepatocellular carcinoma may be rapidly detected by diagnostic paracentesis, in which case the patient should be referred for emergent interventional angiography.
- The diagnosis and treatment of intra-abdominal catastrophes in patients with cirrhosis remains challenging. Specifically, complicated gallstone and peptic ulcer disease may present less acutely in patients with cirrhosis, delaying diagnosis; in those requiring surgical intervention, morbidity and mortality remain very high.
- **Acute portal vein thrombosis**, which may complicate cirrhosis and often denotes development of hepatocellular carcinoma (HCC), should be suspected in patients with abdominal pain, GI bleeding, and ileus, and should prompt screening with Doppler ultrasound.
- If the thrombus propagates acutely into the superior mesenteric vein, bowel ischemia and infarction, and death, usually ensue.

Cardiovascular Complications

- The resting hemodynamic state in decompensated cirrhosis consists of systemic hypotension due to systemic and splanchnic arterial dilation. Consequently, patients with decompensated cirrhosis have marked arterial underfilling of systemic vascular beds in the renal arterial and hypothalamic circulations, resulting in the elaboration of compensatory neurohumoral hormones such as renin, vasopressin, and norepinephrine.
- The primary pathogenic mechanism underlying this hyperdynamic state includes release of vasodilatory mediators such as **endothelins** and **nitric oxide** by the portal endothelium.

TABLE 107.5

CALCULATION OF THE SEQUENTIAL ORGAN FAILURE ASSESSMENT (SOFA) SCORE TO PREDICT IN-HOSPITAL MORTALITY IN PATIENTS WITH CIRRHOSIS ADMITTED TO THE ICU

Organ system (criterion)	0 Points	1 Point	2 Points	3 Points	4 Points
Respiratory (PaO ₂ /FiO ₂)	>400	301–400	201–300	101–200 (ventilated)	≤100 (ventilated)
Hemostatic (platelets [$\times 10^3/\text{mm}^3$])	>150	101–150	51–100	21–50	≤20
Hepatic (bilirubin [mg/dL])	<1.2	1.2–1.9	2.0–5.9	6.0–11.9	>12.0
Cardiovascular ^a (hypotension)	MAP ≥0 mm Hg	MAP <70 mm Hg	Dopamine ≤5 or dobutamine ^a	Dopamine >5 or epi/norepi ≤0.1	Dopamine >15 or epi/norepi >0.1
Neurologic (Glasgow Coma Score)	15	13–14	10–12	6–9	<6
Renal (creatinine [mg/dL])	<1.2	1.2–1.9	2.0–3.4	3.5–4.9	>5.0

PaO₂/FiO₂, arterial oxygen tension/fractional inspired oxygen; MAP, mean arterial pressure; epi, epinephrine; norepi, norepinephrine.

A SOFA score with a cutoff of 8 points had a sensitivity of 95%, specificity of 88%, overall correctness of 91%, PPV of 87%, and NPV of 96% for predicting in-hospital mortality.

^aAdrenergic agents in $\mu\text{g}/\text{kg}/\text{min}$.

Modified from Wehler M, Kokoska J, Reulbach U, et al. Short-term prognosis in critically ill patients with cirrhosis assessed by prognostic scoring systems. *Hepatology*. 2004;34(2):255–261.

TABLE 107.6

DIFFERENTIAL DIAGNOSIS OF ABDOMINAL PAIN IN PATIENTS WITH CIRRHOSIS

Cause of abdominal pain	Etiologic associations	Clinical presentation
Spontaneous bacterial peritonitis	Low protein ascites	Fever, rebound tenderness, HE, azotemia
Incarcerated hernia (umbilical, inguinal)	Ascites, recanalization of the umbilical vein	Localized pain, bowel obstruction
Cholelithiasis and complications	Pigmented gallstones	Localized pain, jaundice, fever, pancreatitis
Peptic ulcer and complications	Decompensated cirrhosis, <i>Helicobacter</i> infection	UGI bleeding, perforated viscous
Hepatocellular carcinoma	Spontaneous rupture	Hemoperitoneum (rare)
Portal/mesenteric venous thrombosis	Hepatocellular carcinoma	Bowel ischemia, GI bleeding, ileus
Rupture of mesenteric varix	Recent large-volume paracentesis	Hemoperitoneum

HE, hepatic encephalopathy; UGI, upper gastrointestinal; GI, gastrointestinal.

In addition to the usual causes of abdominal pain and acute abdomen in the general ICU population, all of the above have been described with higher prevalence in patients with cirrhosis. Appropriate screening tests for the above include diagnostic paracentesis, duplex ultrasonography, contrast-enhanced abdominal computerized tomography (CT), and/or upper endoscopy.

- In addition, patients with decompensated cirrhosis have impaired cardiac contractility in response to stress, in particular, infection or GI bleeding.
- Diagnostic criteria of myocardial failure include blunted inotropic and chronotropic responses to stress, diastolic dysfunction, and prolonged QT interval on electrocardiogram.
- The treatment of **heart failure** in the setting of decompensated cirrhosis remains poorly defined; afterload reduction with angiotensin-converting enzyme inhibitors may precipitate profound hypotension and renal failure, and cardiac glycosides and β -adrenergic agonists have been shown to be relatively ineffective.

Ascites and Renal Complications

- Acute renal failure (ARF) in patients with decompensated cirrhosis is an independent predictor of death in the ICU and frequently denotes the onset of infection.
- The differential diagnosis of ARF in a decompensated cirrhotic includes **prerenal azotemia**, **hepatorenal syndrome (HRS)**, and **acute tubular necrosis (ATN)**.
- Analysis of urine sediment and sodium differentiate the above possibilities: the former two diagnoses present with normal urine sediment and low (<10 mEq/L) urine sodium, and the latter with renal tubular cell debris and high urine sodium.
- The distinction of these causes of renal failure remains paramount, since in its late stages, HRS portends a very poor prognosis and is generally irreversible without OLT, in contrast to prerenal azotemia and ATN.
- In practical terms, the diagnosis of HRS is often made after the exclusion of septic shock, intrinsic renal disease, obstructive uropathy, and most important, prerenal azotemia, the latter after a 1.5-L IV fluid (normal saline with or without colloid) challenge (Table 107.7).
- The treatment of **ascites** in the ICU should include judicious administration of diuretics in subjects without marked azotemia (creatinine >2 g/dL), electrolyte abnormalities, or hypotension.

- A combination of furosemide and spironolactone in a ratio of 40 mg and 100 mg has been shown to better effect a diuresis than either agent alone.
- The administration of IV albumin (12.5 g/day) may improve the efficacy of diuretics.
- Large-volume paracentesis should be performed if ascites interferes with ventilation of the patient or if diuretics result in azotemia or electrolyte abnormalities.
- IV colloid administration (albumin 6–8 g for each liter of ascites removed) should accompany paracentesis of ≥ 5 L to prevent **postparacentesis circulatory dysfunction**.
- The insertion of a transjugular intrahepatic portosystemic shunt (TIPS) may be considered in patients who have failed medical therapy.

TABLE 107.7

DIAGNOSTIC CRITERIA OF HEPATORENAL SYNDROME (HRS)

MAJOR CRITERIA

Low GFR (creatinine >2.5 mg/dL; CrCl <20 mL/min)
 Absence of shock, infection, nephrotoxins
 Absence of improvement after 1.5 L fluid challenge
 Absence of intrinsic renal disease
 Proteinuria <500 mg/d
 Normal renal ultrasound

MINOR CRITERIA

Oliguria (<500 mL/d)
 Urine sodium <10 mEq/L
 Serum sodium <130 mEq/L

GFR, glomerular filtration rate; CrCl, creatinine clearance.
 Adapted from Arroyo V, Gines P, Gerbes AL, et al. Definition and diagnostic criteria of refractory ascites and hepatorenal syndrome in cirrhosis. International Ascites Club. *Hepatology*. 1996;23(1): 164–176.

TABLE 107.8

RELATIVE CONTRAINDICATIONS AND ADVERSE OUTCOMES ASSOCIATED WITH PLACEMENT OF TIPS FOR SALVAGE THERAPY OF ACUTE VARICEAL HEMORRHAGE, REFRACTORY ASCITES, OR REFRACTORY HEPATIC HYDROTHORAX

RELATIVE CONTRAINDICATIONS

Severe liver failure (MELD ≥ 20 ; PT > 20 s; creatinine > 2.0 mg/dL; bilirubin > 3.0 mg/dL)

Active systemic infection (risk of TIPS infection ["endo-TIPSitis"])

Recurrent/severe hepatic encephalopathy

Current hemodynamic instability

Congestive heart failure

Chronic renal failure

Pulmonary hypertension

ADVERSE OUTCOMES

Does not improve long-term patient survival for any indication

TIPS-induced hemolytic anemia

Worsening or precipitation of hepatic encephalopathy

TIPS stenosis ($> 50\%$ at 1 y; lower with covered stents)

Failure of TIPS to prevent recurrence of indication for placement (for rescue in variceal bleeding about 5%, refractory ascites 15%–60%, hepatic hydrothorax 30%–40%)

TIPS, transjugular intrahepatic portosystemic shunt; MELD, model for end-stage liver disease; PT, prothrombin time.

The above relative contraindications and adverse outcomes need to be taken in the context of the risk of immediate death as they assume less importance in the setting of rescue therapy for acute variceal bleeding. Data adapted from Lamer JM. Transjugular intrahepatic portosystemic shunt-role in treating intractable variceal bleeding, ascites, and hepatic hydrothorax. *Clin Liver Dis.* 2006;10(3):583–598; Sanyal AJ. The use and misuse of transjugular intrahepatic portosystemic shunts. *Curr Gastroenterol Rep.* 2000;2(1):61–71; and Sanyal AJ. Pros and cons of TIPS for refractory ascites. *J Hepatol.* 2005;43(6):924–925.

- In an ICU setting, patients may be too ill to undergo TIPS, and it is important for intensivists to recognize when TIPS placement is inappropriate (Table 107.8).
- The optimal treatment of HRS remains undefined. The ultimate treatment of HRS and the hemodynamic abnormalities of cirrhosis is OLT.
- **Vasoconstrictor therapy** holds promise for reversing HRS by reversing the state of systemic vasodilation. The oral α -adrenergic agonist **midodrine** (5–10 mg orally thrice daily) was found to be effective in one widely cited but preliminary study, when used in combination with octreotide (100 μ g SC twice daily).
- **Terlipressin**, an intravenously administered vasopressin analogue with fewer ischemic complications, also reverses systemic vasodilation and has been found to effectively reverse HRS in Europe, but is not yet available in the United States.
- The administration of intravenous colloid, specifically albumin, serves to improve renal vascular perfusion.
- Finally, patients with decompensated cirrhosis should not receive even small therapeutic doses of nonsteroidal anti-inflammatory drugs since these agents exacerbate renal vasoconstriction by inhibiting production of endogenous vasodilatory renal prostaglandins.

- Electrolyte abnormalities frequently accompany ARF in cirrhosis and complicate the treatment of ascites. Hyponatremia and hypomagnesemia result from furosemide administration, and hyponatremia and hyperkalemia result from spironolactone administration.
- Hyponatremia also results from hemodilution in the setting of high vasopressin release from the neurohypophysis and portends a poor prognosis.

Infectious Complications

- Bacterial infections represent the most common cause of admission of cirrhotic patients to the ICU and remain one of the two primary causes of death.
- Risk factors for bacterial infections in hospitalized patients with cirrhosis include ICU admission and GI bleeding.
- Patients with cirrhosis are relatively **immunocompromised** as a result of portal hypertension and immune dysfunction. Portal hypertension results in the formation of a low-protein ascites, which is susceptible to infection because of its low complement concentration and, thus, low opsonic activity.
- **SBP** remains the most common bacterial infection in patients admitted to the ICU, but a shift toward **Gram-positive infections** has occurred. In one major hepatic diseases ICU, 77% of isolates were Gram positive.
- All patients admitted to an ICU with clinical suspicion of sepsis should be empirically given IV antibacterial agents to cover Gram-positive as well as Gram-negative organisms until cultures and sensitivities allow narrowing of the regimen; empiric vancomycin should be considered in patients who have been instrumented.
- The choice of coverage for Gram-negative bacilli should be a third-generation cephalosporin (e.g., cefotaxime [2 g IV every 8 hours] or ceftriaxone [1 g IV every 24 hours]).
- Aminoglycosides should be avoided except in serious infections with a multiply-resistant organism because of the susceptibility of cirrhotic patients to aminoglycoside nephrotoxicity.
- Diagnostic paracentesis should be performed on all cirrhotic patients admitted to the ICU with ascites and renal failure, HE, or any evidence of infection.
- Localizing symptoms and signs of peritonitis—abdominal pain, fever, rebound tenderness—may be absent in up to 30% of patients with this process.
- Blood and ascites should be immediately inoculated into culture bottles at the bedside, which has been shown to increase culture yields. However, **culture yields** may be as low as 40% even with bedside inoculation of a large volume of ascetic fluid (20 mL).
- Culture-negative neutrocytic ascites—that is, with more than 250 PMNs/ μ L—should be considered the equivalent of SBP.
- Patients with ascetic fluid PMN count of ≥ 250 cells/ μ L should receive a third-generation cephalosporin (as above) and IV albumin (1.5 g/kg at diagnosis and 1.0 g/kg 48 hours after diagnosis), which has been shown both to decrease the incidence of HRS after SBP and to improve mortality.
- A similar diagnostic and therapeutic algorithm should be followed for spontaneous bacterial empyema, the infectious equivalent of SBP in patients with hepatic hydrothorax (see below).
- The incidence of **fungal infections** also increases in cirrhotic patients admitted to the ICU. Patients with Child's C cirrhosis have been reported to spontaneously develop invasive

aspergillosis in the ICU. *Candida* species may also infect cirrhotic ascites, with disastrous outcome.

Gastrointestinal Bleeding

- Acute upper gastrointestinal (UGI) bleeding, presenting as hematemesis and/or melena, remains one of the three most common indications for admission of patients with cirrhosis to the ICU.
- Esophageal varices account for most UGI bleeds in patients with cirrhosis, with gastric varices accounting for approximately 5% to 10%, and nonvariceal UGI pathology (gastric or duodenal mucosal lesions) noted in up to 30%.
- Other uncommon causes of UGI bleeding associated with cirrhosis include portal hypertensive gastropathy and gastric antral vascular ectasia, which more often present with occult GI bleeding and anemia.
- Upper endoscopy should be performed in all patients admitted to the ICU with acute UGI bleeding to identify its source as well as administer therapy.
- Patients with cirrhosis who present with acute UGI bleeding should be considered for ICU admission to deliver intensive nursing care and to manage the bleed as well as its complications.
- Despite the trend toward improved survival after variceal hemorrhage in the past two decades, each episode still carries a mortality risk of 10% to 20%, and the risk of rebleeding remains highest during the first few days after the index event.
- General resuscitative measures on admission to the ICU should include correction of hypotension, repletion of blood, and consideration of endotracheal intubation before endoscopy (Table 107.9).
- Factors that should contribute to the decision of whether to intubate a cirrhotic patient with an UGI bleed should include the rate of bleeding, hemodynamic instability, and degree of hepatic encephalopathy.
- Suppression of gastric acid secretion with proton pump inhibitors has been shown to decrease the number, size, and complications from post-band ligation esophageal ulcers.
- Vasopressin, formerly used for lowering portal pressure for this indication, has fallen from favor due to vasospastic adverse effects; although the vasopressin analogue terlipressin has a better safety profile and appears to improve control of acute variceal bleeding.
- The somatostatin analogue octreotide also has a favorable safety profile, and meta-analysis has demonstrated improved

rates of sustained bleeding control after acute hemorrhage from esophageal varices.

- Endoscopic therapy after stabilization of the patient remains the definitive treatment for bleeding esophageal varices and controls active bleeding in more than 75% of cases when combined with vasoactive therapy.
- Endoscopic band ligation and sclerotherapy yield similar rates of control of active bleeding, but band ligation results in fewer local complications (esophageal ulcers, recurrent bleeding).
- Recurrent bleeding should prompt a second attempt at endoscopic treatment. In patients with recurrence after a second endoscopic treatment, or in any recurrence with hemodynamic instability, emergent insertion of a TIPS should be considered.
- In such dire situations, the relative contraindications for TIPS placement, outlined in Table 107.8, become less important.
- Patients with acute hemorrhage from fundic gastric varices present a particular therapeutic challenge because the bleeding is more profuse and interventions have been less successful in controlling the acute bleed.
- In the absence of endoscopic and vasoactive control of gastric variceal bleeding, insertion of a large tamponade balloon (Linton tube) can temporize control before insertion of a TIPS.
- Antibiotic prophylaxis after variceal hemorrhage has been shown to decrease the incidence of infection as well as variceal rebleeding, resulting in improved survival.
- Oral or IV fluoroquinolones (norfloxacin 400 mg orally/day or ofloxacin 200 mg IV twice daily) is recommended. Cephalosporins may be used if there is local resistance to fluoroquinolones.

Pulmonary Complications

- Respiratory failure accounts for up to 40% of admissions of cirrhotic patients to the ICU.
- The differential diagnosis of respiratory distress in patients with cirrhosis may be categorized into complications of cirrhosis, pulmonary vascular diseases resulting from portal hypertension, and primary liver diseases with cardiopulmonary manifestations (Table 107.10).
- Complications of cirrhosis include massive ascites and **hepatic hydrothorax (HH)**, the accumulation of extracellular fluid with similar protein characteristics as ascites (low-protein, high-albumin gradient as compared to serum) within the pleural space.

TABLE 107.9

SPECIFIC MANAGEMENT OF ACUTE VARICEAL HEMORRHAGE AND ITS COMPLICATIONS

Therapeutic maneuver	Dose/route/indication
Transfusion of RBC	To hemoglobin of 8–9 g/dL
Octreotide	100 µg IV bolus, then 50 µg/h for 5 d
Endoscopy	EVL preferred over EVS
Proton pump inhibitors	Pantoprazole 40 mg IV or PO/d for 9 d
Antibiotic prophylaxis	Norfloxacin 400 mg/d for 7 d, or ceftriaxone 1 g/d for 7 d
TIPS	After two failed therapeutic endoscopies

RBC, red blood cells; IV, intravenous; PO, orally; EVL, esophageal variceal ligation; EVS, endoscopic variceal sclerotherapy; TIPS, transjugular intrahepatic porto-systemic shunt.

Sarcoidosis (restrictive lung disease, cardiomyopathy)
Hemochromatosis (cardiomyopathy)
Ethanol (cardiomyopathy)

Adapted from Arguedas MR, Fallon MB. Hepatopulmonary syndrome. *Clin Liver Dis.* 2005;9(4):733–746.

- HH usually occurs in the right pleural space (85%) and may occur in the absence of obvious ascites as a result of negative intrathoracic pressure during inspiration.
- The treatment of HH includes diuretic administration, as for ascites, and therapeutic thoracentesis. Placement of a TIPS in patients with refractory HH may be considered but is not universally effective, and relapse free 1-year survival is only 35%.
- Chest tube placement and pleurodesis are relatively contraindicated in refractory HH as they often contaminate the pleural space, precluding OLT.
- An infectious complication of HH, spontaneous bacterial empyema, should be diagnosed and managed similarly to SBP, but has a high mortality.
- The hepatopulmonary syndrome (HPS) may be defined as a widened alveolar-arterial oxygen gradient due to intrapulmonary vasodilation in a patient with liver disease. The pathogenesis of HPS remains obscure but likely results from the release of vasoactive mediators from the liver, which increase intrapulmonary nitric oxide production.
- In a patient with cirrhosis and resting hypoxemia ($\text{PaO}_2 < 70$ mm Hg while breathing a FiO_2 of 0.21), the diagnosis is confirmed by a contrast echocardiogram.
- Supplemental oxygen usually bridges patients with HPS to OLT, which improves or reverses the process in 85% of patients.
- Patients with HPS have increased transplant waiting list mortality when compared to patients with normal gas exchange; consequently, patients with HPS and $\text{PaO}_2 < 60$ mm Hg on room air are allowed increased priority for OLT in the United States.
- Portopulmonary hypertension (PPH) is the development of increased pulmonary vascular resistance due to vasoconstriction and subsequent vascular remodeling in a patient with portal hypertension.
- The diagnosis must be confirmed with right heart catheterization showing elevated mean pulmonary artery pressure

(PAP > 25 mm Hg), as well as high pulmonary vascular resistance (> 240 dynes/second per cm^{-5}) and normal pulmonary capillary wedge pressure.

- The treatment of PPH—indicated when mean PAP is more than 35 mm Hg—has not been well defined; prostacyclin analogues (epoprostenol titrated via pulmonary artery [PA] catheter; inhaled iloprost [$5 \mu\text{g}$ six times daily]), phosphodiesterase inhibitors (sildenafil, 20 mg orally three times daily), or combination therapy appear to be effective in small case series.
- Unfortunately, the prognosis of patients with PPH is sufficiently poor after OLT that many patients with a mean PAP > 35 mm Hg are not offered transplant.

Neurologic Complications

- Changes in mental status frequently accompany admission of patients with cirrhosis to the ICU and should not automatically suggest the presence of HE (Table 107.11).
- HE usually presents as a global decline in cognition and intellect, but focal neurologic deficits and signs of cerebral

TABLE 107.12**PRECIPITATING EVENTS AND MECHANISMS OF HEPATIC ENCEPHALOPATHY IN PATIENTS WITH CIRRHOSIS**

Event	Mechanism
Excessive protein ingestion	↑ Gut ammonia production
Constipation

TABLE 107.13

INDICATIONS AND CONTRAINDICATIONS FOR LISTING PATIENTS WITH DECOMPENSATED CIRRHOSIS FOR ORTHOTOPIC LIVER TRANSPLANTATION (OLT)

Indications	Contraindications
MELD ≥ 15	Active infection outside the liver
CTP score > 7	Advanced cardiopulmonary disease
Hepatopulmonary syndrome ($PO_2 < 60$ mm Hg)	Recent or metastatic malignancy
HCC (tumor stage 2)	Uncontrolled HIV infection/AIDS
Hyponatremia (< 130 mEq/L)	Cholangiocarcinoma
Ascites refractory to medical therapy ^a	Active substance abuse
Hepatic hydrothorax	Psychosocial issues that would jeopardize posttransplant compliance
Hepatorenal syndrome	

MELD, Model for End-stage Liver Disease; CTP, Child-Turcotte-Pugh; HCC, hepatocellular carcinoma; HIV, human immunodeficiency virus; AIDS, acquired immunodeficiency syndrome.

^aRefractory ascites may be functionally defined as an inadequate response to, or adverse effects (hyponatremia, hyperkalemia, azotemia) from, maximal medical therapy.

edema—decerebrate posturing and seizures—have also been described rarely.

- After screening for toxic and metabolic derangements, a severely obtunded patient should undergo non-contrast-enhanced head CT to rule out intracranial bleeding.
- High serum ammonia levels may help confirm, but are not necessary to make, the diagnosis.
- Most important, the presentation of a patient with advanced-grade HE should prompt a search for precipitating factors, particularly infection and UGI bleeding (Table 107.12).
- The administration of broad-spectrum antibiotics (e.g., ceftriaxone) should be considered until cultures have returned negative.
- The standard therapy, oral lactulose, must be administered via nasogastric tube in an intubated patient, cannot be given if there is an ileus, and its overzealous administration risks aspiration pneumonia, gaseous distention of the bowel, toxic megacolon, and electrolyte imbalance.
- Rectal lactulose offers an alternative route of administration, but its efficacy over tap water or saline enemas is unknown.
- The “non absorbable” antibiotic neomycin should be avoided, as the absorption of even small quantities from the gut risks renal injury.
- Rifaximin, a rifampin derivative that also decreases gut flora production of neurotoxins, appears to be as effective as lactulose and has a good safety profile.
- The benzodiazepine receptor antagonist flumazenil (1 mg IV) improves HE, but the benefit wanes within 2 hours.

- Extracorporeal albumin dialysis also improves HE in refractory cases and may be considered as a bridge to OLT.

Liver Transplantation for Patients with Chronic Liver Failure in the ICU

- ICUs have been increasingly used to care for patients with decompensated cirrhosis. Therefore, intensivists must have a working understanding of the indications and contraindications for listing cirrhotic patients for OLT (Table 107.13)
- The **model of end-stage liver disease (MELD)** score replaced the Child-Turcotte-Pugh (CTP) score by all OLT centers in the United States.
- The MELD score may be calculated from serum bilirubin, creatinine, and INR (most easily online at UNOS.ORG). Subsequent studies have demonstrated the superiority of the MELD over the CTP system in predicting waiting list mortality.
- A minimal MELD score of **15 points** for activating patients on the liver transplant waiting list has been adopted by most programs based on the observation that a MELD of 15 points predicts a 90-day mortality of about 10% without transplant, the same short-term mortality associated with transplant.
- Many patients in the ICU reach very high MELD scores (e.g., 35–40) with the onset of renal failure and are often removed from the OLT waiting list after developing infection and/or multiorgan system failure.

CHAPTER 108 ■ PANCREATIC DISEASE

OVERVIEW

- Acute pancreatitis has an annual incidence of 5 to 40 per 100,000 with an overall mortality of 1.5 per 100,000.
- The clinical course of acute pancreatitis is often self-limited and results in little, if any, structural alteration of the gland and requires no intervention.
- Approximately one-third of patients, however, develop pancreatic necrosis, which has an associated mortality rate that can be as high as 30%.
- All complications of this disease are potentially lethal and may require aggressive intervention to control or abort the process and to support the patient until the condition is resolved.
- Severe acute pancreatitis often demands an extended stay in the intensive care unit and countless hours of multidisciplinary care.

PATHOPHYSIOLOGY

- Numerous causative factors of acute pancreatitis have been recognized. The most important risk factors for pancreatitis in adults are **gallstones** and excessive **alcohol** use.
- The incidence of gallstone pancreatitis is increased among white women older than the age of 60 years and is highest in patients with gallstones <5 mm in diameter.
- Other causes include metabolic derangements such as hypertriglyceridemia, duct obstruction, medications (i.e., azathioprine, thiazides, and estrogens), and trauma. About 20% of cases remain idiopathic.
- Underlying the pathophysiology of acute pancreatitis is the inappropriate conversion of trypsinogen to trypsin and a lack of prompt elimination of **active trypsin** inside the pancreas.
- Activation of other pancreatic enzymes causes injury to the gland and results in an inflammatory process that is out of proportion to the response of other organs to a similar insult.
- In addition to further direct tissue damage, the inflammatory process may result in the systemic inflammatory response syndrome (SIRS), multiorgan failure, and ultimately, death.

DIAGNOSIS OF THE DISEASE PROCESS

- Even with history, physical examination, laboratory values, radiographic studies, and special procedures, a conclusive diagnosis of acute pancreatitis and its complications is often elusive.
- The recurrence rate of acute pancreatitis has been reported to be as high as 33% and can be even higher in the alcoholic population.

- Disease isolated to the head or tail of the pancreas may result in pain localized to the right or left upper quadrant with diaphragmatic irritation and referred pain to the subcapsular areas.
- The classic presentation of epigastric pain that radiates through to the back may be present in only 50% of patients presenting with acute pancreatitis.
- After the patient develops peritoneal signs, pancreatitis can mimic all other acute abdominal crises, especially those necessitating emergent surgery.

Laboratory Testing

- Serum amylase levels that are more than **three times** the upper limit of normal are almost always caused by acute pancreatitis given the appropriate clinical presentation.
- Serum amylase concentration begins to rise shortly after onset of the disease and it may return to normal levels in 2 to 4 days. Thus, a **normal serum amylase** level does not exclude the disease.
- Up to 19% of patients with an attack of acute pancreatitis had a normal serum amylase level and an abnormal computed tomography scan.
- Acute pancreatitis with normal serum amylase levels has a high proportion of patients with an alcoholic etiology and a longer duration of symptoms before admission.
- Other factors that may contribute to the absence of elevated serum amylase levels include return to normal levels prior to presentation or the inability of an inflamed or chronically diseased pancreas to produce a significant quantity of amylase.
- Pancreatitis secondary to biliary tract disease will often present with some of the highest serum amylase levels.
- An elevated **alanine aminotransferase** level in a patient without alcoholism who has pancreatitis is the single best predictor of biliary pancreatitis; a level more than three times the upper limit of normal has a positive predictive value of 95% for gallstone pancreatitis.
- The clinician must remain aware that an elevated serum amylase is not necessarily diagnostic of acute pancreatitis. The differential diagnosis of hyperamylasemia includes perforated or penetrating gastric ulcer, ruptured ectopic pregnancy, and intestinal obstruction or infarction.
- Measuring urinary amylase, amylase-to-creatinine ratios, and amylase isoenzymes have shown little clinical advantage, with the exception of ruling out macroamylasemias.
- An elevated concentration of serum lipase, however, is quite sensitive for diagnosis of acute pancreatitis secondary to alcohol abuse.
- **Lipase** levels tend to remain **elevated longer** than amylase concentrations. Therefore, an elevated lipase level can be useful information for patients who present later in the course of disease and who may have a normal amylase concentration.

- Serum lipase levels, although thought to be more specific for pancreatic destruction, have little, if any, role in predicting severity of disease.
- Although elevated serum amylase and lipase levels are most widely used for the diagnosis of acute pancreatitis, as stated, they have little, if any, value in predicting the severity of disease.

Radiologic and Diagnostic Studies

- Numerous radiologic findings are suggestive of, but not specific for, pancreatitis. These include dilatation of the first portion of the duodenum (duodenal ileus), dilatation of the first loop of the jejunum (jejunal ileus or sentinel loop), dilatation of the transverse colon or colon cutoff sign (secondary to a transverse colonic ileus), and elevated hemidiaphragm and pleural effusion, especially on the left side (secondary to diaphragmatic irritation and sympathetic pleural effusions).
- Transabdominal pancreatic ultrasonography is not sensitive in the diagnosis of acute pancreatitis, often because of gas in the bowel.
- Transabdominal ultrasound is more sensitive than either computed tomography or magnetic resonance imaging for identifying cholelithiasis and sludge and for detecting dilatation of the biliary ducts, but is insensitive for the detection of distal biliary duct stones.
- Endoscopic ultrasonography may be the most accurate test for diagnosing or ruling out biliary causes of acute pancreatitis and may guide the use of endoscopic retrograde cholangiopancreatography (ERCP).
- It is recommended that patients with severe acute gallstone pancreatitis undergo early ERCP and, if indicated, endoscopic sphincterotomy.
- ERCP is used with endoscopic sphincterotomy to extract impacted gallstones and to drain infected bile in severe acute pancreatitis.
- ERCP can also demonstrate ductal disruptions in traumatic pancreatitis and may also allow identification of pancreas divisum, thought to be a rare cause of acute pancreatitis.
- Although ERCP has recognized risks, including bleeding and either causing or exacerbating pancreatitis, complications are uncommon when performed by experienced endoscopists.
- In patients with abdominal pain of unclear cause, computed tomography can confirm the diagnosis of acute pancreatitis or confirm other causes of abdominal pain.
- In the absence of contraindication, computed tomography with radiocontrast is preferred, as contrast-enhanced computed tomography (CT) remains the gold standard in the diagnosis of pancreatic necrosis.
- When the use of intravenous radiocontrast material is contraindicated, the diagnosis of acute pancreatitis can be inferred from homogenous glandular enlargement and the presence of peripancreatic fluid collections.
- Determination of the extent of pancreatic necrosis correlates with prognosis as mortality increases markedly in patients with necrosis involving more than 30% of the gland.
- Radiocontrast allows the identification of pancreatic necrosis, which appears as focal or diffuse zones of nonenhanced parenchyma. Areas of necrosis may not be present, however, for 48 to 72 hours after presentation.
- In the clinically stable patient with a contraindication to intravenous contrast, magnetic resonance imaging (MRI) can diagnose and evaluate the extent of pancreatic necrosis. MRI may also identify early duct disruption that is not visible on CT scan.
- There are no imaging techniques that allow precise and reliable identification of infected pancreatic necrosis.
- The appearance of air in the pancreatic parenchyma, caused by gas-producing bacteria, is uncommon in patients with infected pancreatic necrosis; however, when present it usually indicates infection.
- **Fine-needle aspiration**, under CT or ultrasound guidance, with Gram staining and culture of the aspirate is the gold standard for the diagnosis of infected pancreatic necrosis.
- Most series report sensitivity for the prediction of infected necrosis that ranges from 90% to 100% and specificity between 96% and 100%.

CLASSIFICATION

- The most relevant classification to the intensivist determines the degree of severity and progress of an individual episode of pancreatitis. **Ranson's criteria** are well correlated with morbidity, number of days' stay in the ICU, and eventual mortality.
- Admission criteria:
 - Age older than 55 years
 - Blood glucose level >200 mg/dL
 - Leukocyte count >16,000/mm³
 - Serum lactate dehydrogenase (LDH) level >350 IU/L
 - Serum glutamic-oxaloacetic transaminase (SGOT) >250 Sigma Frankel units
- Criteria to be determined within 48 hours:
 - Serum calcium level <8 mg/dL
 - PaO₂ <60 mm Hg, base deficit >4 mEq/L
 - Increase in blood urea nitrogen (BUN) of more than 5 mg/dL
 - Decrease in hematocrit of more than 10 percentage points
 - More than 6 L fluid sequestration
- The presence of fewer than 3 of these 10 criteria within 48 hours of admission correlates with a more benign form and course of disease, with an eventual mortality rate of 3%.
- The presence of three or more of these parameters on admission or within 48 hours usually implies a more severe form of pancreatitis and is associated with high risk of death and major complication.

TREATMENT OF ACUTE PANCREATITIS

- An overall approach to the therapy for acute pancreatitis should include placing the pancreas "at rest," supporting the patient's nutritional and metabolic needs, correcting the acute causes of mortality, detecting complications of disease that require surgical intervention, and preventing and treating delayed causes of mortality.

Gland Suppression

- Suppression of the secretory function of the pancreas has been attempted by elimination of oral fluids, suppression with H₂

blockers and antacids, and use of anticholinergics and proteolytic enzyme inhibitors. However, controlled randomized studies have not shown significant benefit.

- Recent evidence suggests that **enteral nutrition** is not only feasible but may be desirable in such patients.
- Bacterial translocation from the intestinal tract to the pancreas may have a role in the pathogenesis of infected pancreatic necrosis.
- Lack of enteral feeding may facilitate translocation of bacteria or bacterial products into the circulation. Total parenteral nutrition may, therefore, promote bacterial translocation in patients with pancreatitis.
- Animal studies have shown jejunal feedings result in negligible increases in enzyme, bicarbonate, and volume output from the pancreas. This observation has been confirmed in humans.
- Several studies have shown jejunal feeding to be not only less expensive than total parenteral nutrition but also associated with fewer septic complications and shorter length of stay.
- In addition, enteral nutrition reduces production of proinflammatory mediators that may also have therapeutic potential in such patients.
- Initiating enteral feeding within 48 hours of admission helps to maintain gut function, allowing improved tolerance and fewer problems with ileus and gastric stasis compared with feeding delayed by 4 or 5 days.
- Contrary to the commonly held belief that enteral feedings must be delivered distal to the ligament of Treitz, recent studies suggest that nasogastric feeding is well tolerated and does not appear to exacerbate pancreatitis.
- **Hypocalcemia** can occur in acute pancreatitis, but rarely is there a clinically significant decrease in ionized calcium. If deficits are found, however, calcium and magnesium are easily replaced.

Cardiovascular Collapse, Renal Failure, and Respiratory Insufficiency

- One of the most important determinants of poor outcome in severe acute pancreatitis is the early development and persistence of organ dysfunction.
- The cornerstone of management in early pancreatitis is fluid resuscitation and close monitoring for early manifestations of organ dysfunction.
- In addition to the frequent assessment of vital signs, the intravascular volume status should be monitored by means of physical examination and urinary output.
- Early identification of hypoxemia via either pulse oximetry or arterial blood gas measurement is also paramount.
- **Hypovolemia** occurs as a result of the chemical peritonitis; the associated increased capillary permeability, relative lymphatic obstruction, and partial splanchnic venous obstruction can account for sequestration of up to 40% of the patient's circulatory plasma volume in a few hours. Renal insufficiency may be a result of this massive fluid loss.
- The association of **renal failure** in acute pancreatitis markedly increases the mortality in these patients.
- Whether or not there is a **myocardial depressant factor** associated with severe pancreatitis, inotropic agents may be required to improve cardiac function if cardiac output remains low despite adequate filling pressures.

- The **respiratory insufficiency** associated with severe pancreatitis is complex and is probably a combination of a decrease in functional residual capacity and shunting.
- Respiratory assistance with positive end-expiratory pressure (PEEP) is required until the process resolves and the patient can maintain adequate minute ventilation and oxygenation.
- Patients with severe acute pancreatitis who meet conventional criteria should be admitted to the intensive care unit, as well as those patients who are at high risk of rapid deterioration such as the elderly, patients requiring ongoing volume resuscitation, those with renal failure, respiratory compromise, and evidence of substantial pancreatic necrosis (>30%).
- Morbidly obese patients are at increased risk for developing the severe form of acute pancreatitis. When compared to normal-weight patients, patients with body mass index (BMI) ≥ 25 kg/m² had an increasing rate and types of complications as the BMI increased.

Therapeutic Peritoneal Lavage

- Despite several early, initially enthusiastic reports, the use of continuous lavage in patients with acute pancreatitis is not supported by the currently available evidence.

Antibiotics

- The natural course of severe acute pancreatitis progresses in two phases. The first 14 days are characterized by the development of the SIRS. The second phase, roughly 2 weeks after the onset of disease, is dominated by sepsis-related complications resulting from infection of pancreatic necrosis.
- In the natural course of the disease, **infection of pancreatic necrosis** occurs in up to 70% of patients and has become the most important risk factor for death from necrotizing pancreatitis.
- The frequency of infected necrosis correlates with the duration of disease. In patients with necrotizing pancreatitis, the proportion of patients with proven infected necrosis at the time of surgery increased from 22% to 24% after the first week to 36% to 55% after the second week and up to 72% after the third week.
- The extent of pancreatic necrosis may also be a risk factor for infection. Patients with more than 50% necrosis of the pancreas have the highest infection rates.
- Among patients with sterile necrotizing pancreatitis, **mortality** rates of 10% to 15% are reported, whereas infected pancreatic necrosis carries with it a mortality rate of up to 50%.
- Multiple investigators have identified **imipenem** as the antibiotic agent of first choice as it can reach higher pancreatic tissue levels and it provides higher bactericidal activity against most of the bacteria present in pancreatic infection compared with other types of antibiotics.
- In a comparison between meropenem and imipenem, there were no significant differences in septic complications, indication for surgery, or mortality, indicating that meropenem is equally effective.
- The combination of quinolones and metronidazole is not an effective antibiotic prophylaxis.

- Longer antibiotic administration in patients with acute necrotizing pancreatitis (> 14 days) is not associated with a reduction in the incidence of septic complications of the disease. However, prolonged imipenem administration in patients with persisting systemic complications tends to reduce mortality in acute necrotizing pancreatitis compared to a 14-day regimen.
- Prophylactic antibiotics may reduce local pancreatic infection rates, episodes of sepsis, and mortality.
- Early versus delayed imipenem–cilastatin in the treatment of acute necrotizing pancreatitis may reduce the need for surgery, the overall number of major organ complications, and the mortality rate.
- The **bacterial spectrum** of infection in acute necrotizing pancreatitis has been described as primarily Gram negative and, in part, anaerobic, with the predominant pathogens including *Escherichia coli*, *Pseudomonas* species, *Enterobacter*, *Bacteroides*, and *Proteus*.
- Early antibiotic treatment of necrotizing pancreatitis results in a dramatic **shift in bacteriology** from Gram-negative to Gram-positive pathogens in those patients who develop infection.
- It is likely that these Gram-positive infections do not originate in the gut, but rather are nosocomial infections acquired via venous catheters, urinary catheters, or endotracheal tubes.
- Antibiotic prophylaxis does not appear to increase the incidence of fungal infections.

SURGICAL MANAGEMENT

- Most episodes of acute pancreatitis are mild and self-limiting, resolving spontaneously within 3 to 5 days. The mortality rate in these patients is <1%, and these patients do not routinely require intensive care or surgical management.
- However, there are several absolute indications for operative intervention in patients with severe acute pancreatitis, including prevention of recurrence and treatment of complications.
- As the conservative management of infected pancreatic necrosis associated with multiple organ failure has a mortality rate of up to 100%, proven infected pancreatic necrosis, as well as septic complications directly resulting from pancreatic infection, are indications for surgical intervention.

Treatment of Biliary Pancreatitis

- Biliary pancreatitis is most often associated with the passage of a small common bile duct stone. Occasionally, a stone may become impacted at the ampulla of Vater. In this case, rapid progressive deterioration of the patient's clinical course may soon follow.
- For patients with severe acute gallstone pancreatitis, urgent biliary drainage and clearance of the common bile duct must be considered.
- There is general agreement that open cholecystectomy with supraduodenal bile duct exploration and insertion of a T tube is an unacceptable emergency procedure in patients with severe gallstone pancreatitis, as both higher morbidity and mortality rates have been shown following early surgery.

- Patients with signs and symptoms consistent with **cholangitis** and patients with severe acute gallstone pancreatitis and obstructive jaundice should undergo **urgent endoscopic retrograde cholangiopancreatography**, and, if choledocholithiasis is confirmed, endoscopic sphincterotomy should be performed.
- In patients with severe acute pancreatitis due to suspected or proven cholelithiasis but without obstructive jaundice, the role of ERCP and endoscopic sphincterotomy is less well defined.
- In severe biliary pancreatitis, emergency ERCP and endoscopic sphincterotomy appears to reduce the overall complication rate and mortality rate. In contrast, ERCP and endoscopic sphincterotomy have no influence on the outcome of mild biliary pancreatitis.
- Recurrence of acute pancreatitis in patients with cholelithiasis has been reported in 29% to 63% of cases if the patient is discharged from the hospital without additional treatment. **Cholecystectomy** and clearance of the common bile duct is indicated in these patients to prevent recurrent biliary pancreatitis.
- In mild gallstone pancreatitis, cholecystectomy should be performed as soon as the patient has recovered from the attack and, preferably, during the same hospital stay.
- In severe gallstone pancreatitis, cholecystectomy should be performed once the inflammatory process has subsided and with sufficient clinical recovery to make the procedure technically easier and safer for the patient.
- If endoscopic sphincterotomy was performed, cholecystectomy should be performed within 6 weeks.
- Cholecystectomy can be performed safely after an episode of gallstone pancreatitis via the laparoscopic approach with a reported conversion to open rate of 0% to 16%.

Vascular Complications

- The systemic vascular effects of acute pancreatitis are probably related to the release of pancreatic proteases, such as trypsin, which locally and distally may activate complement C5a and precipitate the coagulation cascade.
- **Bleeding** from pancreatic pseudocysts and ruptured pseudoaneurysms are the most often fatal complication of pancreatitis, carrying a mortality rate of 25% to 40%.
- Bleeding may present as melena from erosion into the proximal gastrointestinal tract or as hypovolemia and abdominal pain if there is rupture into the peritoneal cavity.
- Most patients with gastrointestinal tract bleeding secondary to acute or chronic pancreatitis are alcoholics, and the cause of the bleeding is usually missed because of more common causes of serious bleeding in this patient population (i.e., peptic ulcer disease, gastritis, varices, Mallory-Weiss tears).
- The development of **aneurysms** is probably related to the severe inflammation and enzymatic autodigestion of the pancreatic and peripancreatic arteries with eventual formation of a pseudoaneurysm. With growth and expansion, the pseudoaneurysms may rupture into pseudocysts, adjacent viscera, the peritoneal cavity, or the pancreatic duct.
- The most common vessel involved in splanchnic pseudoaneurysms related to pancreatitis is the splenic artery, followed by the gastroduodenal and the inferior pancreaticoduodenal,

but such involvement may occur with any of the adjacent splanchnic vessels.

- Patients with chronic pancreatitis may have as high as a 10% incidence of pseudoaneurysms demonstrated on angiographic studies, but bleeding from these rarely occurs unless they are associated with pseudocysts.
- The treatment of **ruptured pseudoaneurysms** requires that the diagnosis be recognized; therefore, the clinician must know of it, must have a high index of suspicion, and must have a well-defined diagnostic and therapeutic plan, including emergency upper endoscopy, selective visceral angiography, ultrasonography, and CT scanning.
- Control can be rendered by either selective arterial infusion of vasopressin or angioembolization with Gelfoam, detachable intravascular balloons, Gianturco coils, or polymerizing adhesives.
- Surgical control is indicated only for immediate life-threatening bleeding or failure of interventional control of bleeding.
- **Hemoductal pancreatitis or hemosuccus pancreatitis** is the complication of pseudoaneurysm rupture into the pancreatic duct and usually encompasses the triad of gastrointestinal bleeding, pancreatitis with epigastric pain, and partial common bile duct obstruction.
- The diagnosis can be confirmed by selective visceral angiography or ERCP. The treatment of this rare complication requires ligation of the pseudoaneurysm and possible pancreatic resection.
- Venous **thrombosis of the portal vein** is a potential complication of acute or chronic pancreatitis. The patient's course is complicated by acute decompensation, hypotension with sequestration in the vascular bed, acidosis, hepatic enzyme elevation, alteration in clotting studies, and venous infarction of the bowel.
- Patients who survive this insult all develop portal hypertension, and some present months to years later with bleeding esophageal varices.
- Selective **splenic venous thrombosis** occurs more frequently, and patients usually present with an increased spleen size, unexplained blood loss, pain in the left upper quadrant and subscapular area, and possibly hypotension and cardiovascular collapse because the subscapular hematoma ruptured into the free peritoneal cavity.
- The treatment is splenectomy with preoperative vascular control by angiographic techniques and balloons.
- During drainage procedures for pancreatic pseudocysts in the presence of associated splenic venous thrombosis, the transgastric approach should be avoided to decrease postoperative bleeding from the rich submucosal plexus of high-pressure veins.
- In the absence of bleeding gastric varices, one may elect to leave the spleen *in situ* even with splenic vein thrombosis, because not all patients develop bleeding from gastric varices.

Pancreatic Pseudocyst

- Peripancreatic fluid collections can occur as a result of acute pancreatitis, chronic pancreatitis, surgery (either pancreatic or other abdominal surgery), trauma, or neoplasia.
- With the exception of a cystic neoplasm, peripancreatic fluid collections form either as a result of a disruption in the pancreatic ductal system with subsequent fluid leakage or the maturation of peripancreatic necrosis.
- The critical clinical distinction between an acute fluid collection and a pseudocyst (or pancreatic abscess) is the lack of a defined wall as defined by the International Symposium on Acute Pancreatitis in 1992.
- Acute fluid collections are common in patients with severe acute pancreatitis, occurring in up to 50% of cases. However, more than half of these lesions **regress spontaneously**.
- Pseudocyst is defined as a collection of pancreatic juice that arises as a consequence of acute or chronic pancreatitis or pancreatic trauma that is enclosed by a nonepithelialized wall composed of either fibrous or granulation tissue.
- Formation of an acute pseudocyst takes **four or more weeks** from the onset of acute pancreatitis. In contrast, chronic pseudocysts have a well-defined wall but arise in patients with chronic pancreatitis without a preceding episode of acute pancreatitis.
- Pseudocyst formation is a frequent complication of pancreatitis with a reported incidence of 10% to 20% in acute pancreatitis and 20% to 40% in chronic pancreatitis.
- When pus is present, the lesion is more correctly termed a **pancreatic abscess**. The distinction between pancreatic abscess and infected necrosis is critical as the mortality risk for infected necrosis is double that for pancreatic abscess.
- The traditional management of pancreatic pseudocyst is to proceed with a drainage procedure if the pseudocyst persisted **beyond 6 weeks** and/or was **larger than 6 cm**.
- Operative intervention was the mainstay, and the procedure performed was internal drainage via a cyst-enteric anastomosis, primarily cystogastrostomy or cystojejunostomy, depending on the location of the pseudocyst.
 - The traditional method of surgical drainage has been challenged by the introduction of less invasive techniques; percutaneous or endoscopic drainage techniques are comparable to the outcome of surgical drainage techniques in appropriately selected patients.
- Simple aspiration of the cyst has been associated with a recurrence rate of more than 70% and can, therefore, not be regarded as a definitive treatment.
- Continuous catheter drainage has shown better short-term results, with an 84% success rate and an average 7% recurrence rate.
- The prolonged presence of an indwelling catheter for several weeks and frequent fistula formation remain disadvantages of this technique.
- Endoscopic drainage has been increasingly used during the past 10 years, either via a transpapillary route or through the gastrointestinal wall. The short-term results appear to be encouraging.

Biliary Obstruction Due to Pancreatic Inflammation

- Biliary obstruction may be found in as many as 25% of cases presenting with acute pancreatitis, and this obstruction, caused by pancreatic swelling, can be confused with a stone lodged at the ampulla.

- The intrapancreatic portion of the common bile duct becomes involved in the inflammatory process, but this usually resolves over the course of the disease.
- If the biliary obstruction does not resolve, a workup including ultrasonography, ERCP, or **transhepatic cholangiography** may be necessary to define the problem and the anatomy so that an appropriate decompressive procedure can be performed.
- If the patient develops cholangitis and becomes septic from infected bile in the obstructed duct, transhepatic cholangiography and drainage may be life-saving to provide decompression without subjecting the patient in septic shock to an emergency operation.

Pancreatic Necrosis, Infected Pancreatic Necrosis, and Abscess

- Little is known of what triggers the release of activated pancreatic enzymes that autodigest the gland and surrounding retroperitoneal tissue and convert acute interstitial or edematous pancreatitis to pancreatic necrosis.
- If venous thrombosis and erosion to the small peripancreatic vessels occur, the combination is hemorrhagic necrotizing pancreatitis.
- Enteric bacterial contamination results in combined abscess and infected necrosis, which carries the highest mortality rate.
- It is rare to see septic complications within the first week of presentation but not unusual after the second week, and they are almost universally present if the patient's course requires therapy for more than 3 weeks.
- Clinical signs of abdominal pain, fever, leukocytosis, associated severe systemic manifestations of hypotension, cardiovascular collapse, pulmonary insufficiency, renal failure, and mental status changes all strongly suggest the onset of this complication.
- The problem is rarely that of making the diagnosis of sepsis, but rather, of differentiating pancreatic necrosis and abscess formation from other sources of systemic sepsis such as pneumonia, urinary tract infection, and intravascular catheter-related infection.
- **Sequential contrast-enhanced computed tomography** is the best tool available for diagnosing and following this disease process. The study is diagnostic of abscess formation if air is seen in the phlegmon.
- Percutaneous **fine-needle aspiration** of the intrapancreatic or peripancreatic fluid collections can be used to confirm bacterial contamination in the absence of air. If necrosis is demonstrated on CT scan, aspirates are sterile, and the patient is not toxic, a conservative approach may be attempted.
- At present there is general agreement that surgery for severe pancreatitis should be deferred as long as the patient continues to respond favorably to conservative management.
- Early operation directed toward debridement of devitalized tissue to prevent septic complications has only led to increased morbidity and incidence of sepsis.
- Optimal surgical timing should occur, at the minimum, 2 to 3 weeks after the onset of pancreatitis to allow a sequestrum to form. The rationale for delaying surgical therapy is to permit proper demarcation of pancreatic and peripancreatic necrosis to occur, limiting the extent of surgery that is needed to facilitate debridement.
- In most studies published over the past decade, indication for surgery was defined by necrosis formation on CT scan and positive fine-needle aspiration. In the unstable patient, CT-guided percutaneous aspiration and drainage of pancreatic abscesses used as a temporizing measure before surgery may improve the patient's overall condition.
- Surgical techniques are still necessary for **debridement and drainage** if percutaneous drainage does not improve the septic course. The goal of surgery in patients with necrotizing pancreatitis is to remove all areas of necrotic tissue, including necrotic pancreatic tissue and any infected necrotic tissue.
- Resective procedures, such as partial or total pancreatectomy that also remove vital pancreatic tissue and healthy organs, are associated with high mortality rates.
- Traditionally, three techniques have been used with comparable results; these include:
 - open necrosectomy with closed continuous lavage of the retroperitoneum
 - open necrosectomy that may or may not be staged with planned relaparotomies followed by delayed primary closure and drainage or with multiple drainage and relaparotomy as required
 - open necrosectomy, often with marsupialization, with open packing and planned relaparotomies.
- The surgical techniques for the treatment of pancreatic necrosis are varied, and the ideal method is still debated. Generally agreed-on principles of surgical management include an organ-preserving approach that involves debridement or necrosectomy, minimization of intraoperative hemorrhage, and maximization of postoperative removal of retroperitoneal debris and exudates.

CHAPTER 109 ■ INFLAMMATORY BOWEL DISEASE AND TOXIC MEGACOLON

FULMINANT COLITIS

- **Ulcerative colitis** is characterized by a diffuse, continuous inflammatory process usually limited to the **superficial mucosa** of the colon. **Crohn disease** entails a more focal, **transmural** inflammation that can affect the colon either alone or accompanied by small bowel involvement. Both have the potential for severe, fulminating, or toxic colitis.
- Since the original classification was published by Truelove and Witts in 1955, severe, acute, ulcerative colitis has been defined by:
 - the presence of six or more bloody bowel movements per day associated with temperature $>37.8^{\circ}\text{C}$
 - heart rate >90 beats/minute
 - hemoglobin <10.5 g/dL
 - an erythrocyte sedimentation rate (ESR) >30 mm/hour
- The above criteria are indications for hospitalization and intravenous corticosteroid therapy.
- Additionally, the severity of ulcerative colitis can extend beyond the need for hospitalization to *fulminant colitis* and *toxic megacolon*, implying progression of mucosal inflammation into deeper layers of the colon wall.
- These conditions are medical emergencies and require more intense and combined medical and surgical management.
- Patients with **fulminant colitis** or **toxic megacolon** have evidence of **transmural inflammation**, including more profound tachycardia (heart rate >120 beats/minute), fever ($>38^{\circ}\text{C}$), hypoactive bowel sounds, hypoalbuminemia, and metabolic alkalosis, accompanied by radiologic and endoscopic evidence of transmural disease and circular muscle paralysis, which precipitates dilatation (Table 109.1).
- Approximately 15% of patients with ulcerative colitis will have a severe flare-up that will require hospitalization. Between 6.3% and 9% will have severe colitis as their initial presentation.
- Mortality from severe colitis is $<2\%$, with a colectomy rate of about 30%.
- The risks of surgery or colectomy with fulminant colitis or toxic megacolon have not been independently assessed, but their prognosis is, most certainly, worse than patients presenting with criteria for severe colitis alone.

Clinical Features

- In contrast to patients with severe colitis, those with **fulminant colitis** are characterized by having more than 10 bowel movements per day, rectal urgency, continuous bleeding, abdominal pain and distention, fevers, weight loss, and dehydration.

- On physical examination, patients present with fever, tachycardia, abdominal tenderness and mild distention, tympany, and decreased bowel sounds.
- Laboratory abnormalities include leukocytosis, anemia (hemoconcentration must be taken into account), hypoalbuminemia, hypokalemia, hyponatremia, and elevated sedimentation rate and C-reactive protein (CRP). The degree of metabolic alkalosis correlates with the severity of colitis.
- A plain abdominal radiograph can determine the extent of ulcerative colitis by the absence of fecal material distal to the margin of disease and the presence of air outlining normal haustrations proximal to the disease margin.
- Radiologic features of fulminant colitis include wall thickening, with islands of edematous mucosa surrounded by deep ulcerations. The presence of **colonic dilatation** >5.5 cm is predictive of the presence of—or evolution to—**toxic megacolon**.
- A limited proctoscopic examination or flexible sigmoidoscopy with minimal air insufflation may be performed safely to evaluate the mucosa for pseudomembranes or ischemia. Examination generally shows extensive ulceration with friable, bleeding mucosa.
- In rare instances, however, such as with rectal enema therapy or in the setting of Crohn disease, the rectum may be normal.
- In patients whose initial presentation of inflammatory bowel disease is severe colitis, biopsies should be performed to evaluate for Crohn disease and to rule out acute self-limited colitis.
- In those with an exacerbation of known diagnosis, biopsies can help to exclude *Clostridium difficile* or cytomegalovirus.
- More extensive **endoscopic examinations** are **generally contraindicated** due to the risk of perforation or inducing toxic megacolon. However, they have been performed safely in some experienced centers.
- The presence of severe colitis (deep penetrating ulcers) in conjunction with clinical features of severe disease is a poor prognostic sign. Similarly, the presence of extensive and deep ulcerations is a poor prognostic marker in Crohn disease.
- Stool analysis for ova and parasites, *C. difficile*, *Escherichia coli* O157:H7, *Campylobacter*, *Salmonella*, and *Shigella* should be performed as part of the diagnostic workup.

Management

- Few medical emergencies require as close cooperation between medical and surgical personnel as does fulminant colitis.
- A team approach with early management and continuous assessment by both groups is vital not only to determine whether surgery is indicated but also to support critically ill patients preoperatively and postoperatively.

TABLE 109.1

DETERMINATION OF SEVERITY OF BOWEL DISEASE: CLINICAL/LABORATORY FINDINGS

	Disease severity	
	Severe disease	Fulminant disease
Stools (number/d)	>6	>10
Blood in stool	Frequent	Continuous
Temperature	>37.5°C	>37.5°C
Pulse	>90 bpm	>90 bpm
Hemoglobin	<75% of normal	Transfusion required
Erythrocyte sedimentation rate	<30	>30
Radiographic features	Colon wall edema Thumbprinting	Dilated colon
Clinical examination	Abdominal tenderness	Abdominal distention and tenderness

- Early recognition and institution of therapy by an experienced team can alter the outcome of this life-threatening illness.
- Daily to frequent abdominal radiographs should be performed to follow the progression of the colitis. Additionally, computed tomographic scan may be needed for management in complicated cases.

Medical Treatment

- Resuscitative measures, including vigorous **fluid, electrolyte, and blood** replacement to maintain the serum hematocrit at approximately 30%, are paramount.
- The goal of fluid replacement should be to restore previous losses and continue replenishing those that are ongoing from diarrhea, fever, and third spacing of fluids.
- Despite the fact that bowel rest is an ineffective primary therapy for severe colitis, oral intake of fluids should be discontinued in fulminant colitis or once colonic dilatation is recognized.
- Parenteral **nutritional support** in attempts to correct malnutrition and electrolyte and acid-base balance—including repletion of phosphate, calcium, and magnesium—should be initiated.
- Although severe **hypokalemia** may not be present, total body potassium depletion is common and may be exacerbated by glucocorticoids such that resuscitative measures should include adequate potassium replacement.
- **Aminosalicylates**, a mainstay of maintenance therapy and the treatment of mild to moderate disease, have no role in the treatment of fulminant colitis.
- **Corticosteroids** have long been used in the management of ulcerative colitis as well as in Crohn colitis. Usual doses employed for severe fulminant colitis range from 40 to 80 mg of methylprednisolone (in Europe, often 1 mg/kg) or 400 mg of hydrocortisone provided in divided doses or continuous infusion.
- Prednisone, 25 mg intravenously every 6 hours, and prednisolone sodium phosphate have been used successfully. In the United States, hydrocortisone, 100 mg every 6 hours, and methylprednisolone, 6 to 15 mg every 6 hours, are both available for intravenous administration.
- There is no advantage to doses >60 mg of methylprednisolone daily.
- The use of adrenocorticotrophic hormone (ACTH) has not been shown to be superior to corticosteroids and, although it may be preferred in patients not previously exposed to corticosteroids, at a dose of 100 to 150 U/day, its use has become an anachronism.
- The response to corticosteroids in the setting of severe fulminant colitis has remained constant for the past several decades, with approximately 75% of patients responding and less than half failing to achieve remission.
- The most critical assessment in the setting of fulminant colitis is the response to therapy within the first 5 days.
- The presence of hypoalbuminemia, high CRP, short duration of illness, and prior corticosteroid use are predictors of medical failure. In addition, ex-smokers have a worse prognosis.
- Short-term prognosis to corticosteroids in severe disease can be predicted as early as 24 hours. Persistence of more than nine stools per day, an albumin <3 g/dL, or a pulse rate >90 beats/minute was predictive of >60% risk of colectomy.
- Patients with greater than eight stools per day and a CRP >4.5 mg/dL by day 3 had an 85% likelihood of requiring colectomy or cyclosporine therapy.
- Continuation of intravenous (IV) corticosteroids beyond 7 to 10 days does not provide any additional benefits and may increase morbidity and surgical risks.
- **Cyclosporin A**, administered as a continuous IV infusion (2 or 4 mg/kg/day), either alone or in combination with corticosteroids, has been effective in treating severe ulcerative colitis.
- Immediate response rates up to 85% to 92% have been reported and, similar to the experience with the “intensive intravenous corticosteroid” regime, failure to improve—as defined by having eight or more stools per day or persistence of CRP elevation after 3 days of cyclosporine—is predictive of the need for colectomy.
- Forty percent to 50% of patients treated with intravenous cyclosporine experience long-term remission. Improved outcomes are reported for patients who have been transitioned to oral cyclosporine with the addition of **6-MP** or **azathioprine**.
- Careful daily monitoring for serious side effects of nephrotoxicity, infection, and seizures must be carried out when using cyclosporine.
- Patients who improve, as evidenced by restitution of formed bowel movements with the absence of bleeding and ability to pass flatus without using the toilet, are then transitioned

to oral prednisone at the same daily dose used to achieve the clinical remission.

- Aminosalicylates are added as a maintenance therapy once patients are tolerating oral steroids and a full diet.
- Patients requiring IV cyclosporine are transitioned to oral dosing by doubling the IV dose for twice-daily oral administration (e.g., if the intravenous dose is 100 mg/24 hours, the oral dose would be 100 mg twice daily).
- Patients receiving a combination of corticosteroids and cyclosporine should receive *Pneumocystis* prophylaxis with sulfamethoxazole-trimethoprim three times weekly.
- Patients may be discharged from the hospital when tolerating a low-residue diet with formed stools without blood or rectal urgency; premature discharge is doomed to failure and readmission.
- Most recently, infliximab, a chimeric antitumor necrosis factor (TNF) monoclonal antibody, has been shown to be effective as outpatient therapy for patients with moderate to severe ulcerative colitis. However, the role of infliximab in fulminant ulcerative colitis has been debated; the controversy is likely related to the severity of the disease.

Surgical Management

- Persistence of medical therapy in the setting of fulminant colitis must be balanced against the potential for a surgical “cure” of the disease.
- Indications for surgery in fulminant colitis include clinical deterioration or failure to respond to medical therapy.
- Although the medical management of fulminant colitis and toxic megacolon is similar, the absence of acute colonic dilatation may permit delay of surgical intervention.
- Generally, in the absence of colonic dilatation, medical management may be continued for 5 to 7 days in a further attempt to reverse transmural inflammation, as long as the patient is stable and improving.
- Patients with fulminant colitis who do not begin to respond to the intensive intravenous steroid regimen should be referred to a center experienced in cyclosporin therapy or undergo colectomy.
- The timing of surgical intervention in these less urgent cases requires experienced clinical judgment. Early intervention to reduce mortality must be balanced against the potential for intensive medical management to control the inflammatory process and complications, thereby potentially preventing the psychosocial and medical stigmata of colectomy.
- The type of operation performed for treatment of fulminant colitis depends on the clinical status of the patient and experience of the surgeon.
- A one-stage procedure that cures ulcerative colitis without the need for a second operation is appropriate for older patients or those not desiring restorative ileal pouch–anal anastomosis.
- A limited abdominal colectomy with ileostomy, leaving the rectosigmoid as a mucous fistula or the rectum alone, using a Hartmann procedure has the advantages of limiting the lengthy pelvic dissection in acutely ill patients while allowing for the option of a subsequent restorative, sphincter-saving procedure (ileoanal anastomosis).
- In patients with indeterminate colitis or Crohn disease, preservation of the rectum may provide the opportunity for an eventual ileorectal or ileoanal anastomosis to preserve anal

continence after temporary diversion and pathologic review of the colectomy specimen.

TOXIC MEGACOLON

- Toxic megacolon refers to acute nonobstructive dilatation of the colon, generally as a complication of ulcerative colitis, but it may occur with any severe inflammatory colitis.
- This condition has been described with idiopathic and infectious colitis, including ulcerative colitis, Crohn disease, amebic colitis, pseudomembranous colitis, and other infections (*Shigella*, *Salmonella*, Chagas disease, and cytomegalovirus [CMV]).
- Toxic megacolon has been reported to complicate 1% to 13% of all ulcerative colitis cases and 2% to 3% of Crohn colitis cases.
- Although mortality in early series was as high as 25%, reaching 50% if colonic perforation occurred, early recognition and management of toxic megacolon has substantially lowered mortality to below 15% generally and, in experienced centers, usually below 2%.
- Factors associated with increased mortality include age older than 40 years, the presence of colonic perforation, and delay of surgery.
- Colonic perforation, whether free or localized, is the greatest risk factor leading to increased morbidity or death.

Predisposing Factors

- The severity of disease activity is the most important predictor of toxic megacolon, which is more common in extensive colitis than in proctitis or proctosigmoiditis.
- Limited right- or left-sided segmental colitis has also been associated with toxic megacolon.
- Toxic megacolon typically occurs early in the course of ulcerative colitis, usually within the first 5 years of disease; 25% to 40% of cases present with the initial attack.
- The onset of toxic megacolon has been temporally linked to diagnostic examinations such as barium enemas or colonoscopy, suggesting that manipulation of the inflamed bowel or vigorous laxative preparation may exacerbate the process, possibly through electrolyte imbalance.
- Certain drug therapies have been implicated in the development of toxic megacolon. Diphenoxylate atropine sulfate (Lomotil), loperamide, and other inhibitors of colonic motility such as opiates and narcotics may contribute to the development of toxic megacolon.
- Electrolyte and pH disturbances are risk factors for toxic megacolon. Severe potassium depletion, secondary to significant diarrhea or corticosteroid therapy, or both, is known to inhibit colonic motility.
- Despite early speculations regarding the role of corticosteroids in inducing toxic megacolon, most no longer accept this idea. Concern remains, however, that corticosteroids may suppress signs of perforation, thereby delaying surgical therapy.
- CMV infection may contribute to fulminant colitis or toxic megacolon. There are no controlled trials regarding the utility of treating CMV and, often, in the absence of systemic manifestations of CMV (e.g., fever, hepatitis), no treatment is necessary.

TABLE 109.2**JALAN'S CRITERIA FOR DIAGNOSIS OF TOXIC MEGACOLON**

1. Radiographic evidence of colonic dilatation
2. At least three of the following:
 - a. Temperature $>38.5^{\circ}\text{C}$
 - b. Heart rate >120 bpm
 - c. White blood cell count >10.5 ($\times 10^3/\mu\text{L}$)
 - d. Anemia
3. At least one of the following:
 - a. Dehydration
 - b. Mental status changes
 - c. Electrolyte disturbances
 - d. Hypotension

Jalan KN, Sircus W, Card WI, et al. An experience of ulcerative colitis. I. Toxic dilation in 55 cases. *Gastroenterology*. 1969;57(1):68–82.

Clinical Features

- Toxic megacolon usually occurs in the background of chronic inflammatory bowel disease.
- Clinical criteria based on signs, symptoms, and diagnostic abnormalities for toxic megacolon are listed in Table 109.2.
- The presentation typically evolves with progressive diarrhea, bloody stools, cramping abdominal pain, and abdominal distention. Impaired consciousness and lethargy may be present and are ominous signs.
- Occasionally, in chronically treated patients, a paradoxical decrease in stool frequency with passage of only bloody discharge or bloody membranes may be an ominous sign. Thereafter, clinical signs of toxemia, including pyrexia (temperature $>38.5^{\circ}\text{C}$) and tachycardia, develop as abdominal pain and distention become progressive and bowel sounds diminish or cease.
- On physical examination, peritoneal irritation, including rebound tenderness and abdominal guarding, represent transmural inflammation with serosal involvement, even in the absence of free perforation. Conversely, peritoneal signs may be minimal or absent in elderly patients or those receiving high-dose or prolonged corticosteroid therapy.
- In such patients, loss of hepatic dullness may be the first clinical indication of colonic perforation.
- Mental status changes, including confusion, agitation, and apathy, are occasionally noted.
- Leukocytosis, defined as total white blood cell count $>10,500$ cells/ μL , with a left shift, anemia, hypokalemia, and hypoalbuminemia are common laboratory findings.

Diagnosis

- Plain films of the abdomen are usually sufficient radiographic studies, revealing loss of haustration with segmental or total colonic dilatation (see Table 109.2).
- The magnitude of dilatation may not be severe, averaging 8 to 9 cm (normal is <5 –6 cm), although colonic diameter may reach 15 cm before rupture.
- Clinical studies have demonstrated a strong correlation between colonic dilatation and deep ulceration involving the muscle layers.

- Maximal dilatation can occur in any part of the colon. Accompanying mucosal thumbprinting or pneumatosis cystoides coli reflects severe transmural disease.
- Free peritoneal air should serve as an immediate indication for surgery.
- Infrequently, retroperitoneal tracking of air from a colonic perforation may produce subcutaneous emphysema and pneumomediastinum without pneumoperitoneum.
- In patients with severe colitis, small bowel ileus may herald toxic megacolon and is a bad prognostic sign for medical success.
- Discrepancies may exist between physical and radiographic findings. Abdominal distention by physical examination can be minimal despite massive colonic dilatation. Conversely, physical findings may dominate the presentation, and peritoneal signs in the absence of free air or dilatation should not be ignored.

Management

- Just as in fulminant colitis, a coordinated team approach between medical and surgical services to management and monitoring is necessary in patients with toxic megacolon.

Medical Treatment

- The initial treatment is supportive and similar to treatment outlined for fulminant colitis.
- Aggressive resuscitation with **fluids, electrolytes, and blood** is necessary. Blood transfusions should be given to maintain a hematocrit at about 30%.
- Patients with nausea and vomiting or significant abdominal pain should be on complete bowel rest.
- Anticholinergic and narcotic agents should be discontinued immediately. In the presence of small bowel ileus, a nasogastric tube is usually placed, and despite a lack of clear evidence for the placement of long intestinal tubes, they are advocated by some.
- Patient repositioning from front to back or prone knee–elbow position may redistribute colonic air and assist in decompression.
- Rarely, patients with dilatation in the absence of toxic signs or symptoms may benefit from rectal tube decompression.
- **Broad-spectrum antibiotics**, with adequate Gram-negative and anaerobic coverage, are considered standard therapy and should be administered without delay once transmural inflammation or toxic megacolon is suspected.
- Antibiotics should be continued until the patient stabilizes over several days to a week or through the initial postoperative period.
- Whether antibiotics help avert progression of toxic megacolon is not known.
- Generally, most patients with inflammatory bowel disease (IBD) will have been receiving corticosteroids before toxic megacolon developed, in which case they should be continued.
- Similar to therapy for fulminant colitis, augmented doses of corticosteroids should be administered in view of the additional stress of the toxic state. Close monitoring is necessary as there is concern that corticosteroids could mask signs of perforation or peritonitis.

- In cases of toxic megacolon caused by infectious etiologies, corticosteroids should not be used.
- Just as in fulminant colitis, there is no consensus regarding the corticosteroid preparation for treatment in toxic megacolon.

Surgical Management

- After **12 to 24 hours** of intensive medical management, if no improvement or deterioration occurs, surgical intervention is required for toxic megacolon.
- Some physicians actually view early surgical management of toxic megacolon as the conservative approach, noting that delay of operative therapy may promote higher mortality.
- Evidence of colonic perforation is an unequivocal indication for emergent surgery. If physical signs of perforation are absent, 12- to 24-hour radiographic surveillance is necessary.
- Perforation is associated with severe complications, including peritonitis, extreme fluid and electrolyte imbalance, and hemodynamic instability. Early recognition of perforation should lessen morbidity or mortality.
- Other indications for emergent surgery precluding protracted medical management include signs of septic shock, multi-organ dysfunction, and imminent transverse colon rupture (diameter >12 cm).
- Hypoalbuminemia, persistently elevated C-reactive protein or erythrocyte sedimentation rate, small bowel ileus, and deep colonic ulcers are poor prognostic factors for successful medical therapy.
- The surgical management of toxic megacolon must be individualized for each patient. The type of operation is dependent on the clinical condition of the patient and the experience of the surgeon. The types of surgery are outlined in the fulminant colitis section.
- Rarely, “blow-hole” colotomies may be useful in highly selected individuals with poor operative prognoses.

COMPLICATING SCENARIOS IN INFLAMMATORY BOWEL DISEASE

Thrombosis

- Inflammatory bowel disease is associated with an increased risk of **arterial and venous thromboembolism**.
- The prevalence of thromboembolism in IBD patients is as low as 1% to 8% and as high as 39% in a postmortem study.
- The mechanism is unclear, but systemic inflammation is considered a potent prothrombotic stimulus. In addition, coagulation factor abnormalities—factor V Leiden, decreased antithrombin III, protein C and S, increased levels of factors V and VIII, fibrinogen, and plasminogen activator inhibitor—contribute to the hypercoagulable state.
- **Deep vein thrombosis** and pulmonary embolism are the most common presentation of thrombosis in IBD.
- **Portal vein thrombosis** in IBD has 50% mortality and occurs in 9% of patients with deep vein thrombus.
- **Mesenteric vein thrombosis** occurs in about 5% of patients who undergo total colectomy for IBD.
- Approximately 10% of thromboembolisms in IBD manifest as cerebral vascular accidents.

- The treatment of deep vein thrombosis in IBD patients is similar to non-IBD patients. Options include unfractionated heparin, low-molecular-weight heparins, and warfarin for venous thrombosis.
- Those with contraindications to anticoagulation require an inferior vena cava filter to prevent pulmonary embolus. Thrombolytics can be used for large pulmonary emboli.
- Arterial thrombosis treatment in IBD includes surgical thrombectomy or fibrinolysis.

Managing Pregnant Women with Inflammatory Bowel Disease

- A team approach with early management and continuous assessment by the obstetrician, surgeon, and gastroenterologist is vital for the patient.
- The treatment of fulminant colitis and toxic megacolon in the pregnant woman is similar to the nonpregnant patient. However, continued severe illness poses a greater risk to the fetus than the medical or surgical intervention.
- Diagnostic modalities of ultrasound and **magnetic resonance imaging (MRI)** are safe and can be used for detection of abscess or colonic wall thickening and dilation.
- Low-dose radiographs (<5 rads) have minimal risk to fetus.
- Flexible sigmoidoscopy is a valuable tool to assess the severity of disease and anatomic extent of disease. It is considered a safe procedure to perform when indicated. In contrast, full colonoscopy is rarely indicated.
- Polyethylene glycol solution has not been studied in pregnancy; thus, fetal outcomes are unknown. Generally, oral bowel preparations are not recommended and, if a full colonoscopy is necessary, tap water enemas are recommended.
- The indications for surgery—medically refractory severe colitis, obstruction, perforation, and intractable bleeding—are the same as in the nonpregnant IBD patient.
- Surgery for an acute indication in the setting of pregnancy carries a high risk of fetal loss, but case reports of deliveries of healthy infants following colectomy for fulminant colitis are reported.
- There is no evidence that therapeutic abortion improves the outcome of fulminant colitis, so it is not indicated.

Gastrointestinal Bleeding

- Massive gastrointestinal bleeding is an unusual complication in IBD, occurring in 0.9% to 6% of patients.
- The general management is the same as in non-IBD patients. Resuscitation is the first step, followed by diagnostic evaluation—usually with endoscopy—to localize the site of bleeding.
- Colonoscopy can be used to identify the source of bleeding in IBD patients with a reported success rate of 60%.
- Angiography may be used in cases where colonoscopy is not diagnostic.
- Conservative therapy has been advocated, but surgery is indicated when bleeding is not stabilized by transfusions or if recurrent massive bleeding is present.

CHAPTER 110 ■ MESENTERIC ISCHEMIA

- Mesenteric ischemia is a generic term that implies inadequate blood flow to the intestines. It is relevant from a clinical standpoint as two separate disease processes:
 - **acute mesenteric ischemia (AMI)**
 - **chronic mesenteric ischemia (CMI)**
- Although the underlying process is similar (i.e., inadequate intestinal blood flow), the clinical presentation, diagnostic concerns, and treatment algorithms are different.
- CMI is almost exclusively related to visceral artery occlusive disease from atherosclerosis and is relevant to intensive care physicians primarily because of the multiple organ dysfunction that occurs after revascularization.
- AMI results from a broad spectrum of underlying conditions including arterial emboli, *in situ* thrombosis in the setting of visceral arterial occlusive disease, mesenteric venous thrombosis, nonocclusive mesenteric ischemia (NOMI), and acute aortic dissections. AMI is relevant to intensivists not only because of the early postoperative concerns, but also because it can occur in critically ill patients with other active problems (e.g., post-coronary artery bypass, acute pancreatitis). A thorough understanding of both clinical entities is essential for all intensive care physicians.

CHRONIC MESENTERIC ISCHEMIA

Pathophysiology

- The underlying pathophysiology of CMI is the inability to achieve postprandial hyperemic intestinal blood flow.
- Intestinal blood flow in the normal fasting state is fairly modest but increases markedly postprandially. In the presence of significant arterial occlusive disease, this postprandial hyperemia is not possible and patients develop ischemic pain similar to angina pectoris, appropriately termed **mesenteric angina**.
- The normal visceral circulation is fairly redundant and has a rich collateral network. The symptoms of mesenteric ischemia usually do not occur unless two of the three visceral vessels (i.e., celiac axis, superior mesenteric artery, inferior mesenteric artery) are significantly diseased.
- However, symptoms may occur with isolated disease in the superior mesenteric artery in the absence of adequate collaterals.
- The majority of visceral artery stenoses are due to atherosclerosis. Other causes, less common, include neurofibromatosis, fibromuscular disease, rheumatoid disorders, aortic dissection, radiation, Buerger disease, and certain drugs.
- The risk factors for visceral artery atherosclerosis are the same as those for the other vascular beds.
- The atherosclerotic process usually involves just the origin of the visceral vessels.

- Patients with occlusive disease in the celiac axis and superior mesenteric artery frequently have renal artery lesions (and vice versa).
- Symptomatic CMI is relatively rare despite the prevalence of visceral artery stenoses. Indeed, a hemodynamically significant visceral artery stenosis (>50% diameter reduction) is noted in up to 27% of patients with peripheral arterial occlusive disease undergoing arteriography and in up to 5 to 10% of unselected patients at autopsy.

Clinical Presentation and Diagnosis

- Most patients with CMI are **cachectic, elderly women** with strong **smoking** histories.
- CMI is more common in women, with a reported ratio of approximately 3:1.
- The mean age of patients undergoing surgery for CMI is 66 years of age. However, CMI may also be found in patients in their fourth and fifth decades of life.
- Abdominal pain is usually the presenting symptom. It initially occurs **postprandially** but may progress to a persistent nature in the latter stages of the disease process.
- Mesenteric angina has no specific characteristics but patients develop a fear of food and avoid eating. The net result is **weight loss** with a mean of 20 to 30 lb in several clinical series.
- Patients may develop nausea or vomiting, constipation, or diarrhea. AMI is a fairly strong cathartic, and motility symptoms rather than pain may be the predominate symptom.
- Patients with CMI frequently have evidence of systemic vascular disease, although there are no characteristic physical findings.
- Although the appearance and clinical presentation of patients with CMI is fairly characteristic, the differential diagnosis of patients with abdominal pain and weight loss is extensive and includes gastrointestinal malignancy first and foremost.
- CMI is usually not considered by most primary care providers, and this is reflected by the fact that the mean duration from presentation to diagnosis exceeds a calendar year and 2.8 diagnostic tests.
- The initial diagnostic workup for patients with abdominal pain and weight loss should include esophagogastroduodenoscopy, colonoscopy, abdominal ultrasound, and an abdominal/pelvic computed tomography (CT) scan.
- Notably, **gastric ulcers** are relatively common in patients with CMI and likely result from ischemia.
- A surprising number of patients are subjected to **cholecystectomy** as part of their workup before the definitive diagnosis of CMI is made.
- **Mesenteric duplex scan** is an excellent *screening* tool for visceral artery stenosis with reported sensitivity and specificity rates of approximately 80%. However, it is technically

challenging, operator dependent, and not available in all centers.

- Various provocative tests have been proposed to unmask clinically significant visceral artery stenoses, although their utility is unclear and they have not achieved widespread use.
- **CT arteriography** has largely replaced catheter-based contrast arteriography as the *diagnostic* study of choice for patients with CMI and is usually sufficient to plan open surgical revascularization.
- CT arteriography is safe, noninvasive, and almost universally available. It is very good for identifying occlusive disease in the superior mesenteric artery and celiac axis.
- CT arteriography is also useful for identifying the presence of collateral vessels between the visceral vessels and/or the internal iliac arteries. Additionally, it is very good for evaluating other intra-abdominal processes.
- The major advantage of contrast arteriography over CT arteriography is that therapeutic interventions can be performed at the time of the diagnostic procedure. However, it is an invasive procedure with a small but finite complication rate.
- A lateral arteriogram is mandatory as part of the examination to accurately assess the origins of the celiac axis and superior mesenteric artery due to their anterior/posterior orientation.
- The significant findings on arteriogram include ostial stenoses of the celiac axis and superior mesenteric artery, the presence of visceral collaterals, and the presence of central aortic atherosclerotic disease.
- A small percentage of patients with CMI may have visceral artery aneurysms, presumably from increased flow through the collateral vessels.
- **Magnetic resonance (MR) arteriography** has been used as a diagnostic study for patients with CMI and offers many of the advantages of CT arteriography. However, it is not as universally available as CT arteriography.
- Furthermore, it is not practical and may be contraindicated for many patients including those in the intensive care unit. Last, MR arteriography tends to overestimate the degree of stenosis in the visceral vessels.

Treatment Strategies

- The natural history of the untreated disease process is death either from inanition or bowel infarction and thus, all patients with CMI require treatment.
- Theoretical treatment options include medical management with total parenteral nutrition or revascularization by either endovascular or open surgical techniques.
- The role of long-term parenteral nutrition is very limited. Additionally, patients with CMI may not be able to metabolize the parenteral nutrition.
- **Endovascular treatment** (angioplasty with or without stenting) has emerged as the initial revascularization option for most patients with CMI but should be viewed as an alternative to the open surgical approach.
- Endovascular treatment has consistently been shown to have a lower mortality rate, a lower complication rate, and shorter hospital length of stay when compared to open surgical revascularization. However, the patency rates for the endovascular approach are lower.

- Decreased patency rates have not been associated with a decrease in survival, and vessel thrombosis and/or recurrent stenosis has not necessarily resulted in AMI.
- The endovascular approach can serve as an excellent bridge to open surgical revascularization for debilitated patients who are poor initial candidates for a major surgical procedure.
- The recent development of lower-profile (i.e., smaller-diameter) angioplasty balloon/stent systems has further extended the applications of the endovascular approach, and reasonable short-term results have been reported for patients with occluded (versus stenotic) vessels.

Endovascular Revascularization

- The preoperative evaluation prior to endovascular treatment is essentially the same for all catheter-based contrast arteriography. Patients with a contrast allergy should be treated with an appropriate steroid preparation.
- Patients with elevated serum creatinine levels (serum creatinine 1.5–2.0 mg/dL) should receive gentle **hydration and acetylcysteine**, although admittedly their benefits are somewhat unsubstantiated.
- A flush aortogram is performed in both the anteroposterior and lateral projections. Since most lesions in the superior mesenteric artery and celiac axis are orificial and located in the proximal 2 cm, selective catheterization is not usually necessary unless a distal lesion is suspected or the extent of the lesion cannot be determined.
- A **>50% diameter reduction of the superior mesenteric artery** is usually considered clinically significant regardless of whether or not the celiac axis is involved. In contrast, the diagnosis of CMI should be questioned in the presence of an isolated celiac axis stenosis.
- Symptomatic stenoses can be treated at the time of the diagnostic arteriogram. The orificial stenoses in the mesenteric vessels are refractory to angioplasty alone, and primary stenting is recommended.
- Balloon angioplasty with selective stenting is reserved for midsegment lesions. Balloon-expandable stents (vs. self-expanding stents) are preferred for the orificial stenoses due to their superior radial forces and controlled deployment mechanism.
- The postoperative care after mesenteric angioplasty/stenting is comparable to that for other peripheral endovascular procedures.

Open Surgical Revascularization

- The preoperative workup for patients undergoing open mesenteric revascularization is comparable to that for other major vascular surgical procedures and includes optimization of all organ systems.
- Multiple algorithms have been developed to reduce the **cardiac risk** for vascular surgical patients undergoing noncardiac procedures, although their utility is unclear given the results of several recent publications.
- Regardless of the specific preoperative cardiac evaluation, all patients should likely be on aspirin, a beta-blocker (if not contraindicated), and a cholesterol-lowering agent (preferably a statin/HMG Co-A reductase inhibitor). A CT or contrast arteriogram is mandatory to both confirm the diagnosis and plan the operative procedure.
- Various open surgical procedures have been reported, although the antegrade aortoceliac/superior mesenteric artery

bypass and the retrograde aortosuperior mesenteric artery bypass are the most common.

- The advantages of the antegrade aortoceliac/superior mesenteric bypass are that both visceral vessels are revascularized and that the supraceliac aorta (the origin of the bypass) is usually free of atherosclerotic occlusive disease. The major disadvantage is the complexity of the procedure.
- In contrast, retrograde aortosuperior mesenteric artery bypass is relatively straightforward, although only a single vessel is revascularized and the graft is prone to kinking given its obligatory retrograde course that traverses both caudal to cephalad and posterior to anterior.
- The optimal choice for a specific patient is contingent on his or her comorbidities with the retrograde bypass generally reserved for patients who will not tolerate the more complex antegrade procedure.
- The immediate postoperative care for patients undergoing revascularization for CMI is frequently complicated by the development of **multiple organ dysfunction** and is distinctly different from that associated with most other abdominal vascular surgical procedures such as aortobifemoral bypass for aortoiliac occlusive disease.
- This propensity to develop multiple organ dysfunction likely accounts for the prolonged intensive care and total hospital length of stays and is one of the leading causes of death in the postoperative period.
- The responsible mechanism for this multiple organ dysfunction is likely the visceral ischemia and **reperfusion phenomenon** inherent to the revascularization. This process has been reported to induce a complex response involving several interrelated inflammatory mediators that have the potential to cause both local and distant organ injury.
- Multiple organ dysfunction syndrome (MODS) occurs after revascularization for both AMI and CMI as demonstrated by marked elevations in serum hepatic transaminases over a 7- to 10-day period, the development of a transient coagulopathy and **thrombocytopenia** below 40,000/ μ L within 12 to 24 hours, and the development of a significant pulmonary injury.
- The **pulmonary injury** associated with revascularization of AMI or CMI is characterized by an elevated mean shunt fraction and a radiographic picture of the acute respiratory distress syndrome that manifested between 1 to 3 days and persists for 5 to 8 days.
- The optimal management strategy for patients in the early postoperative period after mesenteric revascularization is to support the individual organ systems until the MODS resolves.
- Not all patients develop organ dysfunction, but the incidence is quite high and unpredictable.
- The optimal ventilator management remains unresolved, but it is possible to extubate patients in the early postoperative period when they satisfy the various weaning criteria.
- The thrombocytopenia and coagulopathy are usually managed expectantly with platelet and/or plasma transfusions reserved for severely depressed platelet counts and/or any clinical evidence of bleeding.
- The inherent coagulopathy after mesenteric revascularization does not appear to be responsive to vitamin K.
- Patients should be maintained on total parenteral nutrition throughout the postoperative period until their bowel function returns. This is particularly important given the fact that

most patients are severely compromised from a nutritional standpoint.

- Patients may have a **prolonged ileus** after revascularization and parenteral nutrition is required for some time.
- The bypass should be interrogated prior to discharge to confirm the technical adequacy of the reconstruction.
- Patients with acute changes in their clinical status should also undergo visceral imaging to confirm that their bypass is patent.
- It can be difficult to differentiate MODS from AMI secondary to graft thrombosis. Serum lactate levels may be helpful in this setting.
- All patients who undergo revascularization for CMI require long-term follow-up. Patients are usually seen frequently in the early postoperative period until all their active issues resolve and then every 6 months thereafter with a mesenteric duplex to confirm graft patency.
- Objective assessment of graft patency is critical and significantly better than the return of symptoms that has been used as a surrogate marker. All abnormalities on duplex imaging merit further investigation with additional imaging and/or intervention.
- Diarrhea is a common complaint after revascularization for CMI and can persist for several months. It is more common in patients with preoperative diarrhea and can be so severe that it necessitates total parenteral nutrition.
- The cause of the diarrhea is unclear but may be related to intestinal atrophy, bacterial overgrowth, or disruption of the mesenteric neuroplexus.

Outcome

- The outcome after mesenteric revascularization for CMI is quite good. The perioperative mortality rate after open surgical revascularization is <15%, whereas that for the endovascular treatment is <5%.
- The corresponding complication rates are approximately 30% and 15% for the open and endovascular treatments, respectively.
- The initial technical success rate for the endovascular treatment is ~90%. The objectively documented 5-year patency rates after open revascularization are ~75%; patency rates after endovascular treatment are not as well described, but likely fall short of those reported for the open treatment.
- The 5-year survival after either treatment is ~75%, and most patients return to their presymptoms weight.

ACUTE MESENTERIC ISCHEMIA

- Mesenteric **emboli** and *in situ* **thrombosis** are the most common causes of AMI and account for approximately 50% and 25% of the cases, respectively. Nonocclusive mesenteric ischemia (NOMI, 20%), mesenteric venous thrombosis (5%), and aortic dissections account for the balance.
- Impaired intestinal perfusion leads to mucosal compromise, the release of the intracellular contents, and the influx of substances (including bacteria) from the lumen of the bowel and may lead to the activation of the **systemic inflammatory response**.

- If the impaired perfusion persists, bowel infarction with perforation and peritonitis ensues.
- The immediate clinical concerns for patients with AMI are to reverse the underlying clinical condition and prevent bowel infarction.
- The optimal therapy requires prompt diagnosis and definitive treatment, although this is often difficult given the susceptible patient population and common clinical scenarios.
- The morbidity and mortality associated with AMI are significant. The mortality of patients with AMI and portal/mesenteric venous gas is 86%.

Embolus

Pathophysiology

- Emboli responsible for AMI usually originate from the heart and lodge in the superior mesenteric artery. The intracardiac thrombus is related to either atrial fibrillation, an acute myocardial infarction, or a ventricular aneurysm.
- Patients frequently have prior embolic events from the same source, although they are not necessarily limited to the superior mesenteric artery (e.g., common femoral artery bifurcation presenting with acute lower extremity ischemia).
- The extent of bowel ischemia and/or infarction after an embolus to the superior mesenteric artery is contingent on the extent of the collateral circulation, the pattern of the arterial occlusion, and the duration of the ischemia.
- In AMI, the bowel progresses from ischemia to infarction in a time-dependent fashion, although it may remain viable for 6 to 12 hours.
- Acute embolic occlusion of the superior mesenteric usually results in ischemia/infarction of the bowel from the proximal jejunum to the transverse colon. The duodenum and descending colon are usually spared due to separate arterial sources.

Clinical Presentation

- The diagnosis of AMI from an embolus (or other causes of AMI) may be difficult. The differential list of diagnoses includes all the more common causes of acute abdominal pain.
- The diagnosis is confounded by the fact that the patients are often critically ill, and thus, their history and physical examination may not be reliable.
- Diagnosis requires a high index of suspicion and an aggressive approach since delays in diagnosis adversely affect outcome.
- Patients with AMI from an embolus usually present with diffuse abdominal pain. The classic description of the pain secondary to AMI is **pain out of proportion to the physical findings**, although this scenario is not always present.
- Unfortunately, the pain is neither specific nor localized to a particular abdominal quadrant.
- Patients often experience nausea/vomiting and/or diarrhea, but again these are fairly nonspecific complaints.
- Peritoneal signs can be present, but they usually occur late in the process and suggest bowel perforation.
- The hemodynamic status of the patients at the time of presentation ranges from normovolemia to profound hypovolemic shock and is contingent on the status of the bowel and the duration of symptoms.

Laboratory Testing and Diagnostic Studies

- Routine chemistry and hematologic laboratory studies are usually nonspecific and insensitive. Patients frequently have an elevated white blood cell count, a decreased platelet count, an elevated hematocrit, and a mildly elevated amylase level.
- Patients with AMI frequently have either normal plain radiographs or demonstrate nonspecific findings (e.g., ileus) early in the disease process.
- **CT arteriography** is the diagnostic study of choice for patients with AMI secondary to an embolus. Notably, the study is performed using only intravenous contrast since both oral and rectal contrast potentially interfere with the arteriogram itself.
- In patients with AMI secondary to an embolus, a meniscus sign can often be seen in the mid- or distal superior mesenteric artery.
- The images obtained during CT arteriography are also excellent for the nonvascular structures. Significant nonvascular findings of AMI include bowel wall thickening, bowel wall gas, bowel or solid organ infarction, and hepatic or portal venous gas;
- Mesenteric duplex, although an excellent screening test for CMI, is not usually helpful in patients with AMI due to abdominal distention or gas.
- Standard contrast arteriography can be used as an alternative to CT arteriography. Major disadvantages are the obligatory time required to obtain the procedure and the small, but finite, complications associated with the contrast agent and vessel cannulation.
- **Laparoscopy** offers an additional diagnostic modality for patients with AMI. It can be used to assess the viability of the bowel and confirm the diagnosis. Furthermore, it can be performed in the intensive care unit with sedation and, therefore, is feasible for unstable patients with a suspected intra-abdominal process.
- Laparotomy remains the definitive diagnostic test for patients with AMI. However, the diagnostic studies outlined above are usually sufficient.

Treatment Strategies

- Patients should be taken emergently to the operating room for definitive treatment once the diagnosis of AMI from an embolus is made.
- Patients should be systemically **anticoagulated** with heparin to prevent further clot development and started on broad-spectrum **antibiotics** against enteric organisms.
- An extensive preoperative evaluation is unnecessary and may delay urgent and definitive therapy. There is no role for medical management alone in the setting of embolic AMI.
- Patients with AMI are frequently in shock and should be volume resuscitated prior to the induction of anesthesia. This should not delay transfer to the operating room.
- Both midline and transverse abdominal incisions provide adequate exposure to the visceral vessels, and the choice is contingent on surgeon preference.
- A distribution of ischemic/infarcted bowel that extends from the **proximal jejunum to the transverse colon** is consistent with a diagnosis of AMI. Intraoperative interrogation of the visceral vessels with continuous wave Doppler may further substantiate the diagnosis.

- The embolus may be extracted from the superior mesenteric artery using a Fogarty **thromboembolectomy catheter** through various surgical approaches.
- The easiest approach to the superior mesenteric artery is to incise the base of the transverse mesocolon after retracting the transverse colon itself cephalad.
- The arteriotomy in the superior mesenteric artery may be performed either longitudinally or horizontally. Although the longitudinal arteriotomy needs to be closed with a vein patch to prevent narrowing its lumen, it is the preferred approach because it affords greater flexibility in case a bypass procedure is necessary.
- The differentiation between viable and nonviable bowel is difficult. Various complicated modalities have been described but have not been universally adopted. Simple adjuncts include visual inspection for peristalsis, use of continuous wave Doppler to detect arterial signals within the mesentery, and intravenous fluorescein in combination with a Wood lamp.
- Bowel that is ischemic though not frankly necrotic should be revascularized and then reexamined before any final decision about resection. A conservative approach is justified in this setting because many of the borderline areas will remain viable after revascularization.
- Bowel that is obviously dead should be resected, and intestinal anastomoses should be avoided in favor of proximal and distal stomas.
- Approximately **100 to 150 cm** of small bowel is necessary for nutritional absorption.
- A decision to perform a **second-look operation** to reassess the viability of the bowel should be made at the time of the initial procedure. This is routinely performed 24 to 48 hours after the first procedure, a time usually sufficient for the marginal bowel to declare itself.
- A **“damage control” operation** may be justified in a small subset of unstable patients with AMI. This includes emergent laparotomy, resection of obviously dead bowel, and creation of proximal or distal stomas, leaving the abdomen open and deferring the definitive vascular or gastrointestinal procedure until later.
- Despite its definitive role for patients with CMI, there is likely little role for endovascular therapies in patients with AMI secondary to an embolus. The obligatory time for endovascular treatment, including chemical lysis, is too long given the threatened bowel and the potential to progress from ischemic bowel to infarcted bowel. Furthermore, it does not allow direct assessment of the bowel, and the chemical lysis may cause intestinal bleeding from mucosal sloughing.
- The postoperative course after embolectomy for AMI is similar to that after revascularization for CMI, although the incidence of postoperative complications and multiple organ dysfunction are greater.
- Revascularization may cause an ischemia or reperfusion injury that affects both local and distant organ systems. Accordingly, patients are at risk for developing an abdominal compartment syndrome. Bladder pressures can be measured, and the abdomen closure can be dissembled as necessary.
- Patients should be continued on broad-spectrum antibiotics throughout the early postoperative period. Furthermore, they need to be anticoagulated long term due to the potential for recurrent emboli.

Outcome

- The **mortality rate** for patients with AMI is approximately **70%**, and this rate has changed very little over the past several decades.
- Mortality rates for AMI from mesenteric venous thrombosis (32%) are better than those for arterial problems (54% to 77%) and the mortality rates for mesenteric emboli (54%) are better than those for *in situ* thromboses (77%). Most are due to multiple organ failure.
- Several factors associated with mortality are patient age, time to definitive surgery, shock, acidosis, leukocytosis, cardiac status, and coagulopathy.

In Situ Thrombosis

- Patients with visceral artery occlusive disease may also present with AMI secondary to *in situ* thrombosis.
- The presentation is **superimposed on the symptoms of CMI** in more than 50% of the patients and can usually be differentiated from the other causes of AMI by the history and clinical setting.
- The clinical presentation, diagnostic approach, and immediate postoperative care of patients with AMI secondary to *in situ* thrombosis is similar to that outlined above for embolic AMI, although the operative approach is somewhat different.
- Patients with AMI secondary to *in situ* thrombosis require a **mesenteric bypass**. Although antegrade aortoceliac/superior mesenteric artery bypass is probably the optimal bypass for CMI, retrograde bypass from the infrarenal aorta or common iliac artery is likely the optimal procedure for AMI.
- The main objective is to restore blood flow to the ischemic vascular bed as safely and expeditiously as possible. This usually requires only bypass to the superior mesenteric artery.
- Patients with isolated celiac axis stenosis rarely develop AMI because the **collateral blood flow** to the foregut is so good and the liver may be sustained on portal blood flow alone.
- Prosthetic conduits are relatively contraindicated in the setting of bowel infarction and/or perforation due to the potential for postoperative graft infection. Autogenous conduits with either saphenous or superficial femoral vein are suitable.
- The role of endovascular treatment for patients with AMI secondary to *in situ* thrombosis is likely limited for the reasons noted above for AMI secondary to an embolus.
- An appropriate imaging study (i.e., CT arteriogram, contrast arteriogram) should be obtained in the early postoperative period and the necessary treatment including anticoagulation and revascularization implemented in a timely fashion.

Nonocclusive Mesenteric Ischemia

Pathophysiology

- **Nonocclusive mesenteric ischemia** represents an abnormal or paradoxical mesenteric **vasoconstriction** characterized by the loss of autoregulation. Shock or circulatory stress normally causes mesenteric vasoconstriction in an attempt to maintain cerebral and/or cardiac perfusion. The mesenteric vasoconstriction ordinarily resolves when the underlying circulatory disorders are corrected; persistent vasoconstriction results in NOMI.
- There are multiple potential causes for NOMI, including cardiogenic shock, sepsis, burn injury, trauma, pancreatitis,

digitals, vasopressors, and renal failure. Indeed, almost any underlying condition that can precipitate shock or circulatory stress may precipitate NOMI.

Clinical Presentation and Diagnosis

- Similar to the other causes of AMI, the diagnosis of NOMI requires a high index of suspicion and the proper clinical setting.
- Patients may develop abdominal pain, although the physical examination is frequently unreliable due to the other active medical issues and altered sensorium.
- Laboratory abnormalities are common, including acidosis, leukocytosis, elevated lactate levels, and hyperamylasemia, but these are all relatively nonspecific markers of the underlying shock state.
- Contrast **arteriography** has traditionally been the diagnostic study of choice and is also potentially therapeutic. The significant findings on arteriogram for patients with NOMI include segmental stenosis or narrowing of the superior mesenteric artery in a **string-of-beads** appearance. Furthermore, there is narrowing of the branches of the superior mesenteric artery at their origins, spasm of the mesenteric arcades, and impaired filling of the intramural branches.
- The published experience with CT arteriography in the setting of NOMI is limited, although it likely affords the same advantages as contrast arteriography with fewer risks.

Treatment Strategies

- The initial treatment of patients with NOMI is **nonoperative** and directed at correcting the underlying condition that precipitated the circulatory stress. Specifically, patients should be resuscitated in an attempt to improve their **cardiac output** and systemic perfusion.
- All vasoactive drugs should be stopped (if possible), and patients should be started on broad-spectrum antibiotics directed against enteric organisms. Furthermore, patients should be systemically anticoagulated unless contraindicated.
- Despite these efforts, the characteristic mesenteric vasoconstriction may persist. Continuous intra-arterial papaverine, administered through an infusion catheter placed into the superior mesenteric artery, may reverse the vasoconstriction. A 45-mg test dose of **papaverine** (i.e., short-acting calcium channel blocker) should be given over 15 minutes, and a continuous infusion of 30 to 60 mg/hour should be started if no adverse reactions are encountered.
- **Serial mesenteric arteriograms** should be performed to monitor the response to the papaverine, with the first performed 1 hour after initiating therapy. The intra-arterial infusion may be continued up to 24 hours. It should be noted that the infusion will reverse the mesenteric vasoconstriction only if the underlying hemodynamic instability is corrected.
- Operative treatment of NOMI should be reserved only for the clinical scenario when bowel infarction is suspected.

Mesenteric Venous Thrombosis

Pathophysiology

- Mesenteric venous thrombosis may also result in AMI. However, the associated degree of bowel ischemia is usually less

than with arterial occlusion from either an embolus or *in situ* thrombosis.

- Mesenteric venous thrombosis results in **edema in the bowel and mesentery** with significant third-space fluid losses. This may result in bloody ascites and, indeed, a bloody tap at the time of paracentesis may be diagnostic.
- Progression to bowel infarction is contingent on the magnitude of the clot load and its distribution. Clot localized to the portal or superior mesenteric vein does not usually lead to bowel infarction because of the collateral channels, whereas clot in the peripheral mesenteric veins is more likely to do so.
- The natural history of untreated mesenteric venous thrombosis is poor and almost universally progresses from bowel infarction to perforation and death.
- Mesenteric venous thrombosis may result from abnormalities in any of the components of the **Virchow triad** (i.e., stasis, intimal injury, hypercoagulable state). Stasis may result from congestive heart failure or portal hypertension, whereas intimal injury may result from general anesthesia or any number of intra-abdominal infectious processes. A hypercoagulable state is perhaps the strongest of the contributory factors and has been identified in up to 90% of patients with mesenteric venous thrombosis.

Clinical Presentation and Diagnosis

- Patients with mesenteric venous thrombosis usually present with **vague, mild abdominal pain**. The pain is usually insidious in onset and frequently present for some time before the patients seek medical attention. Furthermore, the pain is not usually localized to any specific quadrant.
- Physical examination is notable only for mild, diffuse abdominal pain. Peritoneal signs suggest bowel infarction, but are found only later in the disease process.
- An **abdominal CT scan** is the diagnostic study of choice. The significant findings include bowel edema and thrombus within the mesenteric veins with inflammation of the vessel wall.
- Plain abdominal radiographs may suggest abdominal wall edema and are helpful to rule out other causes of the abdominal pain.
- Standard catheter-based contrast arteriography may be helpful but is inferior to CT. The arteriographic findings that suggest mesenteric venous thrombosis include arterial spasm with a prolonged arterial phase, opacification of the bowel wall, extravasations of the contrast into the bowel lumen, and visualization of the venous thrombus.

Treatment Strategies

- The primary treatment of patients with mesenteric venous thrombosis is **anticoagulation**. Patients should be aggressively anticoagulated with heparin when the diagnosis is made and should be maintained on long-term oral anticoagulation.
- Similar to patients with massive iliofemoral deep venous thrombosis, it may be difficult to achieve effective anticoagulation initially using the standard dosing schedules for heparin, presumably secondary to the clot burden.
- Larger doses of heparin may be required, and the adequacy of heparinization (e.g., partial thromboplastin time) may need to be monitored more frequently.
- Although the required dosage of heparin may be unsettling, the potential clot propagation and its associated complications likely exceed any increased risk from bleeding.

- A **hypercoagulable workup** for the standard hematologic abnormalities should be performed prior to initiation of anticoagulation. However, long-term anticoagulation should be continued even in the absence of an *identifiable* hypercoagulable state since it is likely that many of these patients have some type of hypercoagulable disorder even though it may not be characterized on initial screening.
- Additionally, patients frequently require fluid resuscitation at the time of diagnosis due to the significant third-space losses from the bowel edema.
- Exploratory laparotomy should be reserved for cases in which bowel infarction is suspected. The intraoperative findings include edematous/rubbery bowel, bloody ascites, and thrombus within the mesentery.
- A wide resection of the bowel should be performed in the presence of infarction. Primary enteric anastomosis is probably safe if the margins of resection are free of thrombus within the mesentery. Proximal and distal stomas are advisable if the viability of the bowel at the margins of resection is questionable.
- Patients are at risk for additional or ongoing thrombosis with the most common site being the margins of the resection and/or the anastomosis. Mechanical thrombectomy is not advocated at the time of laparotomy because of the extensive clot burden.
- Endovascular treatment including chemical lysis likely has a limited role for patients with mesenteric venous thrombosis despite several case reports.

Outcome

- The mortality rate (~30%) for mesenteric venous thrombosis is significantly less than for the arterial causes of AMI.
- Death has been associated with portal vein thrombosis, systemic venous thromboembolism, and obesity. The increased mortality rate associated with venous thromboembolism underscores the importance of early, adequate anticoagulation.

Aortic Dissection

- Patients with acute aortic dissection can present with visceral malperfusion and AMI.
- The presence of visceral malperfusion significantly increases the mortality rate. Various endovascular approaches have been used to treat the visceral malperfusion in this setting.
- Endovascular revascularization is probably superior to the open approach provided the patients are candidates from an anatomic and technical standpoint.

COLON ISCHEMIA

- Isolated **colon ischemia** can occur after both open and endovascular aneurysm repair. Furthermore, it can develop as a complication of hemodynamic shock, similar to NOMI.

- Ischemic colitis has been reported to occur in approximately 2% to 13% of open aneurysm repairs. The reported incidence depends on the diagnostic algorithm and modality (routine sigmoidoscopy vs. selective sigmoidoscopy) and is dramatically increased after ruptured aneurysm repair.
- The incidence of colonic ischemia after ruptured aneurysm repair in patients undergoing routine colonoscopy is approximately 25% to 40%.
- The sigmoid colon is affected most frequently, although all the sections of the colon may be involved.
- The ischemia may result from inadequate resuscitation, disruption of collaterals, and/or failure to revascularize a hemodynamically significant inferior mesenteric artery.
- Interestingly, routine reimplantation of the inferior mesenteric artery at the time of aortic reconstruction does not prevent colon ischemia.
- The ischemic colitis associated with endovascular aneurysm repair is more commonly related to atheroembolism rather than acute internal iliac artery occlusion, as might be suspected. The prognosis for ischemic colitis after endovascular aneurysm repair is worse than that for open repair.
- Patients with ischemic colitis usually present with **bloody diarrhea** in contrast to patients with AMI who usually present with abdominal pain.
- In the most common scenario, patients develop bloody diarrhea on the first or second postoperative day after aortic reconstruction. However, the diagnosis should be considered after aortic reconstruction in the absence of bloody diarrhea in patients with thrombocytopenia, multiple-organ dysfunction, increasing abdominal pain/peritonitis, and generalized failure to thrive.
- The diagnosis may be confirmed by endoscopy. Although **sigmoidoscopy** is used most frequently, a complete colonoscopy is likely optimal due to the potential involvement of the other colon segments.
- Treatment depends on the endoscopic findings and clinical setting. The endoscopic findings range from mucosal ischemia to transmural necrosis. Unfortunately, it is often difficult to differentiate diffuse mucosal ischemia from transmural necrosis.
- Patients with mucosal ischemia alone should be treated with bowel rest, broad-spectrum antibiotics, total parenteral nutrition, and serial endoscopic examinations.
- Many of these lesions resolve spontaneously without long-term sequelae, although colonic strictures may develop in a small subset of patients. Patients with **transmural colonic necrosis** should undergo laparotomy with resection of the involved segment, a proximal diverting colostomy, and a distal Hartmann pouch.
- The reported mortality rate in patients with transmural colon necrosis after aortic reconstruction is ~85%.
- Maintaining antegrade flow through the internal iliac vessels, routinely implanting the inferior mesenteric artery, and preserving the colonic collateral circulation may reduce or prevent this adverse outcome.

CHAPTER 111 ■ ACUTE RENAL FAILURE (ARF)

- ARF is a major diagnostic and therapeutic challenge for critical care physicians.
- *Acute renal failure* describes a syndrome characterized by rapid decrease in the kidney's ability to eliminate waste products.
 - Hours to days
- Clinically manifested by accumulation of end products of nitrogen metabolism
 - Such as urea and creatinine
- Other typical clinical manifestations include:
 - Decreased urine output (not always present)
 - Accumulation of nonvolatile acids
 - Increased concentration of potassium and phosphate

DEFINITION AND CLASSIFICATION OF ARF

- Depending on definition of presence
- ARF reported in 5% to 25% of critically ill patients
- Consensus definition and classification for ARF developed and validated in hospitalized and critically ill patients
 - Goes by the acronym of *RIFLE*
 - Divides renal dysfunction into the categories of risk, injury, and failure (Fig. 111.1)
 - Likely to be dominant approach to defining ARF in intensive care unit (ICU) for next 5 to 10 years
 - Using this classification incidence of at least some degree of renal dysfunction reported as high as 67%
 - Development of renal dysfunction with a maximum RIFLE category failure has been reported in up to 28% of critically ill patients
 - Associated with an increased risk of in-hospital death by several fold

ASSESSMENT OF RENAL FUNCTION

- Renal function involves:
 - Acid-base balance
 - Water balance
 - Tonicity control
 - Regulation of calcium and phosphate
 - Erythropoiesis
 - Disposal of some cytokines
 - Lactate removal
- In clinical context monitoring of renal function reduced to indirect assessment of glomerular filtration rate (GFR) by measurement of serum creatinine and urea
 - Waste products insensitive markers of GFR
 - Heavily modified by numerous factors such as age, gender, muscle mass, nutritional status, the use of steroids, the presence of gastrointestinal blood, or muscle injury

- Generally start becoming abnormal only when GFR is reduced by more than 50%
 - Thus fail to reflect dynamic changes in GFR
 - Can be grossly modified by aggressive fluid resuscitation
- Use of creatinine clearance via a 2- or 4-hour urine collection or of calculated clearance by means of formulae might increase accuracy of GFR estimation
 - Rarely changes clinical management
- Use of more sophisticated radionuclide-based tests cumbersome in the ICU
 - Useful only for research purposes
- Urine output (UOP) another commonly measured parameter of renal function
 - Often more sensitive to changes in renal hemodynamics than biochemical markers of solute clearance
 - Alone of limited value
 - Patients capable of developing severe ARF while maintaining normal UOP
 - *Nonoliguric ARF*

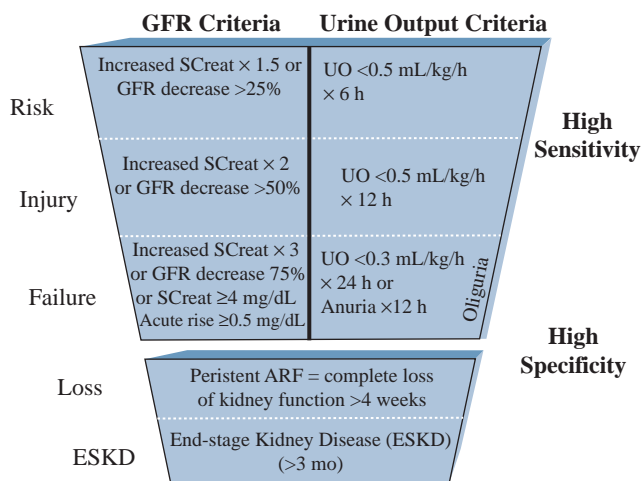

FIGURE 111.1. RIFLE (Risk, Injury, Failure, Loss, End-stage) classification scheme for acute renal failure. The classification system includes separate criteria for creatinine and urine output. The criteria that lead to the worst possible classification should be used. Note that RIFLE-F (F = failure) is present even if the increase in serum creatinine concentration (SCreat) is less than threefold so long as the new SCreat is >4.0 mg/dL ($350 \mu\text{mol/L}$) in the setting of an acute increase of at least 0.5 mg/dL ($44 \mu\text{mol/L}$). The designation RIFLE-FC should be used in this case to denote acute-on-chronic disease. Similarly when RIFLE-F classification is reached by urine output criteria only, a designation of RIFLE-FO should be used to denote oliguria. The shape of the figure denotes the fact that more patients (high sensitivity) will be included in the mild category, including some without actually having renal failure (less specificity). In contrast, at the bottom, the criteria are strict and therefore specific, but some patients with renal dysfunction might be missed. GFR, glomerular filtration rate; ARF, acute renal failure; UO, urine output.

- As this has lower mortality rate than oliguric ARF
- UOP is frequently used to differentiate ARF
- Oliguria defined approximately as UOP <5 mL/kg/day or 0.5 mL/kg/hour
- RIFLE classification has incorporated oliguria as an important measure for categories of severity of ARF (see Fig. 111.1)

EPIDEMIOLOGY

- Some acute renal injury demonstrated in most ICU patients; manifested by:
 - Albuminuria or loss of small tubular proteins
 - Inability to excrete a water, sodium, or amino acid load
 - Any combination of the above
- Syndrome of ARF occurs in 5% to 8% of all hospitalized patients
 - Incidence greater in ICU patients
 - Occurs in 5% to 25%, depending on definition and specific population studied
 - Incidence and mortality of ARF may be increasing
 - May be attributable to major shift from single-organ ARF to the multiorgan dysfunction syndrome typically seen in ICU patients
- Risk factors for ARF in ICU patients include:
 - Older age
 - Male gender
 - Preexisting comorbid illness
 - Diagnosis of sepsis
 - Major surgery
 - Specifically cardiac surgery
 - Cardiogenic shock
 - Hypovolemia
 - Exposure to nephrotoxic drugs
 - Multiorgan dysfunction—specifically concomitant acute circulatory, pulmonary, and hepatic organ dysfunction—commonly associated with ARF

APPROACH TO CLINICAL CLASSIFICATION

- Most practical and useful approach to the etiologic diagnosis of ARF is to divide causes according to probable source of renal injury:

- Prerenal
- Renal (parenchymal)
- Postrenal

Prerenal Failure

- By far the most common in the ICU
- Kidney malfunctions predominantly because of systemic factors that decrease GFR
 - Renal blood flow (RBF) is diminished by:
 - Decreased cardiac output
 - Hypotension
 - Raised intra-abdominal pressure
 - Suspected on clinical grounds
 - Confirmed by measuring bladder pressure with a urinary catheter
 - Pressure > 25 to 30 mm Hg above the pubis prompts consideration of decompression
- If systemic cause of renal failure rapidly removed or corrected
 - Renal function improves and relatively rapidly returns to near normal levels
- If intervention is delayed or unsuccessful, renal injury becomes established
 - Days or weeks then necessary for recovery
- Several tests promoted to help identify development of established ARF
 - Measurement of urinary sodium
 - Fractional excretion of sodium, and other derived indices
 - Accuracy and significance questionable (Fig. 111.2)
 - Clinical value of tests in ICU patients receiving vaso-pressors, massive fluid resuscitation, and loop diuretics is low
 - Prerenal ARF and established ARF part of a continuum and that their separation has limited clinical implications
- Principles of management essentially the same:
 - Treatment of cause
 - Promptly resuscitating patient by using invasive hemodynamic monitoring to guide therapy

Parenchymal Renal Failure

- Used to define a syndrome where principal source of damage is within the kidney

FIGURE 111.2. Histogram showing the effect of experimental sepsis in sheep on the fractional excretion of sodium (FeNa). FeNa decreased in sepsis as would be expected during decreased perfusion. In fact, all experimental animals had a two- to threefold increase in renal blood flow, providing proof of the concept that FeNa cannot be used to infer renal hypoperfusion.

TABLE 111.1**CAUSES OF PARENCHYMAL ARF**

Glomerulonephritis
 Vasculitis
 Renovascular
 Interstitial nephritis
 Nephrotoxins
 Tubular deposition/obstruction
 Renal allograft rejection
 Trauma

- Typical structural changes seen on microscopy
- Numerous disorders affecting the glomerulus or the tubule responsible (Table 111.1)
 - Nephrotoxins particularly important (Table 111.2)
 - Many cases of drug-induced ARF rapidly improve on removal of offending agent
- More than a third of patients developing ARF in ICU have chronic renal dysfunction, due to:
 - Age-related changes
 - Longstanding hypertension
 - Diabetes mellitus
 - Atheromatous disease of renal vessels
- Chronic renal disease may be manifest by an elevated serum creatinine
 - Not always the case
 - What may seem a relatively trivial insult not fully explaining the onset of ARF in a normal patient is sufficient to unmask lack of renal functional reserve in patient with chronic renal disease

Postrenal Failure

- Obstruction to urine outflow:
 - The most common cause of functional renal impairment in the community
 - Uncommon in the ICU
- Pathogenesis of obstructive ARF involves humoral responses as well as mechanical factors
 - Typical causes of obstructive ARF include:
 - Bladder neck obstruction from an enlarged prostate

TABLE 111.2**DRUGS THAT MAY CAUSE ACUTE RENAL FAILURE IN THE INTENSIVE CARE UNIT**

Radiocontrast media
 Aminoglycosides
 Amphotericin
 Nonsteroidal anti-inflammatory drugs
 β -Lactam antibiotics (interstitial nephropathy)
 Sulphonamides
 Acyclovir
 Methotrexate
 Cisplatin
 Cyclosporin A
 FK-506 (tacrolimus)
 Sirolimus

- Ureteric obstruction from pelvic tumors or retroperitoneal fibrosis
- Papillary necrosis
- Large calculi
- Clinical presentation of obstruction:
 - May be acute or chronic in patients with longstanding renal calculi
 - May not always be associated with oliguria
 - If obstruction is suspected, ultrasonography can be easily performed at the bedside
 - Not all cases of acute obstruction have an abnormal ultrasound.
 - In many cases, obstruction occurs in conjunction with other renal insults:
 - Staghorn calculi
 - Severe sepsis of renal origin
 - Sudden and unexpected development of anuria in an ICU patient suggests obstruction of urinary catheter as the cause.
 - Flushing or changing of catheter should be implemented in this setting

PATHOGENESIS OF SPECIFIC SYNDROMES**Hepatorenal Syndrome (HRS)**

- A form of ARF that typically occurs in setting of advanced cirrhosis
 - Can occur with severe liver dysfunction due to alcoholic hepatitis or other forms of acute hepatic failure
- Pathogenesis of HRS is incompletely understood
 - Several potential mechanisms may contribute to HRS, including:
 - Activation of renin-angiotensin system in response to systemic hypotension
 - Activation of sympathetic nervous system in response to systemic hypotension and increased intrahepatic sinusoidal pressure
 - Increased release of arginine vasopressin due to systemic hypotension
 - Reduced hepatic clearance of various vascular mediators such as endothelin, prostaglandins, and endotoxin
- HRS can occur spontaneously in patients with advanced cirrhosis
 - Other precipitants more common
 - Sepsis—specifically, spontaneous bacterial peritonitis (SBP)
 - Raised intra-abdominal pressure due to tense ascites
 - Gastrointestinal bleeding
 - Hypovolemia due to paracentesis, diuretics and/or lactulose administration
 - Any combination of these factors
 - Other contributing factors for ARF should be routinely ruled out, including:
 - Cardiomyopathy due to alcoholism
 - Nutritional deficiencies
 - Viral infection
 - Exposure to nephrotoxins

- Typically, HRS develops in patients with advanced cirrhosis and evidence of portal hypertension with ascites, absent other apparent causes of ARF
- Generally presents as oligoanuria, with progressive increases in serum creatinine and/or urea, along with bland urinary sediment
- These patients develop profound sodium and water retention, with evidence of hyponatremia, a urine osmolality higher than that of plasma, and a very low urinary sodium concentration (<10 mmol/L)
- Management is challenging and includes:
 - Systematic identification and treatment of potential reversible precipitants
 - Attenuation of hypovolemia by albumin administration in patients with SBP shown to decrease incidence of ARF
 - Vasopressin derivatives (terlipressin) may improve GFR in this condition
 - Placement of a transjugular intrahepatic, portosystemic shunt (TIPS) associated with modest improvements in kidney function in HRS
 - As well as improvement in outcome
 - Palliative measure for those who are not candidates or awaiting transplant
 - Treatment for reversal of ARF in these patients is to improve hepatic function with therapy for the underlying primary liver disease and/or referral for successful liver transplantation

ARF with Rhabdomyolysis

- Incidence of rhabdomyolysis-induced ARF estimated at 1% in hospitalized patients
- In critically ill patients, may account for close to 5% to 7% of cases of ARF
- Pathogenesis involves interplay of prerenal, renal, and postrenal factors, including:
 - Concurrent hypovolemia
 - Ischemia
 - Direct tubular toxicity mediated by the heme pigment in myoglobin
 - Intratubular obstruction
- Causes of muscle injury resulting in rhabdomyolysis include:
 - Major trauma
 - Drug overdose such as occurs with narcotics, cocaine, or other stimulants
 - Vascular embolism
 - Prolonged seizures
 - Malignant hyperthermia
 - Neuroleptic malignant syndrome
 - Various infections such as pyomyositis, necrotizing fasciitis, influenza, human immunodeficiency virus (HIV)
 - Severe exertion
 - Alcoholism
 - Result of various agents that can interact to induce major muscle injury, such as the combination of macrolide antibiotics or cyclosporin and statins
- Clinical manifestations of rhabdomyolysis include:
 - Elevated serum creatine kinase
 - Evidence of pigmented granular casts
 - Red-to-brown coloring of the urine
- Patients can also have various electrolyte disorders including:
 - Hyperphosphatemia
 - Hyperkalemia
 - Hypocalcemia
 - Hyperuricemia
- Principles of prevention of ARF include:
 - Identification and elimination of potential causative agents and/or correction of underlying compartment syndromes
 - Prompt and aggressive fluid resuscitation and maintenance of polyuria
 - ≥ 1.5 to 2 mL/kg ideal or adjusted body weight/hour
 - Usually more than about 300 mL/hour
 - To restore vascular volume and potentially flush obstructing cellular casts
 - Urine alkalinization to a goal of pH >6.5
 - To reduce renal toxicity by myoglobin-induced lipid peroxidation and improve the solubility of myoglobin
 - Mannitol may act as a scavenger of free radicals and reduce cellular toxicity
 - Role of forced diuresis with mannitol controversial

ARF Due to Nephrotoxins

- Alterations in intrarenal hemodynamics is an important initial consequence of many nephrotoxins.
- Changes to regional renal blood flow may occur through the increased activity of local vasoconstrictors such as angiotensin II, endothelin, adenosine.
- Also diminished activity of important vasodilators such as nitric oxide and prostaglandins
 - Imbalance can lead to renal vasoconstriction and ischemia
 - Particularly to susceptible regions such as the outer medulla
 - For example, in response to radiocontrast media
 - Imbalance can induce humorally mediated vasoconstriction of afferent arterioles
 - For example, as a result of exposure to nonsteroidal anti-inflammatory drugs and cyclosporine
 - End result of a reduction in regional blood flow is a critical reduction in oxygen delivery, thus predisposing to tubular hypoxia
- Additionally nephrotoxins can directly contribute to impaired tubular metabolism and oxygen usage, for example, after exposure to aminoglycosides.
 - Lead to generation of oxygen-free radical species, including superoxide anions, hydrogen peroxide, hydroxyl radicals, reduced intrinsic antioxidant enzyme activity, intracellular calcium accumulation, mitogen-activated protein kinases, and phospholipase A₂
- Responses to nephrotoxins can induce tubular cell vacuolization, interstitial inflammation, altered cell membrane properties, and disruption of normal tubular adhesion to basement membranes.
 - Failure of these mechanisms contributes to tubular cell apoptosis and necrosis, as well as tubular sloughing into the luminal space, cast formation, and obstruction.
 - Raised intraluminal pressures due to obstruction, altered cellular permeability, and interstitial inflammation can contribute to backup diffusion of fluid and secondary edema formation.

- Radiocontrast media and aminoglycosides are leading agents contributing to nephrotoxin-induced ARF.
- Radiocontrast media-induced toxicity believed to occur from interplay of alterations in renal hemodynamics due to vasoconstriction, increased intravascular viscosity and erythrocyte aggregation, direct tubular epithelial cell toxicity, and concomitant atheroembolic microshowers in the renovasculature
- Aminoglycosides are taken up via organic anion transport systems in proximal tubules where they accumulate and generate oxygen-free radical species and increased intracellular calcium, which lead to tubular apoptosis, necrosis, and nonoliguric ARF.

Radicontrast Nephropathy

- The leading cause of iatrogenic ARF in hospitalized patients
 - Results in prolonged hospitalization, higher mortality rates, excessive health care costs, and potentially long-term kidney impairment
 - Presents with acute rise in serum creatinine within 24 to 48 hours following injection of radiocontrast media
 - Serum creatinine level generally peaks within 3 to 5 days
 - Returns toward baseline within 7 to 10 days
 - In some patients, kidney function may not return to baseline, and a persistent reduction in function may occur.
 - Often associated with preexisting risk factors:
 - Preexisting chronic kidney disease
 - $\text{GFR} < 60 \text{ mL/minute/1.73 m}^2$
 - Diabetes mellitus
 - Use of large quantities of radiocontrast media
- Strategies for prevention include:
 - Early identification of patients at risk and consideration either to delay the investigation or to use an alternative modality until kidney function can be optimized
 - Every effort should be made to correct volume depletion and discontinue potential nephrotoxins.
 - No evidence to support routine use of diuretics, mannitol, or dopamine
 - Periprocedure hydration and use of nonionic iso-osmolar (for example, iodixanol) radiocontrast media can reduce risk
 - Randomized trials and meta-analyses suggest potential benefit with use of *N*-acetylcysteine

Septic ARF

- Sepsis a leading predisposing factor to ARF in critically ill patients
- Epidemiologic studies estimate 45% to 70% of all ARF encountered in ICU is associated with sepsis
 - Distinction between septic and nonseptic ARF may have particular clinical relevance
 - Considering recent evidence to suggest that septic ARF may be characterized by a unique pathophysiology
 - Classic teaching is:
 - Sepsis brings about hypotension, reducing critical organ blood flow, including to the kidney, causing ischemic injury and ARF
 - Additionally sepsis leads to activation of sympathetic nervous system, stimulating potent vasoconstrictors release

that induce renal vasoconstriction and aggravate kidney ischemia, thus worsening ARF

- Recent data raise serious questions about this ischemic-induced paradigm of septic ARF.
 - A large mammalian model of hyperdynamic sepsis found that RBF was markedly increased above baseline despite significant reductions in kidney excretory function.
 - Small clinical studies of resuscitated patients with septic ARF also show increases in RBF.
 - Implications are that in hyperdynamic sepsis, ARF is hyperemic rather than ischemic, with global RBF considerably increased.
 - Regional cortical and medullary RBF is preserved in sepsis and can be further augmented by infusion of norepinephrine.
 - Evolving evidence suggests pathogenesis of septic ARF predominantly involves toxic and immune-mediated mechanisms.
 - Sepsis releases a vast array of proinflammatory and anti-inflammatory mediators such as cytokines, arachidonic acid metabolites, and thrombogenic agents, all of which may participate in the development of ARF.
 - Evidence of renal tubular cell apoptosis in response to inflammatory mediators in endotoxemia
 - May prove to be an important mechanism of septic ARF in critically ill patients
 - Interventions with antiapoptotic properties such as:
 - Intensive insulin therapy
 - Human recombinant activated protein C
 - Selective caspase inhibitors
 - May aid in attenuating renal injury and promote recovery of function

ARF in Association with Major Surgery

- Common complication following major surgery:
 - Incidence variable and dependent on prevalence of preexisting comorbid illnesses, preoperative kidney function, and the type and urgency of surgery being performed
 - Intraoperative events can negatively affect kidney function, including:
 - Hemodynamic instability (e.g., intravenous or inhaled anaesthetic agents)
 - Hypovolemia due to blood loss or third spacing
 - Details of the operative field (e.g., aortic cross-clamping in major vascular surgery)
 - Increases in intra-abdominal pressure (e.g., laparoscopic insufflation of CO_2)
 - Concomitant sepsis
 - Use of nephrotoxin drugs
 - Alone or in combination these contribute to critical reduction in RBF and ischemia, impaired oxygen delivery, and toxin- or inflammatory-mediated injury.
 - Postoperative ARF believed partly mediated by proinflammatory mechanisms:
 - Increased endothelial cell adhesion
 - Tubular cell infiltration
 - Generation of reactive oxygen species and proinflammatory cytokines
 - Reperfusion injury

- Cardiac surgery with cardiopulmonary bypass (CPB) commonly induces early postoperative renal injury.
- Mechanisms of CPB injury incompletely understood
 - Suggestion that CPB is proinflammatory, activating components of the nonspecific immune system
 - Leads to oxidative stress with the generation of oxygen-free radical species and serum lipid peroxidation products
 - CPB shown to deplete serum antioxidative capacity for a prolonged duration after surgery
 - Oxidant stress directly induces renal injury in experimental studies

ARF in Association with Mechanical Ventilation (MV)

- Application of positive pressure MV, particularly with positive end-expiratory pressure (PEEP), can have important physiologic effects on kidney function.
- Clear association between MV and PEEP and alterations in kidney function
- Can occur through several mechanisms including:
 - Alterations in cardiovascular function
 - Alterations in neurohormonal activation
 - Abnormalities in gas exchange
 - Alterations in systemic inflammatory mediators
- Positive pressure during MV increases intrathoracic, intrapleural, and intra-abdominal pressures.
 - During inspiration and for the duration of the respiratory cycle
 - Increased intrathoracic pressure can reduce intrathoracic blood volume, decrease transmural pressure, reduce right ventricular preload, increase right ventricular afterload, exert alterations to pulmonary vascular resistance and volume, and contribute to changes in left ventricular filling and geometry
 - Monitored clinically by changes in mean airway pressure
 - Result may be decreased cardiac output and renal perfusion
- Raised intrathoracic pressure alters transmural pressures and reduces cardiac output and can unload intrathoracic baroreceptors.
 - Initiates a cascade of compensatory neurohormonal events characterized by:
 - Increased systemic and renal sympathetic nervous activity
 - Increased activation of the renin–angiotensin–aldosterone system
 - Increased secretion of vasopressin
 - Reduction in release of atrial natriuretic peptide
 - Culminate in altered renal perfusion and kidney excretory function
 - Renal function may not be, *per se*, impaired with MV
 - Rather may appropriately respond to stimuli by reducing osmolar, sodium, and water clearance
- Acute hypoxemia and/or hypercapnia can act to alter systemic hemodynamics and increase systemic inflammation, both of which may exert negative effects on renal perfusion and function.
- Particular strategies of MV, specifically in ARDS, contribute to or provoke ventilator-induced lung injury (VILI).
 - Pathophysiology of VILI multifactorial and results from combined effects of:
 - Volutrauma (excessive tidal or end-expiratory volumes)
 - Barotrauma (excessive end-inspiratory peak and plateau pressures)
 - Atelectatic trauma (cyclical opening and closing of alveolar units)
 - Biotrauma (local release of inflammatory mediators from injured lung)
 - Such injurious MV can initiate a cascade of events that increase systemic inflammation and adversely affect kidney function

THE CLINICAL PICTURE

- Most common clinical picture seen in the ICU is a patient who has sustained or is experiencing a major systemic insult, such as trauma, sepsis, myocardial infarction, severe hemorrhage, cardiogenic shock, or major surgery.
- Resuscitation is typically well under way, or surgery may have just been completed.
- Patient may already be anuric or profoundly oliguric, serum creatinine is rising, and a metabolic acidosis is developing; serum potassium and phosphate levels may be rapidly rising.
- Need for mechanical ventilation and vasoactive drugs is common.
- Fluid resuscitation typically undertaken with the guidance of invasive hemodynamic monitoring.
- Vasoactive drugs often used to restore mean arterial pressure (MAP) to acceptable levels
 - Typically >65 to 70 mm Hg
- Patient may improve over time, and urine output may return with or without the assistance of diuretic agents.
- If urine output does not return, renal replacement therapy (RRT) considered
 - If cause of ARF removed and patient is physiologically stable:
 - Slow recovery occurs within 4 to 5 days to as long as 3 or 4 weeks
 - In some cases, urine output can be above normal for several days.
 - If the cause of ARF has not been adequately remedied, patient remains gravely ill, the kidneys do not recover, and death from multiorgan failure may occur.

PREVENTING ARF

- Fundamental principle of ARF prevention is to treat its cause.
- If prerenal factors contribute, these must be identified and hemodynamic resuscitation quickly instituted.

Fluid Resuscitation

- Intravascular volume must be maintained or rapidly restored.
 - Often best done using invasive hemodynamic monitoring
 - Arterial cannula and central venous catheter, pulmonary artery catheter, or pulse contour cardiac output catheter
 - Oxygenation must be maintained

- Adequate hemoglobin concentration, usually more than about 7.0 g/dL, must be maintained or immediately restored
- Once intravascular volume restored some patients remain with MAP <70 mm Hg
 - Autoregulation of RBF may be lost
 - Restoration of MAP to near normal levels may increase GFR
 - Such elevations in MAP require addition of vasopressor drugs
- Patients with preexisting hypertension or renovascular disease, MAP of 75 to 80 mm Hg may still be inadequate
 - Vasopressor support in hypotensive sepsis increases renal blood flow and renal medullary blood flow
 - Renal protective role of additional fluid therapy in patient with normal or increased cardiac output and blood pressure is questionable
 - Renal failure may still develop if cardiac output is inadequate.
 - May require various interventions, from the use of inotropic drugs to the application of ventricular assist devices

Fluid Therapy

- The cornerstone in resuscitation of the critically ill patient
 - Primary strategy for preservation of kidney function in the setting of increases in serum creatinine and/or urea and oliguria
 - Evidence has suggested there may be negative consequences to overly aggressive fluid therapy for both renal and nonrenal organ function.
 - No significant difference in incidence of ARF when comparing fluid resuscitation with crystalloid to albumin in critically ill patients
 - Some synthetic colloid therapies, such as hydroxyethyl starches, associated with higher rates of ARF in critically ill patients after resuscitation for severe sepsis
 - Exact mechanism(s) remain uncertain, the hydroxyethyl starches may influence intrarenal hemodynamics or glomerular filtration through alterations in vascular oncotic pressure
 - After apparent optimization of hemodynamics and intravascular volume status achieved
 - Little evidence to support continued aggressive fluid resuscitation to improve kidney function
 - Continued fluid administration and a positive cumulative balance can contribute to notable deteriorations in nonrenal organ function, in particular that of the lungs
 - Restrictive strategy improved lung function, increased ventilator-free days, and reduced ICU length of stay. Moreover, those in the restrictive group had a trend toward a reduced need for RRT

Renal Protective Drugs

Renal Dose or Low-Dose Dopamine

- Evidence of efficacy or safety of dopamine in critically ill patients is lacking
 - Is a tubular diuretic and occasionally increases urine output
 - Incorrectly interpreted as an increase in GFR

- Low-dose dopamine as effective as placebo in the prevention of renal dysfunction

Mannitol

- A biologic rationale exists for the use of mannitol, as is the case for dopamine
 - No controlled human data exist to support its clinical use.
 - Effect of mannitol as a renal protective agent remains questionable

Loop Diuretics

- May protect the loop of Henle from ischemia by decreasing its transport-related workload
 - Animal data are encouraging, as are *ex vivo* experiments
 - No double-blind randomized controlled studies of suitable size to prove that these agents reduce the incidence of renal failure
- Loop diuretics may decrease the need for RRT in patients developing ARF
 - Achieve this by inducing polyuria
 - Allows for easier control of volume overload, acidosis, and hyperkalemia, the three major triggers for RRT in the ICU
 - Because avoiding dialysis simplifies treatment and reduces the cost of care, loop diuretics are occasionally used in patients with renal dysfunction, especially in the form of continuous infusion

Other Agents

- Other agents such as theophylline, urodilatin, and anaritide, a synthetic atrial natriuretic factor, have also been proposed.
- So far no beneficial effect
- Fenoldopam's role in ARF remains uncertain.
- Similarly, in a single-center study, recombinant human atrial natriuretic factor (rhANF) has been shown to attenuate renal injury in higher-risk patients undergoing cardiac surgery.
 - Large multicenter study of ARF failed to show a benefit

DIAGNOSTIC INVESTIGATIONS

- Etiologic diagnosis of ARF must always be established
 - Such diagnosis may be obvious on clinical grounds; it is best to consider all possibilities and exclude common treatable causes by simple investigations
 - Microscopic examination of the urinary sediment
 - Dysmorphic RBCs or RBC casts virtually diagnostic of active glomerulonephritis or vasculitis
 - Heavy proteinuria suggests some form of glomerular disease
 - White blood cell casts suggests interstitial nephropathy or infection
 - Normal urinalysis can provide important information
 - Suggests ARF is due to a prerenal or obstructive cause
 - Provides evidence of whether a urinary tract infection is present
 - Additional investigations may be necessary to establish diagnosis
 - Evidence of marked anemia in absence of blood loss may suggest acute hemolysis, thrombotic microangiopathy, or paraproteinemia related to malignancy
 - In microangiopathic hemolytic anemia, peripheral blood smear will typically show evidence of hemolysis

- With the presence of schistocytes
- Additional measurement of lactic dehydrogenase, haptoglobin, unconjugated bilirubin, and free hemoglobin are needed
- If paraproteinemia due to multiple myeloma or lymphoma is suspected:
 - Serum and urine protein electrophoresis and serum calcium should be measured
 - History of recent cancer diagnosis or chemotherapy should prompt measurement of uric acid for tumor lysis syndrome
- For patients with possible mechanism for muscle injury:
 - Creatine kinase and free myoglobin for possible rhabdomyolysis should be determined
- An elevated anion gap metabolic acidosis with suggestion of a toxic ingestion:
 - Ethylene glycol, methanol, and salicylates should be measured
- Systemic eosinophilia a clue suggesting systemic vasculitis, allergic interstitial nephritis, or atheroembolic disease
- Measurement of specific antibodies—antiglomerular basement membrane (GBM), antineutrophil cytoplasmic antibodies (ANCA), antinuclear antibodies (ANA), anti-DNA, antismooth muscle, and cryoglobulins extremely useful screening tests to support the diagnosis of vasculitis or certain types of collagen vascular diseases or glomerulonephritis
- Imaging by renal ultrasonography a rapid noninvasive investigation principally designed to rule out:
 - Obstruction
 - Stones
 - Cysts
 - Masses
 - Overt renovascular disease
- Chest radiograph important to assess for pulmonary complications of ARF and if diagnosis of systemic vasculitis is considered
- Occasionally percutaneous renal biopsy necessary to:
 - Confirm diagnosis
 - Determine severity of renal injury
 - Guide therapy
 - Estimate potential for renal recovery
- Indicated when thorough noninvasive investigation fails to yield diagnosis, when prerenal and postrenal causes are excluded, and prior to administration of aggressive immunosuppressive therapy
- Can be performed under ultrasound guidance with local anesthetic in critically ill patients undergoing mechanical ventilation without additional risks when compared to standard conditions

MANAGEMENT OF ESTABLISHED ACUTE RENAL FAILURE

- Principles of management of established ARF always include:
 - Confirmation of probable cause
 - Elimination of potential contributors
 - Institution of disease-specific therapy if applicable
 - Prevention and management of ARF complications with maintenance of physiologic homeostasis while recovery takes place

- Encephalopathy, pericarditis, myopathy, neuropathy, electrolyte disturbances, or other major electrolyte, fluid, or metabolic derangements are never events in a modern ICU.
 - Prevented by several measures, from fluid restriction to the initiation of extracorporeal RRT
- Nutritional support must be started early and must contain adequate calories:
 - Around 30 to 35 Kcal/kg/day, as a mixture of carbohydrates and lipids
 - Sufficient protein of at least 1 to 2 g/kg/day needed
 - No evidence of specific renal nutritional solutions are useful.
 - Vitamins and trace elements should be administered at least according to their recommended daily allowance.
 - Role of newer immunonutritional solutions controversial
 - Enteral route is preferred to the use of parenteral nutrition
- Hyperkalemia
 - Serum potassium level of >6 mmol/L
 - Must be promptly treated either with:
 - Insulin and dextrose administration
 - Infusion of bicarbonate if acidosis is present
 - Administration of nebulized salbutamol
 - All of the above combined
 - If “true” serum potassium is >7 mmol/L, or if electrocardiographic signs of hyperkalemia appear:
 - Calcium gluconate, 10 mL of 10% solution administered intravenously used
 - These measures are temporizing actions while RRT being arranged
 - Presence of hyperkalemia a major indication for immediate institution of RRT
- Metabolic acidosis, almost always present, rarely requires treatment *per se*
- Anemia requires correction to maintain Hgb $>$ about 7.0 g/dL
 - More aggressive transfusion may be needed based on individual patient assessment
- Drug therapy adjusted to take into account effect of decreased clearances associated with loss of renal function
- Stress ulcer prophylaxis is advisable and should be based on H_2 -receptor antagonists or proton pump inhibitors in selected cases.
- Assiduous attention should be paid to the prevention of infection.
- Fluid overload prevented by use of loop diuretics in polyuric patients
 - If patient is oliguric only way to avoid fluid overload is to institute RRT at an early stage
 - Marked azotemia, defined as:
 - Urea >40 mmol/L (BUN [blood urea nitrogen] of 112 mg/dL)
 - Creatinine level >400 μ mol (4.5 mg/dL)
 - Undesirable and is treated with RRT, unless recovery is imminent or already under way
 - And return toward normal values is expected within 24 to 48 hours
 - Recognized that no randomized trials exist to define the ideal time for intervention with artificial renal support

Recovery and Its Management

- Recovery of renal function after episode of ARF increasingly acknowledged as significant clinical measure of morbidity

TABLE 111.3**INTERVENTIONS THAT MAY POTENTIALLY INFLUENCE RENAL RECOVERY RENAL REPLACEMENT THERAPY (RRT)**

Biocompatible membrane
 Higher-dose prescription
 Modality Continuous Renal Replacement Therapy (CRRT)
 Early initiation of RRT
 Nutritional support
 Intensive insulin therapy
 Erythropoietin
 Loop diuretics

- Persistent chronic renal impairment, or need for long-term RRT, can negatively influence the health status and quality of life of patients and contribute to considerable annual health care expenditures
- Recovery to independence from RRT occurs in estimated 68% to 85% of critically ill patients by hospital discharge
 - Generally peaks by 90 days
 - Older patients and those with preexisting comorbid illnesses
 - Such as chronic kidney disease or advanced cardiovascular disease
 - Less likely to recover function
 - Those with septic ARF may be more likely to recover function
 - Other potentially modifiable factors linked with improved rates of recovery:
 - Including early and aggressive initiation of RRT when indicated
 - Use of continuous rather than intermittent RRT
 - Early and adequate nutritional support
 - Intensive insulin therapy (Table 111.3)
 - Controversial whether adjuvant erythropoietin and routine use of loop diuretics influence renal prognosis and promote early recovery

PROGNOSIS

- ARF can independently influence both short- and long-term prognoses.

- In hospitalized patients, mortality estimated at 20% among all those developing ARF
 - Rate greatly influenced by severity of renal injury
- Prognosis is worse for critically ill patients and those in whom RRT necessary
 - In-hospital mortality for critically ill patients with ARF estimated at 50% to 60%
 - Depending on case mix, can range between 40% to 80%
 - Better uremic control and more intensive artificial renal support may improve survival
 - Prevent uncontrolled uremia and maintain low urea levels throughout the patient's illness
- Those who survive episode of ARF associated with critical illness:
 - Long-term health status, including health-related quality of life (HRQoL)
 - Functional status
 - Hospital discharge location
 - All important indicators of morbidity
 - These patients frequently describe limitations in daily activities, difficulties with mobility, and high levels of sleep disturbance, fatigue, anxiety, and depression
 - HRQoL is generally good and perceived as acceptable, despite evidence that their quality of life is considerably lower than that of the general population.

FUTURE DEVELOPMENTS

- Consensus definition developed and published that will guide research and translate into improved patient outcome
- Research needed to explore relationship between survival and subsequent morbidity
 - Specifically recovery of kidney function, HRQoL, and the economic consequences of decisions made during care of critically ill patients with ARF
- Some recent advances made in the prevention of ARF associated with radiocontrast nephropathy with use of N-acetylcysteine
- Although studies with fenoldopam provocative
 - No specific drugs found to help
- Apoptosis shown an important mechanism of renal tubular injury in ARF
 - Therapeutic potential for molecular targets
 - Selective inhibitors of proapoptotic proteins (e.g., caspase inhibitors)
 - May attenuate injury or promote recovery
 - At present, no evidence in humans has emerged

CHAPTER 112 ■ RENAL REPLACEMENT THERAPIES IN THE CRITICALLY ILL PATIENT

ACUTE RENAL FAILURE (ARF) AND THE CRITICALLY ILL PATIENT

- Multinational, multicenter prospective epidemiologic survey of ARF conducted in intensive care unit (ICU) patients who either were treated with renal replacement therapy (RRT) or fulfilled at least one of the predefined criteria for ARF :
 - Predefined ARF criteria were:
 - Oliguria, defined as urine output <200 mL in 12 hours
 - And/or marked azotemia, defined as a blood urea nitrogen level >30 mmol/L
 - Data collected at 54 hospitals in 23 countries
 - Of 29,269 critically ill patients admitted during the 16-month study period
 - 1,738 (5.9%) had ARF during ICU stay
 - Including 1,260 (4.3%) treated with RRT
 - Overall hospital mortality 60.3%
 - Most common contributing factor to ARF was septic shock (47.5%)
 - Approximately 30% of patients had preadmission renal dysfunction
 - 86.2% survivors were independent from dialysis at hospital discharge
 - Independent risk factors for hospital mortality included:
 - Use of vasopressors
 - Mechanical ventilation
 - Septic shock
 - Cardiogenic shock
 - Hepatorenal syndrome
 - Crude mortality assessment shows overall hospital outcome of ARF has not changed in past 30 years
 - Despite profound differences indicating much greater illness severity for patients treated in 2005
 - Mortality of ARF has not increased, and perhaps has slightly decreased
 - Incidence of ARF requiring extracorporeal support is 11 per 100,000 population per year
 - Annual mortality rate is 7.3 per 100,000 residents
 - Highest rates in males older than 65 years
 - Renal recovery occurs in 78% (68 of 87) of survivors at 1 year
 - Although a great number of patients with severe ARF will die, most survivors will become independent from RRT within a year

INDICATIONS FOR INITIATION AND CESSATION OF RENAL REPLACEMENT THERAPY

General Indications

- Uremic complications of ARF such as pulmonary edema, severe fluid overload, hyperkalemia-induced arrhythmias, and uncontrolled metabolic acidosis have long been described.
 - No predefined established indications on when to start RRT
 - Medical management attempts to prevent renal dysfunction include the use of diuretics, bicarbonate, fluid restriction, and nutritional restriction to control hyperkalemia.
 - When these fail, treatment is escalated to RRT.
 - Recently more aggressive blood purification approach advocated and a prevention-based algorithm for initiation of RRT can be used (Table 112.1)
- Once RRT started, there is no scientifically established biochemical or clinical marker that should be targeted by therapy
 - Routine clinical practice is to maintain urea concentration below 30 mg/dL, creatinine below 2.5 mg/dL, and electrolytes within normal values
- Techniques and timing of weaning patients from RRT are poorly described

TABLE 112.1

INDICATIONS FOR STARTING RRT

The presence of one indication *suggests*, two indications *strongly suggest*, three indications *mandate* initiation of RRT.

- Anuria/oliguria (diuresis ≤ 200 mL in 12 hours)
- Severe metabolic acidosis (pH <7.10)
- Hyperazotemia (BUN ≥ 80 mg/dL) or creatinine >4 mg/dL
- Hyperkalemia ($K^+ \geq 6.5$ mEq/L)
- Clinical signs of uremic toxicity
- Severe dysnatremia ($Na^+ \leq 115$ or ≥ 160 mEq/L)
- Hyperthermia (temperature $>40^\circ\text{C}$ without response to medical therapy)
- Anasarca or severe fluid overload
- Multiple organ failure with renal dysfunction and/or systemic inflammatory reaction syndrome, sepsis, or septic shock with renal dysfunction

- Following practical clinical concepts
 - Recommended when patient has reached hemodynamic stability, and/or need for vasopressors reduced, and/or severity of illness decreased
 - Intensity of blood purification can be decreased
 - If patient was on a continuous schedule, can be switched to intermittent or semicontinuous modality
 - Process accelerated when urine output and fluid balance become adequate

CONTINUOUS, INTERMITTENT, DIFFUSIVE, CONVECTIVE: AN ONGOING MATTER

RRT Modalities: Description and Nomenclature

- Renal replacement consists of the purification of blood by semipermeable membranes
 - A wide range of molecules, from water to urea to low-, middle-, and high-molecular-weight solutes, transported across such membranes by mechanism of ultrafiltration (water), convection, and diffusion (solute)
 - During *diffusion*, movement of solutes depends on tendency to reach same concentration on each side of membrane
 - Practical result is passage of solutes from compartment with highest concentration to compartment with lowest concentration
 - Other components of the semipermeable membrane deeply affect diffusion:
 - Thickness and surface, temperature, and diffusion coefficient
 - *Dialysis* a modality of RRT and is predominantly based on the principle of diffusion:
 - A dialytic solution flows through the filter countercurrent to blood flow to maintain the highest solute gradient from inlet to outlet port
 - During *convection*, movement of solute across semipermeable membrane takes place in conjunction with significant amounts of *ultrafiltration* (water transfer across the membrane)
 - As solvent (plasma water) is pushed across membrane in response to transmembrane pressure (TMP) by ultrafiltration (UF), solutes are carried with it, as long as the porosity of the membrane allows the molecules to be sieved from blood
- As UF proceeds and plasma water and solutes are filtered from blood, hydrostatic pressure within the filter is lost and oncotic pressure is gained because blood concentrates and hematocrit increase
- Fraction of plasma water removed from blood during UF is called *filtration fraction*
 - Should be kept in 20% to 25% range to prevent excessive hemoconcentration within the filtering membrane and to avoid the critical point at which oncotic pressure is equal to TMP and a condition of filtration/pressure equilibrium is reached
- Finally, replacing plasma water with a substitution solution completes the *hemofiltration* (HF) process and returns purified blood to patient
 - Replacement fluid administered after filter, with a process called *postdilution HF*
 - Otherwise, solution infused before filter to obtain predilution HF
 - Postdilution allows urea clearance equivalent to therapy delivery (i.e., 2,000 mL/hour)
 - Predilution, in spite of theoretical reduced solute clearances, prolongs the circuit lifespan, reducing the hemoconcentration and protein caking effects occurring within filter fibers
 - Conventional hemofiltration is performed with a highly permeable membrane with a surface area of about 1 m², steam sterilized, with a cutoff point of 30 kd

The Concept of RRT Dose

- Conventional view of RRT dose is that it is a measure of quantity of blood purification achieved by means of extracorporeal techniques
- *Operative* view of RRT dose is that it is a measure of quantity of representative marker solute removed from a patient
- Hence, the amount (measure) of delivered dose of RRT can be described by various terms:
 - The *efficiency* of RRT is represented by the concept of clearance (K)
 - The volume of blood cleared of a given solute over a given time
 - K depends on solute molecular size and transport modality (diffusion or convection)
 - As well as circuit operational characteristics (blood flow rate [Q_b], dialysate flow rate [Q_d], ultrafiltration rate [Q_f], and hemodialyzer type and size)
 - K normally used to compare treatment dose during each dialysis session
 - Cannot be used as an absolute dose measure to compare treatments with different time schedules
 - The *intensity* of RRT defined by product of clearance times time (Kt)
 - Kt more useful than K in comparing various RRTs
 - The *efficacy* of RRT represents effective solute removal outcome resulting from administration of a given treatment to a given patient
 - Can be described by a fractional clearance of a given solute (Kt/V), where V is the volume of distribution of the marker molecule in the body
 - Kt/V an established marker of adequacy of dialysis for small solutes correlating with medium-term (several years) survival in chronic hemodialysis patients
 - Urea is typically used as a marker molecule in end-stage kidney disease to guide treatment dose, and a Kt/V_{UREA} of at least 1.2 is currently recommended
 - However, Kt/V_{UREA} application to patients with ARF not rigorously validated
 - These aspects particularly evident during intermittent hemodialysis (IHD), less so during sustained low-efficiency daily dialysis (SLEDD), and even less during continuous renal replacement therapy (CRRT)
 - Difference due to fact that, after some days of CRRT, the patient's urea levels approach a real steady state

TABLE 112.2

GUIDELINES FOR RRT PRESCRIPTION

Clinical	Operational	Setting
Fluid balance	Net ultrafiltration	A continuous management of negative balance (100–300 mL/h) is preferred in hemodynamically unstable patients. A complete monitoring (CVC, S-G, arterial line, ECG, pulse oximeter) is recommended.
Adequacy and dose	Clearance/modality	2,000–3,000 mL/hour K (or 35 mL/kg/h) for CRRT; consider first CVVHDF. If IHD is selected, a prescription of every day for 4 h is recommended. Prescribe a $Kt/V > 1.2$.
Acid-base balance	Solution buffer	Bicarbonate buffered solutions are preferable to lactate buffered solutions in case of lactic acidosis and/or hepatic failure.
Electrolyte	Dialysate/replacement	Consider solutions without K^+ in case of severe hyperkalemia. Accurately manage $MgPO_4$.
Timing	Schedule	Early and intense RRT is suggested.
Protocol	Staff/machine	Well-trained staff should routinely use RRT monitors according to predefined institutional protocols.

CVC, central venous catheter; S-G, Swan-Ganz catheter; ECG, electrocardiogram; CRRT, continuous renal replacement therapy; CVVHDF, continuous venovenous hemodiafiltration; IHD, intermittent hemodialysis.

RRT Prescription

Theoretical Aspects

- Despite uncertainty and shortcomings, the idea that there might be an optimal dose of solute removal continues to have a powerful hold in the literature
- Tables 112.2 and 112.3 provide details that could be followed each time an RRT prescription is indicated

From Continuous to Intermittent:
One Treatment Fits All?

- Clearance-based dose quantification methods may not be adequate to compare effectiveness.
 - For example, peritoneal dialysis (PD), traditionally providing less urea clearance per week than IHD, has comparable patient outcomes.
- When the critical parameter is metabolic control, an acceptable mean blood urea nitrogen level of 60 mg/dL—easily

TABLE 112.3

EXAMPLE OF A POSSIBLE PRESCRIPTION FOR CONTINUOUS TREATMENT IN A 70-KG PATIENT (V_{UREA} : 42 L) DURING AN IDEAL SESSION OF 24 HOURS (T: 1,440 MINUTES) (NET ULTRAFILTRATION [PATIENT FLUID LOSS] IS CONSIDERED ZERO IN K_{CALC} FOR SIMPLICITY)

	Estimated urea clearance (K_{CALC})	Notes	Value of Q to obtain 35 mL/kg/h	Value of Q to obtain a Kt/V of 1
CVVH postdilution	$K_{CALC} = Q_{rep}$	Always keep filtration fraction <20% (Q_b must be 5 times Q_{rep})	Q_{rep} : 41 mL/min or 2,450 mL/h	Q_{rep} : 29 mL/min or 1,750 mL/h
CVVH predilution	$K_{CALC} = Q_{uf}/[1 + (Q_{rep}/Q_b)]$	Filtration fraction computation changes (keep <20%)	For a Q_b of 200 mL/min, Q_{rep} : 53 mL/min or 3,200 mL/h	For a Q_b of 200 mL/min, Q_{rep} : 35 mL/min or 2,100 mL/hour
CVVHD	$K_{CALC} = Q_{do}$	Keep Q_b at least thrice Q_{do}	Q_{do} : 41 mL/min or 2,450 mL/h	Q_{do} : 29 mL/min or 1,750 mL/h
CVVHDF postdilution (50% convective and diffusive K)	$K_{CALC} = Q_{rep} + Q_{do}$	Consider notes of both CVVH and CVVHD	Q_{rep} : 20 mL/min + Q_{do} : 21 mL/min	Q_{rep} : 14 mL/min replacement solution + Q_{do} : 15 mL/min

CVVH, continuous venovenous hemofiltration; Q_{rep} , replacement solution flow rate; Q_b , blood flow rate; Q_{uf} , ultrafiltration flow rate ($Q_{uf} = Q_{rep} + Q_{net}$); CVVHD, continuous venovenous hemodialysis; Q_{do} , dialysate solution flow rate; CVVHDF, continuous venovenous hemodiafiltration; Q_{net} , patient's net fluid loss.

Urea volume of distribution V (L): patient's body weight (Kg) \times 0.6.

Estimated fractional clearance (Kt/V_{CALC}): K_{CALC} (mL/minute) \times prescribed treatment time (minute)/V (mL).

A quantity of 35 mL/kg/hour roughly corresponds to a Kt/V of 1.4. A Kt/V of 1 corresponds to approximately 25 mL/kg/hour.

Filtration fraction calculation (postdilution): $Q_{rep}/Q_b \times 100$. Filtration fraction calculation (predilution): $Q_{rep}/Q_b + Q_{rep} \times 100$.

obtainable in a 100-kg patient with a 2 L/hour continuous venovenous hemofiltration in a computer-based simulation—has been shown to be very difficult to reach, even by intensive IHD regimens.

- Increased RRT frequency results in decreased ultrafiltration requirements per treatment.
 - Avoidance of volume swings related to rapid ultrafiltration rates may also represent another dimension of dose where comparability is difficult.
- Surviving Sepsis Campaign guidelines for management of severe sepsis and septic shock concluded continuous RRT should be considered equivalent to IHD for the treatment of ARF
 - In 166 critically ill patients with ARF randomized to either CRRT or IHD, the CRRT population, despite randomization, had significantly greater severity of illness scores.
 - In part explains why, despite better control of azotemia and a greater likelihood of achieving the desired fluid balance, CRRT had increased mortality
 - Smaller trial at the Cleveland Clinic failed to find a difference in outcome between one therapy and another
 - Meta-analysis unable to solve debate of continuous versus intermittent treatment
 - Remains uncertain whether the choice of RRT modality (intermittent or continuous) actually matters to patient outcome

TECHNICAL NOTES

RRT Modalities: Description and Nomenclature

- Apart from evidence-based medicine dictates, continuous therapies are used in 80% of ICUs worldwide, whereas intermittent hemodialysis (17%) and peritoneal dialysis (3%) have less common use.
- Accurate ultrafiltration control is now obtained by integrated roller volumetric pumps (blood, replacement dialysate, and effluent) and scales.
 - Monitors display pressure measurements of all crucial segments of the circuit (catheter inlet and outlet, filter inlet and outlet, UF, and dialysate ports)
 - Information is integrated with adequate alarm systems and allows the ICU staff to increase filter efficiency and lengthen circuit patency, with the ability to detect potential sources of clotting, thereby improving patient safety.
 - A complete monitoring of fluid balance also provided by continuous recording of the history of the past 24 hours of treatment
 - When an alarm occurs, a “smart” message on the screen suggests the most appropriate intervention required.
- A complete range of ICU RRT therapeutic modalities includes:
 - Slow continuous ultrafiltration (SCUF)
 - Continuous venovenous hemofiltration (CVVH)
 - Continuous venovenous hemodialysis (CVVHD)
 - Continuous venovenous hemodiafiltration (CVVHDF)
 - Therapeutic plasma exchange (TPE)

Intermittent Hemodialysis

- IHD is a prevalently diffusive treatment in which blood and dialysate are circulated in countercurrent mode, and generally, a low permeability, cellulose-based membrane is used.
- Dialysate must be pyrogen free but not necessarily sterile, since dialysate-blood contact does not occur.
- Ultrafiltration rate is equal to the scheduled weight loss
 - Treatment can typically be performed 4 hours three times a week or daily

Peritoneal Dialysis

- PD is a predominantly diffusive treatment in which blood circulating along the capillaries of the peritoneal membrane is exposed to dialysate.
- Access is obtained by insertion of a peritoneal catheter.
 - Allows abdominal instillation of dialysate
 - Solute and water movement is achieved by means of variable concentration and tonicity gradients generated by the dialysate
 - Treatment can be performed continuously or intermittently

Slow Continuous Ultrafiltration

- SCUF is a technique by which blood is driven through a highly permeable filter via an extracorporeal circuit in venovenous mode.
 - Ultrafiltrate produced during membrane transit is not replaced and corresponds to weight loss.
 - Used only for fluid control in overloaded patients (i.e., congestive heart failure patients who do not respond to diuretic therapy)

Continuous Venovenous Hemofiltration

- CVVH is a technique by which blood is driven through a highly permeable filter via an extracorporeal circuit in venovenous mode.
- Ultrafiltrate produced during membrane transit is replaced, in part or completely, to achieve blood purification and volume control.
 - Replacement fluid is delivered after the filter, the technique is defined as *postdilution hemofiltration*
 - If delivered before the filter, the technique is defined as *predilution hemofiltration*
 - Replacement fluid can also be delivered both prefilter and postfilter
 - Clearance for all solutes is convective and equals the ultrafiltration rate

Continuous Venovenous Hemodialysis

- CVVHD is a technique by which blood is driven through a low-permeability dialyzer via an extracorporeal circuit in venovenous mode.
 - A countercurrent flow of dialysate is delivered in the dialysate compartment.
 - Ultrafiltrate produced during membrane transit corresponds to the patient's weight loss.
 - Solute clearance is mainly diffusive, and efficiency is limited to small solutes only.

Continuous Venovenous Hemodiafiltration

- CVVHDF is a technique by which blood is driven through a highly permeable dialyzer via an extracorporeal circuit in venovenous mode.

- Countercurrent flow of dialysate is delivered in the dialysate compartment.
- Ultrafiltrate produced during membrane transit is in excess of the patient's desired weight loss.
 - Replacement solution is needed to maintain fluid balance.
 - Solute clearance is both convective and diffusive.

Hemoperfusion (HP)

- In HP, blood is circulated on a bed of coated charcoal powder to remove solutes by adsorption.
- Technique is specifically indicated in cases of poisoning or intoxication with agents that can be effectively removed by charcoal
- Treatment may cause platelet and protein depletion

Plasmapheresis (PP)

- PP a treatment that uses specific plasma filters.
- Molecular-weight cutoff of the membrane is much higher than that of hemofilters (100,000 to 1,000,000 kd)
- Plasma as a whole is filtered and blood is reconstituted by the infusion of plasma products such as frozen plasma or albumin.
 - This technique is performed to remove proteins or protein-bound solutes.

High-flux Dialysis (HFD)

- HFD a treatment that uses highly permeable membranes in conjunction with an ultrafiltration control system
- Due to characteristics of membrane, ultrafiltration occurs in proximal part of filter that is counterbalanced by positive pressure applied to dialysate compartment
 - Causes, in the distal part of the filter, a phenomenon called *backfiltration*
 - The convective passage of the dialysate into the blood
 - Diffusion and convection are combined, but due to the use of a pyrogen-free dialysate, replacement is avoided.

High-volume Hemofiltration (HVHF)

- HVHF is a treatment that uses highly permeable membranes and hemofiltration with a high volume setting.

High-permeability Hemofiltration (HPPH)

- HPPH a treatment that uses high-cutoff (60 kd) permeable membranes and hemofiltration
- High treatment flows are not necessary
 - Strict control of bigger molecules, like albumin, is recommended

Anticoagulation

- Need for anticoagulation of CRRT circuit arises from the fact that the contact between blood and the tubing of the circuit and the membrane of the filter induces activation of the coagulation cascade
 - Extracorporeal activation inevitably results in filter or circuit clotting
 - Aims of anticoagulation are as follows:
 - Maintenance of extracorporeal circuit and dialyzer patency
 - Reduction of off-treatment time (downtime) that could have a clinical impact on the overall RRT clearance
 - Reduction of treatment cost by the use of as little material as possible

- Achievement of the above aims with minimal risk for the patient
 - Under no circumstances should the patient be put at risk of bleeding to prolong circuit life.

Circuit Setup Optimization and No Anticoagulation

- Several technical features of the RRT circuit are likely to affect the success of any anticoagulant approach.
 - Vascular access must be of adequate size
 - Tubing kinking should be avoided
 - Blood flow rate should exceed 100 mL/minute
 - Pump flow fluctuations must be prevented (in modern machines this event is mainly due to increased circuit resistances rather than flow rate inaccuracies)
 - Venous bubble trap, where air–blood contact occurs, must be accurately monitored.
- Another component of circuit setup has to be addressed:
 - Plasma filtration fraction should be kept as far as possible below 20%
 - When possible or considered correct, predilutional hemofiltration should be selected
 - Evidence that, when setup is perfectly optimized, anticoagulants are only a relatively minor component of circuit patency
 - Whenever the patient's clinical features present risk factors for bleeding (prolonged clotting times, thrombocytopenia), RRT can be safely performed without use of any anticoagulant

Unfractionated Heparin (UFH)

- UFH a commonly available anticoagulant
 - Easy to use
 - Antidote available (protamine)
 - Heparin doses generally range from 5 to 10 IU/kg/hour
 - In patients with very limited circuit duration, it can also be used in combination with protamine (regional heparinization), with a 1:1 ratio
 - 150 IU of UFH per mg of protamine
 - A strictly monitored activated prothrombin time (aPTT)
 - Problem with UFH is its relatively unpredictable bioavailability, the necessity for antithrombin III (ATIII) level optimization, and the occurrence of heparin-induced thrombocytopenia (HIT)

Low-molecular-weight Heparins (LMWH)

- LMWH a relatively new kind of anticoagulant
 - Prospective studies not yet shown these to be superior to prolong circuit life
 - Molecules appear to have a better bioavailability than UFH and a lower incidence of HIT with a 10% increased cost

Prostacyclin

- Prostacyclin (PGI₂) a potentially useful drug for RRT anticoagulation
 - The most potent inhibitor of platelet aggregation with the shortest half-life
 - PGI₂ infused at a dose of 4 to 8 ng/kg/hour, with or without adjunct of low dose of UFH
 - Hypotension may be induced by higher doses of PGI₂
 - High cost and harmful side effects might limit the use of this agent to patients with short circuit duration

TABLE 112.4**ANTICOAGULATION STRATEGIES**

Drug	PRO	CON
No anticoagulation	High risk of bleeding in patients	Relatively shorter circuit life span
Unfractionated heparin	Routine	HIT
Low-molecular-weight heparin	Routine (alternative to UH)	HIT
Prostacyclin	Very short circuit life span	Hypotension
Citrate	Routine/very short circuit life span	Hypocalcemia
Danaparoid	HIT	Insufficient data available
Argatroban	HIT	Insufficient data available
Irudine	HIT	Insufficient data available
Nafamostat mesilate	HIT	Insufficient data available
Heparin-coated circuits	Routine	Insufficient data available

HIT, heparin-induced thrombocytopenia; UH, unfractionated heparin.

Citrate

- Citrate provides a form of regional anticoagulation
 - Depends on the ability of citrate to chelate calcium, which prevents clot formation
 - A calcium-free sodium citrate containing replacement solution and/or dialysate solution is prepared and administered at the appropriate rate to achieve the desired aPTT (60 to 90 seconds)
 - Calcium chloride is then administered to replace chelated/dialyzed calcium and maintain normocalcemia
 - Effective in maintaining excellent filter patency and compares favorably with heparin
 - Avoids the risk for HIT and does not lead to systemic anticoagulation
 - Relative drawbacks of this anticoagulation management strategy include:
 - Risk for hypocalcemia and metabolic alkalosis
 - Use of cumbersome replacement/dialysate fluid preparation

Other Strategies

- Alternatives to the techniques presented above are listed in Table 112.4 for completeness.

Vascular Access

- The fundamental role played by vascular access must be emphasized
 - Circuit failure more often due to inadequate vascular access than insufficient anticoagulation
 - Optimal dialysis catheter can save patient from inappropriate increases of anticoagulation dose
 - Venovenous RRT relies on use of temporary double-lumen catheter
 - Such catheters inserted in a central vein and available in different brands, shapes, and sizes
 - Site of insertion of double-lumen catheters implies several considerations (clinician expertise, body habitus of the patient, the presence of other intravenous catheters)
 - Femoral vein is generally the first choice of vascular access
 - Internal jugular or subclavian accesses often associated with inadequate performance

- Inguinal puncture is safer and easier to perform in coagulopathic critically ill patients
- Valid alternative may be achieved by cannulation of the right internal jugular vein with tip of catheter reaching right atrium
- Circuit blood flow rates with this approach can reach 300 mL/minute
- Catheter sizes for adult patients range from 12 to 14 French and length from 16 to 25 cm
 - The bigger and shorter the catheter, the higher the performance
 - When femoral vein is selected, a 20-cm-long catheter has its tip positioned close to the inferior vena cava, allowing optimal flows within the circuit
 - When an inadequate blood flow or a catheter malfunction is suspected, venous and arterial lumens should be flushed with saline.
 - With goal of testing resistance to injection and aspiration
 - Limb clotting of the line versus kinking due to the patient's position must be distinguished
 - In the first case, a switching of arterial and venous limb can be attempted
 - Maneuver increases circuit recirculation, but clinical consequences are negligible
 - In the second case, a heparin or urokinase lock can be tried for a few hours
 - Another approach is a catheter (guidewire) exchange

THE ROLE OF RENAL REPLACEMENT THERAPIES IN DIFFERENT SETTINGS**Sepsis and Multiple Organ Dysfunction Syndrome**

- Interest in the past 10 years concerning extracorporeal blood purification therapies (EBPT) as adjuvants in the complex therapy of sepsis and multiple organ dysfunction syndrome (MODS)
 - RRT was first and still is most used and effective type of EBPT

- Evidence is growing about its ability to maintain homeostatic balance in critically ill patients—specifically, septic patients with MODS
- Beyond correcting specific uremic toxins
 - RRT seems to restore other physiologic homeostatic mechanisms (*renal dose* of CRRT)
 - At *overdoses*, it may play a role in blood purification from water-soluble cytokines produced during systemic inflammatory and septic states (*sepsis dose*)
 - Concept leads to speculation that higher-volume hemofiltration may be beneficial in septic patients beyond the removal of classic markers
 - If a UF rate of 1,400 to 2,400 mL/hour for a 70-kg man (equivalent to 20 to 35 mL/kg/hour) can be considered *traditional dose*
 - Then increasing effluent production to more than 45 mL/kg/hour can be considered as high-volume CVVH
 - One of the main challenges of HVHF is the technical limit of currently available machines (UF ranges from 4 L/hour to 9 or 10 L/hour)
 - Sessions are often intermittent or interrupted by traditional CVVH after 2 to 8 hours
 - The first reports of application of HVHF to the treatment of septic shock in humans with MODS have appeared recently.
 - Beneficial effect on macrophage function with restoration of the ability to produce tumor necrosis factor- α (TNF- α) in response to endotoxin exposure, showing the potential of EBPT for immunomodulation at a cellular and humoral level in sepsis
 - Prospective cohort analysis in 306 patients who received HVHF at a mean UF rate of 4 L/hour found an improvement in cardiac index (CI), blood pressure (BP), and stroke volume (SV) in hypodynamic patients, and an increase in systemic venous resistance (SVR) with a decrease in dopamine dose in those who were hyperdynamic.
 - Evaluation of the effects of short-term, high-volume hemofiltration (STHVH), lasting 4 hours with 9 L/hour hemofiltration flow and followed by conventional CVVH in 20 patients affected by intractable cardiocirculatory failure resulting from severe septic shock
 - Eleven patients (“responders”) attained all therapeutic end points (increase in CI; increase in mixed venous saturation; increase in arterial pH; reduction in epinephrine dose)
 - Rate of survival to 28 days in this group was markedly higher (9 of 11) than among nonresponders (0 of 9)
 - Hemodynamics, serum cytokines, and complement concentration measured in 11 patients with septic shock and MODS
 - Patients randomly assigned to HVHF (8 hours at 6 L/hour) or to standard CVVH
 - Decrease in vasopressor requirement significantly higher in HVHF group
 - In the HVHF group, the concentration of the measured soluble mediators in the ultrafiltrate was negligible, indicating a greater role in filter adsorption of studied mediators.
 - All of these data support the hypothesis that HVHF techniques are safe and feasible and show that adequate blood purification can restore and maintain cardiac and circulatory function as well as metabolic and gas exchange parameters.

- Large randomized trials are still lacking, and these types of therapies are still far from becoming routine.
- A more complex evolution of EBPT, combining the need for high-sieving coefficients of larger molecules and continuous therapy, led to a technique called *coupled plasma filtration adsorption* (CPFA).
 - Technique separates plasma from blood using a plasma filter
 - Plasma then passed through a synthetic resin cartridge and returned to the blood
 - A second blood filter is used to remove excess fluid and low-molecular-weight toxins
 - The resin was chosen based on its adsorption capacity for important inflammatory mediators, low levels of extractable toxins, and good pressure flow performance.
 - In a randomized clinical trial, the adsorbent removed almost 100% of TNF- α and interleukin- β (IL- β), allowing a significant reduction of vasopressor dosage when compared to CVVH alone.

Congestive Heart Failure (CHF)

- Fluid overload may occur in patients with CHF
 - When diuretics fail, fluid removal becomes uncontrolled, and other therapeutic options must be undertaken
 - Extracorporeal ultrafiltration a possible solution
 - Acute isolated schedules of ultrafiltration may be too aggressive and could result in severe hemodynamic instability
 - Continuous extracorporeal techniques applied in such patients
 - Excellent hemodynamic stability, a good cardiovascular response
 - Often, diuresis restoration the most common effects encountered
 - One specific comment must be made concerning difference between CVVH and other techniques, including dialysis and use of diuretics.
 - In all pharmacologic and dialytic techniques, removal of sodium and water cannot be dissociated.
 - Diuretic effect is based on a remarkable natriuresis.
 - Ultrafiltration during dialysis may result in hypotonicity or hypertonicity, depending on interference with diffusion and removal of other molecules such as urea and other electrolytes.
 - In such circumstances, water removal is linked to other solutes in proportions that are dependent on the technique used.
 - In SCUF, the mechanism of ultrafiltration produces a fluid that is substantially similar to plasma water except for a minimal interference due to Donnan effects.
 - Ultrafiltration is basically iso-osmotic and isonatremic.
 - Water and sodium removal cannot be dissociated, with sodium elimination linked to the sodium–plasma water concentration
 - In CVVH and hemofiltration in general, the ultrafiltrate composition is definitely similar to plasma water.
 - Sodium balance can be significantly affected by sodium concentration in replacement solution.
 - Sodium removal can be dissociated from water removal.
 - This effect cannot be achieved with any other technique.

Contrast-induced Nephropathy

- Radiocontrast-induced nephropathy (RCIN) causes acute kidney injury and increases mortality
- Systematic review of published trials to determine whether periprocedural extracorporeal blood purification prevents RCIN:
 - Incidence of RCIN, defined as an increase in serum creatinine concentration (>0.5 mg/dL [>44 mmol/L]), was 35.2% in the standard medical therapy group and 27.8% in extracorporeal blood purification group
 - Extracorporeal blood purification did not decrease the incidence of RCIN significantly as compared with standard medical therapy (risk ratio, 0.97; 95% confidence interval, 0.44–2.14)
 - Periprocedural hemodialysis did not decrease the incidence of RCIN

RRT for Children

- Important differences in RRT indications, methods, and prescription between children and adult patients; nevertheless, the technique is essentially the same
- Main indication is correction of water overload
 - Different from adult setting, where solute control may play a key role
 - Shown that restoring adequate water content in small children is the main independent variable for outcome prediction
- This concept is much more important in critically ill, smaller children, in whom a relatively larger amount of fluid must be administered to deliver an adequate amount of drug infusion, parenteral/enteral nutrition, blood derivatives, and so on.
- Corrections of acid-base imbalance and electrolyte disorders strong indications for RRT in children
- Catheter size ranges from:
 - 6.5 French (10 cm long) for patients weighing <10 kg
 - 8 French (15 cm long) for patients weighing 11 to 15 kg
- Blood priming may be indicated if more than 8 mL/kg of patient's blood volume necessary to fill a RRT circuit
- Full anticoagulation must always be maintained to avoid excessive blood loss in case of circuit clotting.
- Predilution hemofiltration is generally the preferred modality and is delivered in a continuous fashion.
- Fluid balance requires strict monitoring and highest accuracy due to the risk of excessive patient dehydration.
- Prescription of RRT clearance should be titrated based on the patient body surface area, an approach that will usually lead to relatively higher doses for small children with respect to adult patients when considered per kilogram.
- Critically ill children weighing below 10 kg and neonates with ARF are often treated with peritoneal dialysis (PD).
- An important exception to this general approach is the case of children with ARF during an extracorporeal membrane oxygenation treatment (ECMO).
 - In this case, the RRT circuit is placed in parallel to the ECMO circuit, and it is possible to let a significant blood flow run into the filter even in the smallest patients.

SECTION XVII ■ ENDOCRINE DISEASE AND DYSFUNCTION

CHAPTER 113 ■ ENDOCRINOPATHY IN THE INTENSIVE CARE UNIT

- During critical illness, the stressors are multiple and include emotional and physical stress such as trauma or infection, and various therapeutic or diagnostic interventions such as surgery, arterial or venous catheterization, laryngeal intubation and mechanical ventilation, and drugs. In response, the host adapts to counteract prolonged stress while maintaining the ability to adjust to unpredictable surges of stress. The integrity and flexibility of host response to these stressors is essential to survive critical illness.
- It is now recognized that the “stress system” has two main components: the corticotropin-releasing hormone (CRH)/vasopressin neurons of the hypothalamus and the locus ceruleus noradrenaline/autonomic neurons of the brainstem. This chapter summarizes recent knowledge on how immune molecules signal the brain to generate both neurologic and hormonal responses aimed at downgrading the immune system when the inflammatory response is no longer needed. Abbreviations used in this chapter are presented in Table 113.1.

TABLE 113.1

ABBREVIATIONS

ACTH	adrenocorticotrophic hormone
ADH	antidiuretic hormone
CRH	corticotropin-releasing hormone
FSH	follicle-stimulating hormone
GABA	gamma-aminobutyric acid
GH	growth hormone
GHRH	GH-releasing hormone
GHRP	GH-releasing peptide
GLUT	glucose transporter isoform 4
GNRH	gonadotropin-releasing hormone
HMGB	high mobility group box
IGF	Insulin-like growth factor
IL	interleukin
iNOS	inducible nitric oxide synthase
IRR	insulin receptor-related receptor
LH	luteinizing hormone
LHRH	LH-releasing hormone
LTH	luteotrophic hormone
MIF	macrophage migration inhibitory factor
NO	nitric oxide
NTIS	nonthyroidal illness syndrome
PRL	prolactin
T ₃	tri-iodothyronine
T ₄	serum thyroxine
Th1	helper T cell 1
Th2	helper T cell 2
TNF	tumor necrosis factor
TRH	thyrotropin-releasing hormone
TSH	thyroid-stimulating hormone

PHYSIOLOGY OF THE ENDOCRINE RESPONSE

- Two pathways are used by the organism for interorgan communication—the central nervous system and the endocrine system.
- The central nervous system and its peripheral arms allow rapid communication between different tissues.
- The endocrine system is made of several organs or tissues distributed throughout the body. Nevertheless, all endocrine tissues are directly linked to the pituitary and the hypothalamus.
- In vertebrates, the endocrine organs include anterior and posterior pituitary, ovary and testis, adrenal cortex and medulla, thyroids and parathyroids, islets of Langerhans in the pancreas, and various parts of the intestinal mucosa. The pineal and thymus can also be considered endocrine organs.
- Many other organs have some endocrine properties. The kidney secretes renin and the heart secretes natriuretic factors.
- Hormones are divided into steroids (cholesterol-derived proteins), peptides, and amines.
- The main known **hormones** are listed in Table 113.2.

General Organization of the Endocrine System

- The **pituitary gland (hypophysis)** is a pivotal endocrine organ. It is connected to the central nervous system by the pituitary stalk and is divided into two parts: the anterior pituitary and the posterior pituitary, which is developed from the brain.
- The **anterior pituitary** is made up of the *pars distalis*, which is richly vascular and has three cell types (chromophobe and two types of chromophil cells), the *pars intermedia*, which is the least vascular part and contains only a few cells, and the *pars tuberalis*.
- The anterior pituitary produces seven hormones: gonadotropic hormones (follicle-stimulating hormones (FSH), luteinizing hormone (LH) and luteotropic hormone (LTH), thyrotropic (thyroid-stimulating) hormone (TSH), adrenocorticotrophic hormone (ACTH), growth hormone (GH), and prolactin (PRL).
- The **posterior pituitary** has three parts: the median eminence, infundibular stem, and infundibular process or neural lobe. Its tissues consist of unmyelinated fibers, fusiform cells, neurons, and mast cells.
- The posterior pituitary produces mainly vasopressin, also called the antidiuretic hormone (ADH).

TABLE 113.2

LIST OF HORMONES

Hormones	Organ	Carrier in bloodstream	Target tissues	Main actions
Insulin	Pancreas: β cells of the islets of Langerhans	Free	Liver, muscle, fat	Decreases blood glucose level Decreases gluconeogenesis, proteinolysis, lipolysis Increases fatty acid and glycogen synthesis
Glucagon	Pancreas: α cells of the islets of Langerhans	Free	Liver	Increases blood glucose level by increasing glycogenolysis and gluconeogenesis
Somatostatin	Hypothalamus cells and cells of pancreas, intestine, stomach	Free	Pancreas	Suppresses gastrointestinal hormone secretion Inhibits insulin and glucagon secretion Inhibits GH and TSH release
Thrombopoietin	Liver, kidney, striated muscle, stromal cells of the bone marrow	Free	Bone marrow	Regulates the differentiation of megakaryocytes and platelets
Angiotensinogen	Liver	Free	Plasma	Releases aldosterone Causes vasoconstriction
Insulin growth factor	Liver	IGF-binding proteins	Muscle, cartilage, bone, liver, kidney, nerves, skin, and lungs	Regulates cell proliferation and apoptosis
Tri-iodothyronine (T_3) Thyroxine (T_4) Calcitonin	Thyroid	Thyroxine-binding globulin (TBG 70%) Thyroxine-binding prealbumin (TBPA 10%–15%) Albumin (15%–20%) Free	Whole body Intestines, bone, kidney, central nervous system	Increases metabolic rate Promotes growth Metabolic effects: stimulates carbohydrate metabolism, fat metabolism; decreases cholesterol, phospholipid, and triglyceride plasma levels Prohormone for the active T_3 Reduces blood calcium levels Regulates vitamin D and bone mineral metabolism Controls satiety
Adrenocorticotropin hormone (ACTH)	Anterior pituitary	Free	Adrenal cortex	Produces glucocorticoids and mineral corticoids
Luteinizing hormone (LH)		Free	In females, granulosa cells and theca cells In males, Leydig cells of the testis	Reproduction: In females, triggers ovulation and maintains luteal function during the first 2 weeks of menstruation. In males, increases testosterone production
Follicle-stimulating hormone (FSH)		Free	In females, graafian cells In males, Sertoli cells of the testes	Reproduction: In females, initiates follicular growth In males, enhances androgen-binding protein and acts in the spermatogenesis

(continued)

TABLE 113.2

CONTINUED

Hormones	Organ	Carrier in bloodstream	Target tissues	Main actions
Growth hormone (GH)	Posterior pituitary	Free	Liver, chondrocytes, and whole body	Anabolic hormone: promotes lipolysis, increases protein synthesis, reduces liver uptake of glucose Enables height growth in childhood Increases calcium retention and increases bone mineralization Stimulates the immune system
Prolactin		Free	Mammary glands	Stimulates lactation
Oxytocin		Free	Brain, mammary gland, myometrium, endometrium, kidney, heart	Peripheral actions: Letdown reflex in lactating Uterine contraction Reduces diureses and stimulates sodium excretion Embryonal development of heart Brain actions: Sexual arousal Social behavior Maternal behavior Increases trust and reduces fear
Antidiuretic hormone (ADH)		Free	Vessels, liver, pituitary gland, kidney, brain	Peripheral actions: V1a: vasoconstriction, gluconeogenesis, platelet aggregation and release of factor VIII and von Willebrand factor V1b: ACTH secretion V2: water reabsorption in the collecting ducts Brain actions: Memory formation Response to stress
Cortisol	Adrenal cortex	Corticosteroid-binding globulin (CBG 90%) Albumin Free (about 4%)	Liver, vessels, immune system, hippocampus	Metabolic properties: Enhances hepatic gluconeogenesis and glycogenolysis Induces peripheral insulin resistance Induces free-fatty acid and amino-acid release Cardiovascular properties: Maintains vascular tone Maintains endothelial and vascular permeability Anti-inflammatory and immunosuppressive actions
Aldosterone		Free	Collecting ducts of the kidney	Reabsorption of sodium and excretion of potassium H ⁺ secretion
Estrogen	Ovary, placenta	Free	Uterus, coagulation system, liver, gastrointestinal tract	Promotes development of female secondary sex characteristics Regulates the menstrual cycle Causes thickening of the endometrium Promotes lipid metabolism, protein synthesis, fluid balance

(continued)

TABLE 113.2

CONTINUED

Hormones	Organ	Carrier in bloodstream	Target tissues	Main actions
Progesterone		Free	Endometrium, vaginal epithelium, brain, smooth muscle, immune system, thyroid, skeleton	Reproduction Neurosteroid: involved in myelination, synaptic function
Testosterone	Testes of males and ovaries of females	Sex hormone binding globulin (SHBG)	In males,	Anabolic effects: Growth of muscle mass Increases bone density and maturation Virilizing effects: Maturation of sex organs Development of male secondary sex characteristics
Parathormone	Parathyroid	Free	Skeleton, gastrointestinal tract, kidney	Increases blood calcium concentration in three ways: Enhances calcium release from the bone Enhances calcium reabsorption from renal tubules Enhances calcium absorption in the intestine
Human chorionic gonadotropin (HCG)	Placenta	Free	Uterus	Maintains the corpus luteum and progesterone production during pregnancy
Atrial natriuretic peptide (ANP)	Atrial myocytes of the heart	Free	Kidney, vessels, adrenal, adipose tissue	Reduces blood volume, central venous pressure, cardiac output, arterial blood pressure
Brain natriuretic peptide (BNP)	Cardiac ventricles			Increases renal sodium secretion and excretion Increases lipolysis
Melatonin	Pineal gland, retina, gastrointestinal tract	Free	Brain	Circadian rhythms Antioxidant Immune system: increases T-cell response
Renin	Kidney	Free	Plasma	Activates the renin–angiotensin–aldosterone system by cleaving angiotensinogen to angiotensin 1
Calcitriol	Kidney	Free	Intestinal epithelium	Increases calcium absorption from the gastrointestinal tract

- The anterior pituitary exerts control of most endocrine organs, and insufficiency of the anterior pituitary results in atrophy of ovary or testis, adrenal cortex, and thyroid.
- The thyroid and adrenal cortex have no specific target organ, and the hormones they secrete act broadly to contribute to homeostasis.
- The gonads also produce hormones that act on tissues in general and on specific target organs (urogenital apparatus).
- The adrenal medulla secretes adrenalin and noradrenalin, which are released during stressed states enhancing the sympathetic system in a “fight or flight” response.

Physiologic Control of the Endocrine System

- There is no single mechanism for the regulation of hormone activity. However, two main mechanisms of endocrine activity regulation occur though (1) feedback loops, and (2) interaction with the central nervous system.
- Feedback mechanisms allow circulating hormones from the target organs as well as from the anterior pituitary to down- or up-regulate the release of hypothalamic molecules.

- The feedback loop also involves the central nervous structures such as the hippocampus, which contains the highest concentration of glucocorticoid receptors in the central nervous system.
- This self-balancing system stabilizes the endocrine activity under resting conditions but is insufficient in case of enhanced endocrine activity. In the latter case, neurologic control is the key regulator of the endocrine activity, and the hypothalamus plays a key role in the regulation of these hormones.
- The hypothalamus is directly connected to the posterior pituitary and the adrenal medulla. Additionally, it influences the anterior pituitary by releasing in synchronous pulses stimulatory or inhibitory hormones in the hypophyseal portal vessels of the pituitary stalk.
- Complex interactions between distinct feedback loops can occur through interconnections between distinct functional regions within the hypothalamus.
- The effect of CRH on ACTH release by the pituitary is permissive, and vasopressin acts in synergy with CRH. In addition, there are tight interconnections between projections of CRH-synthesizing neurons from the parvocellular nuclei to the brainstem, and reciprocally noradrenergic projections originating from the locus coeruleus and ending in the parvocellular reticular nuclei. Thereby, noradrenaline, CRH, and vasopressin can stimulate one another.
- CRH, vasopressin, and noradrenaline are under the stimulatory control of the serotonergic, cholinergic, and histaminergic systems, and are inhibited by gamma-aminobutyric acid, benzodiazepine, and opioids.

POTENTIAL MECHANISMS OF REGULATION OF THE ENDOCRINE ACTIVITY DURING CRITICAL ILLNESS

The Stressors

- Critical illness is a condition involving multiple stressors of both emotional and physical types.
- Physical stressors can be classified into disease related (e.g., infection, burns, trauma) and intervention related (e.g., surgery, invasive diagnostic or therapeutic procedures, drugs).
- The unpredictable nature, duration, and intensity of the stressors renders the host response more problematic.

Mechanisms of Neuroendocrine Activation in Acute Inflammation

Signals Sent to the Hypothalamic–Pituitary Axis

- Acute inflammatory response to insults such as lipopolysaccharide (LPS) include the release of a number of mediators such as tumor necrosis factor alpha (TNF- α), interleukin (IL)-1, IL-6, IL-8, nitric oxide (NO), and the late mediators, macrophage migration-inhibiting factors (MIF), and high mobility group box-1 (HMGB-1).
- These mediators reach the hypophyseal portal capillaries in the median eminence via the anterior hypophyseal arteries. Cytokines can diffuse into the pituitary as these areas are free of the blood–brain barrier and be carried to the hypothalamus and the brain areas lacking a blood–brain barrier. Addition-

ally, active transport of cytokines can provide a pathway to nuclei inside the blood–brain barrier.

- In addition to the blood-borne cytokines, glial cells can produce a number of cytokines, such as IL-1, IL-2, and IL-6. Similarly, LPS challenge induces IL-6 expression in the anterior pituitary in animals.
- In humans, sepsis induces hypothalamic expression of TNF and IL-1 β within the parvocellular and supraoptic nuclei.
- The induction of IL-1 β and inducible nitric oxide synthase (iNOS) occurs in the meninges, areas lacking a blood–brain barrier, and also in the parvocellular nuclei and the arcuate nucleus, which contain the hypothalamic-releasing and -inhibiting hormones.
- LPS can also be carried by the cerebrospinal fluid to the third ventricle where it crosses the ependyma or acts on projections from parvocellular neurons. Thus, it is likely that delayed overexpression of NO through iNOS activation prolongs the synthesis of hypothalamic hormones induced by LPS.
- In addition, cytokines, via activation of GABAergic (gamma-aminobutyric-acid-releasing) neurons, block NO-induced LH-releasing hormone (LHRH) but not FSH release, inhibit GH-releasing hormone (GHRH) release, and stimulate somatostatin and prolactin release. The regulatory action of NO is mediated by the combined activation of guanylate cyclase, cyclo-oxygenase, and lipoxigenase.
- Cytokines can also directly act on the anterior pituitary, particularly to stimulate ACTH synthesis and release.
- A second pathway of activation of the hypothalamic–pituitary axis is the neural route. Various afferent neurons of the peripheral system sense the threat at the inflammatory sites and stimulate the noradrenergic system and the hypothalamus.
- Stimulation of vagal afferent fibers by LPS results in activation of the locus coeruleus where neurons have projections that synapse on cholinergic interneurons in the parvocellular nucleus.
- It has been shown that CRH is released on acetylcholine stimulation of muscarinic receptors, and that this effect is prevented by nonspecific NO antagonists.
- NO diffuses in the parvocellular cells and induces the generation of both cyclo-oxygenase and lipoxigenase, which in turn stimulate CRH synthesis.

PATTERNS OF ENDOCRINE ACTIVITY DURING CRITICAL ILLNESS

- Infection, LPS challenge, major surgery, trauma, or burns elicit very similar patterns of pituitary hormone secretion. Plasma ACTH and prolactin increase within a few minutes following the insult and are associated with a rapid inhibition of LH and TSH but not FSH. Growth hormone secretion is also stimulated in humans but inhibited in rats.

Hypothalamic–Pituitary–Adrenal Axis

- Acute stress is associated with an immediate increase in the amplitude of hypothalamic hormones, mainly CRH and vasopressin, resulting in increases in amplitude and frequency of ACTH and cortisol pulses and the loss of the circadian rhythm.

- To achieve this enhanced and accelerated release of hormones, the host recruits additional secretagogues of CRH, vasopressin, and ACTH, mainly magnocellular vasopressin and angiotensin II.
- In addition, catecholamines, neuropeptides Y, and to a lesser extent CRH released from the adrenal medulla, as well as direct autonomic neural input to the adrenal cortex, stimulate glucocorticoid secretion.
- The common feature is characterized by high circulating levels of ACTH and cortisol, which remain in plateau as long as the stressful condition is maintained. However, in critical illness, circulating levels of cortisol reflect not only cortisol release, but also cortisol clearance from plasma.
- In critically ill patients, cortisol levels may vary from $<5 \mu\text{g/dL}$ to $>100 \mu\text{g/dL}$ and do not reflect the hypothalamic–pituitary–adrenal (HPA) axis function.

Vasopressin

- Circulating vasopressin levels are regulated through various stimuli including changes in blood volume or blood pressure, plasma osmolality, cytokines, and other neuromediators.
- Acute illness may be associated with inappropriately high circulating levels of vasopressin resulting in water retention and hyponatremia.
- In sepsis, vasopressin levels in plasma seem to follow a biphasic response with initially high concentrations, probably related to the release from posterior pituitary stores on strong baroreflex activation, followed by a decline in 72 hours with relative vasopressin insufficiency occurring in about one-third of cases.
- The delayed decrease in vasopressin levels in plasma is not related to altered hormone clearance from plasma and may result from NO overexpression in the parvocellular nuclei.

The Hypothalamic–Pituitary–Thyroid Axis

- Low T_3 – T_4 syndrome has been described for more than 20 years in fasting conditions and in a wide variety of diseases (e.g., sepsis, surgery, myocardial infarction, transplantation, heart, renal and hepatic failure, cancers, malnutrition, inflammatory diseases) and is also called euthyroid sick syndrome or nonthyroidal illness syndrome (NTIS).
- In the early phase following an acute stress, there is a decrease in serum tri-iodothyronine (T_3) level, an increase in rT_3 level. Then serum thyroxine (T_4) levels decrease within 24 to 48 hours, and TSH levels remain within normal range without a circadian rhythm.
- Underlying mechanisms include the following:
 - Decrease in conversion of T_4 and T_3 in extrathyroid tissues due to inhibition of the hepatic 5'-monodeiodination;
 - The lack of substrates due to the presence of transport protein inhibitors preventing T_4 fixation on the protein;
 - Dysfunction of the thyrotrophic negative feedback on the hypothalamic–pituitary axis;
 - Cytokines (IL-1, IL-6, $\text{TNF-}\alpha$, interferon-gamma [$\text{IFN-}\gamma$]) inhibiting the thyrotrophic centers and/or affecting the expression of thyroid hormone nuclear receptors;
 - The presence of other inhibitory substances such as dopamine.

- Prolonged critical illness is associated with centrally induced hypothyroidism as suggested by restoration of T_3 and T_4 pulses by exogenous thyrotropin-releasing hormone (TRH) infusion.

Growth Hormone

- The acute phase of critical illness is characterized by high GH levels with attenuated oscillatory activity associated with low levels of insulin-like growth factor-1 (IGF-1).
- This pattern is interpreted as a state of resistance to GH that is mainly related to decreased expression of GH receptors.
- This GH resistance seems to be beneficial: the direct lipolysis and anti-insulin effects may be enhanced, liberating metabolic substrates such as free fatty acids and glucose to vital organs, while costly metabolism mediated by IGF-1 is postponed.
- When critical illness–related stress is sustained, the pattern of GH secretion shows less pulsatile fraction and elevated nonpulsatile fraction. It correlates with the low circulating levels of peripheral effectors such as IGF-1.
- However, contrary to the acute phase of critical illness, this reduced secretion of IGF-1 does not reflect resistance to GH, but rather, suggests a hypothalamic origin as confirmed by the restoration of the pulsatile GH secretion pattern by infusion of GH secretagogues.

Adrenal Medulla Hormones

- It is well known that under resting conditions very small amounts of adrenaline and noradrenaline are released from the adrenal medulla (i.e., $<50 \text{ ng/kg/minute}$ in the dog). Therefore, absence of the adrenal medulla is well tolerated under resting conditions.
- However, exposure to stressors like fright, pain, anesthesia, exercise, cold, or endotoxin cause within seconds an increase in circulating adrenaline and noradrenaline concentrations by 2 to 3 logs. This response is absent if the adrenal medulla is removed.
- The release of catecholamines into the circulation accounts for the tachycardia, pupillary dilation, pilar erection, and spitting observed in the stressed animals.
- Adrenaline is stored in the adrenal medulla in vesicles. Noradrenaline is present in the subcellular granules of the sympathetic nervous endings.
- Catecholamines have a very short half-life (10 to 20 seconds for adrenaline) and are metabolized through captation, enzymatic inactivation (methylation in liver or kidney; oxidative deamination by monoamine oxydase), or renal excretion.
- The regulation of catecholamine secretion involves hormonal and nervous factors and negative feedback through calcium channels.
- The hormonal regulation depends on cortisol, which is necessary for the enzymatic degradation of catecholamine synthesis. This interaction relies on nerve transmission, paracrine effect, and the local vascular system.
- The neurogenic regulation involves the cholinergic preganglionic parasympathetic nervous system through the splanchnic nerves.
- Like cortisol, catecholamine levels in plasma can remain elevated as long as the stress is maintained, even up to a few months after recovery.

- Obtaining circulating plasma levels of adrenaline and norepinephrine is useless to assess the appropriateness of the catecholamine response to critical illness.

Insulin

- Insulin is involved in glucose metabolism through (1) mobilization of the store of glucose transport molecules in target cells such as muscle and fat tissue, (2) activation of hepatic glucokinase gene transcription, and (3) activation of glycogen synthetase and inhibition of glycogen phosphorylase.
- Other actions of insulin include growth stimulation, cellular differentiation, intracellular traffic, increased lipogenesis, glycogenesis, and protein synthesis. Insulin also modulates leptin and other adipokine release from fat cells.
- Insulin binds a ubiquitous membrane receptor belonging to the tyrosine kinase family, the IGF-1 and insulin receptor-related (IRR) receptor.
- Insulin levels in plasma are rapidly increased following an acute stress as a result of both increased secretion and tissue resistance.
- Insulin suppresses and antagonizes the effects of TNF, macrophage migration inhibitory factor (MIF), and superoxide anions and decreases the synthesis of the acute phase reactants.

CLINICAL CONSEQUENCES OF ENDOCRINE ACTIVITY DURING CRITICAL ILLNESS

- The immediate activation for the endocrine system, mainly the sympathoadrenal hormones, results in alertness, insomnia,

hyperactivity, pupillary dilation, piloerection, sweating, salivary secretion, tachycardia, rise in blood pressure with vasodilation of skeletal muscle and coronary arteries, bronchiolar dilation, skin vasoconstriction, mobilization of glucose from liver with hyperglycemia, increased oxygen capacity of the blood via spleen constriction and mobilization of red blood cells, and shortening of coagulation time.

- However, in the intensive care unit where flight is not possible, fighting is the only option, and the appropriateness of the neuroendocrine activity to the intensity and duration of the stress determines host survival and recovery (Table 113.3).
- The clinical consequences of the stress system activation include behavioral changes and cardiovascular, metabolic, and immune adaptations.

Behavioral Changes

- In animals, infections are associated with anorexia and body weight loss, hypersomnia, psychomotor retardation, fatigue, and impaired cognitive abilities. Similar behavioral changes are consistently reported in humans after cytokine or LPS challenge.
- The so-called depression due to a general medical condition is likely mediated through release of peripheral and brain cytokines.
- When glucocorticoids and catecholamine responses are insufficient, critically ill patients will develop brain dysfunction that can result to coma.

Cardiovascular Changes

- The cardiovascular adaptation is mainly driven by the sympathoadrenal hormones, even though thyroid hormones and

TABLE 113.3

CLINICAL CONSEQUENCES OF ENDOCRINE ACTIVITY DURING CRITICAL ILLNESS

	Appropriate response to stress	Inappropriate response to stress
Behavioral changes	Alertness, hyperactivity Insomnia, depression	Psychomotor retardation Hypersomnia Impaired cognitive abilities
Cardiovascular changes	Tachycardia Rise in blood pressure Dilation of skeletal blood vessels and coronary arteries Skin vasoconstriction	Anorexia and body weight loss Vasodilatory shock Multiple organ dysfunction
Metabolic changes	Mobilization of glucose from liver Hyperglycemia Mobilization of red blood cells Shortening coagulation time	Generation of free radicals and peroxynitrites Mitochondrial dysfunction Acquisition of superinfection Damage to central and peripheral nervous system Catabolism of muscle protein
Immune changes	Leukocytes accumulating into the inflammatory focus Activation of immune and immune accessory cells Generation of cytokines, neuropeptides, and lipid mediators of inflammation	Change the Th1/Th2 balance toward excess Th2 cells Release of proinflammatory mediators Apoptosis of T lymphocytes, eosinophils, epithelial cells Immune suppression

vasopressin contribute to cardiac adaptation, blood volume, and vasomotor tone regulation.

- Corticosteroids exert important actions on the various elements of the cardiovascular system, including the capillaries, the arterioles, and the myocardium.
- Corticosteroids enhanced vessel responsiveness to various vasoactive agents, particularly catecholamines.
- The underlying mechanisms are not fully understood and may involve direct mobilization of intracellular calcium, enzymatic metabolism of adrenaline, increased binding affinity of adrenaline for its receptor, or facilitation of the intracellular signalization that follows the coupling of adrenaline to its receptor.
- Corticosteroids also have catecholamine-independent effects on the heart and the vessels, and by retaining salt and water help maintain an appropriate blood volume.
- When the hypothalamic—pituitary—adrenal axis or the noradrenergic responses are inappropriate, critically ill patients will develop cardiovascular dysfunction.
- It has been shown that **septic shock patients with adrenal insufficiency**, as defined by an increase in cortisol of 9 $\mu\text{g/dL}$ or less to ACTH challenge, have more pronounced hypotension than those with presumed normal function and are more likely to develop refractory shock. Adrenal failure also resulted in a more prolonged cardiovascular dysfunction and death in the septic patients.
- Adrenal insufficiency can develop in other critical illnesses, particularly in chronically ventilated patients where an association with weaning failure has been observed.
- Adrenal insufficiency is at best diagnosed in critically ill patients by either low baseline cortisol levels (of 10 $\mu\text{g/dL}$ or less) or cortisol increment after 250 μg of corticotropin (ACTH) of 9 $\mu\text{g/dL}$ or less.
- Failure of the noradrenergic system will also result in cardiovascular dysfunction during critical illness.
- A decrease in the pulsatile activity of the HPA axis and the noradrenergic system results in regularity within the circulatory and respiratory functions, enabling the patient to adjust to stressful conditions, losing the interorgan communications that result in multiple organ dysfunction and death.
- Finally, inappropriately low vasopressin levels contribute to the vasodilatory shock associated with many critical illnesses.

Metabolic Changes

- The net result from the activation of the endocrine system is hyperglycemia. The rise in blood glucose follows the activation of the so-called counter-regulatory hormones (glucocorticoids, adrenaline, and glucagon) and results in mobilization of glucose mainly from the liver.
- Subsequently, tissues that are insulin dependent cannot uptake glucose, which is then available for insulin-independent tissues like the brain or inflammatory cells.
- The main reason for critical illness-associated insulin resistance is impairment in glucose transporter isoform-4 (GLUT-4) metabolism. Proinflammatory cytokines such as TNF result in the generation of intracellular ceramides that block the transcription of the gene coding for GLUT-4, preventing the translocation of GLUT-4 to the cell's membrane and entry of glucose into the cells.

- Hyperglycemia has been shown to increase mortality in critical illness. The mechanism underlying glucose toxicity for the cells is still unknown and may include an overloading of the insulin-independent cells such as neurons.
- Excess in the catabolic hormones (cortisol, adrenaline, and glucagon) will also elicit an imbalance between muscle protein breakdown rate and the rate of muscle protein synthesis, resulting in a net catabolism of muscle protein, which may contribute to critical illness-induced muscle weakness and affect long-term prognosis.

Immune Changes

- The changes in the immune function are mainly related to the sympathoadrenal hormones, even though insulin and vasopressin can also influence immunity.
- Glucocorticoids suppress most, if not all, T-cell-derived cytokines and change the T-helper (Th)1/Th2 balance toward excess Th2 cells.
- Glucocorticoids up-regulate lymphocyte-derived IL-10 but do not effect IL-10 synthesis. They also inhibit the synthesis of many other inflammatory mediators such as cyclo-oxygenase and iNOS and down-regulate cell surfaces markers such as endotoxin receptor and adhesion molecules.
- Glucocorticoids enhance the occurrence of apoptosis of thymocytes, mature T lymphocytes, eosinophils, epithelial cells, and precursors of dermal/interstitial dendritic cells, but delay apoptosis of neutrophils.
- Catecholamines also drive a Th2 shift in both antigen-presenting cells and Th1 cells. In LPS-stimulated human blood cultures, noradrenaline and adrenaline inhibit IL-12 synthesis and enhance IL-10 release, an effect that is mediated via beta-adrenergic receptors.
- While the stress hormones glucocorticoids and catecholamines induce systemically a shift of the Th1/Th2 balance in favor of Th2 cells, catecholamines also promote locally at the level of inflamed tissues the synthesis of proinflammatory mediators.
- In addition, at the inflammatory sites, tight cross talk between cytokines and the cortisone/cortisol shuttle, with TNF and IL-1 converting cortisone to cortisol and IL-4 and IL-13 inactivating cortisol into cortisone, helps balance the proinflammatory and anti-inflammatory responses.
- When critical illness is associated with an impaired HPA axis, the Th1/Th2 shift favors the release of proinflammatory mediators in the circulation and in body tissues, allowing cytokine-induced cell deaths either through ischemic or apoptotic mechanisms.

MANIPULATION OF ENDOCRINE ACTIVITY DURING CRITICAL ILLNESS

- The use of exogenous hormones in critical illness has become a standard of care (Table 113.4).
- Although there are no randomized controlled trials of adrenaline, noradrenaline, or dopamine versus a placebo or no treatment, these drugs are routinely administered in critically ill patients with cardiovascular dysfunction.

TABLE 113.4**MANIPULATION OF ENDOCRINE ACTIVITY DURING CRITICAL ILLNESS**

Endocrine intervention	Main effects
Vasopressin	Increases systemic vascular resistance and mean arterial pressure Improves cardiac performance Improves renal function
Corticosteroids	Improves systemic hemodynamics and hastens shock recovery Improves organ dysfunction and mortality
Insulin	Improves morbidity and mortality in both surgical and medical patients
Thyroid hormones	Improves hemodynamics No evidence of survival benefit
Growth hormone	High doses associated with increased morbidity and mortality
Coadministration of GHRP-2, TRH, and GNRH	Beneficial metabolic effects?

Refer to Table 113.1 for abbreviations.

- Although it is clear that exogenous administration of catecholamines or vasopressin can restore hemodynamic stability in critical illness, whether manipulating these hormones helps survival remains uncertain.

- The use of corticosteroids in patients with septic shock has been controversial for several decades and continues to be controversial.
- The effects of corticosteroid administration have been studied, particularly in patients with severe infections. There is enough evidence in the literature supporting the benefit of corticosteroids on hemodynamic and systemic inflammation.
- It is well recognized that a short course of high-dose glucocorticoids should be avoided. In contrast, combined administration of low doses of glucocorticoid and mineralocorticoid improved survival in septic shock patients with demonstrable failure of the HPA axis.
- The updated Surviving Sepsis campaign has given the following recommendation: “We suggest intravenous hydrocortisone be given only to adult septic shock patients after blood pressure is identified to be poorly responsive to fluid resuscitation and vasopressor therapy.”
- Additional recommendations are as follows: fludrocortisone is optional when hydrocortisone is used, and steroid therapy should not be guided by the corticotropin test results.
- In critically ill patients who failed to wean from the ventilator because of adrenal insufficiency, hydrocortisone replacement significantly improved outcome.
- Although there is conflicting evidence, intensive treatment with insulin may significantly improve morbidity and mortality in both surgical and medical patients.
- Thyroid hormone replacement in various critical illnesses, including in patients with cardiac disease, sepsis, acute respiratory distress syndrome, or with burn and trauma patients, was associated with some hemodynamic improvement. However, there is also evidence for side effects—related increased risk of death.
- Growth hormone therapy in critically ill patients is associated with increased mortality.

CHAPTER 114 ■ DISORDERED GLUCOSE METABOLISM

- Disordered glucose metabolism is a significant medical problem in patients in the outpatient, emergency room, ward, and intensive care settings. Diabetes mellitus (DM), the most important group of medical conditions resulting from disordered glucose metabolism, results in significant short-term and chronic morbidity and is increasing in prevalence around the globe.
- In the United States alone, nearly 6% of the population (18.2 million people) are estimated to have this disease. In addition to the many associated chronic health conditions developed by patients with DM, there are several acute and life-threatening conditions that also develop in these patients. Hyperglycemic emergencies, such as diabetic ketoacidosis

(DKA) and hyperosmotic hyperglycemic nonketotic syndrome (HHS), are important causes of morbidity and mortality in patients with DM who are admitted to the intensive care unit.

DIABETIC KETOACIDOSIS

- DKA remains a serious and potentially fatal complication of DM. Overall mortality from DKA is <5%; however, mortality increases substantially with extremes of age, the presence of coma, or the development of hypotension.

- DKA is the initial presentation of DM in up to 30% of patients overall, with approximately 40% of children and 17% of adults presenting in DKA without prior diagnosis of DM.
- While most patients presenting with DKA have type 1 DM, those with type 2 DM can also develop DKA during times of significant physiologic stress.

Pathophysiology

- Normal glucose metabolism is typically tightly regulated to maintain a serum glucose concentration between **70 and 115 mg/dL** (about 3.9–6.4 mm/L) by carefully balancing glucose production in the liver and glucose utilization in peripheral tissues.
- Insulin is mainly responsible for this tight glucose control by stimulating hepatic glucose uptake and storage (glycogen synthesis) and suppressing hepatic gluconeogenesis and glycogenolysis.
- In DKA, either relative or absolute insulin deficiency combined with increased counter-regulatory hormones (CRHs)—glucagon, catecholamines, cortisol, and growth hormone—promotes metabolic pathways opposite to insulin in both hepatic and peripheral tissues.
- Most patients with **type 1 DM** who develop DKA have an absolute or near-absolute insulin deficiency, whereas most patients with **type 2 DM** have either normal or elevated insulin levels.
- These changes are typically the result of a **precipitating event** in patients with severely imbalanced DM (Table 114.1). Infection accounts for 30% to 50% of precipitating causes of DKA, with urinary tract and pulmonary infections making up the vast majority.
- Myocardial infarction, cerebrovascular accident, pulmonary embolism, pancreatitis, trauma, alcohol abuse, and drugs that affect carbohydrate metabolism can also precipitate DKA.
- DKA is also associated with **ketosis**, an additional product of worsening glucose homeostatic decompensation, which occurs as a result of increased lipolysis from increased action of hormone-sensitive lipase.
- Hormone-sensitive lipase is highly up-regulated during periods of insulin deficiency and elevations in CRHs. Hepatic oxidation of free fatty acids induced by hormone-sensitive lipase produces **ketone bodies**, mainly β -hydroxybutyrate (β -OHB) and acetoacetic acid, strong acids that present a large hydrogen ion load to the body.
- The normal buffering systems are rapidly overwhelmed by the ongoing hydrogen load, and an **anion gap acidosis** develops.
- Hyperglycemia and ketonemia produce a hypertonic intravascular environment, resulting in an intracellular water shift into the intravascular and interstitial compartments. The ensuing **cellular dehydration** is accompanied by electrolyte shifts as well.
- When the renal glucose reabsorption rate is exceeded, an osmotic diuresis of water and electrolytes occurs. Sodium, potassium, magnesium, calcium, chloride, and phosphate are all lost during this osmotic diuresis. Commonly, water and electrolyte deficits are compounded by poor oral intake and protracted vomiting.
- The effects of hypovolemia are responsible for the clinical picture as the depletion of the intravascular space produces

TABLE 114.1

PRECIPITATING FACTORS IN DIABETIC KETOACIDOSIS AND HYPEROSMOLAR HYPERGLYCEMIC NONKETOTIC SYNDROME

INFECTION

- Urinary tract infection
- Pneumonia
- Dental infection
- Cellulitis

COEXISTING CONDITIONS

- Acute myocardial infarction
- Cerebral vascular accident
- Pancreatitis
- Pulmonary embolism
- Hyperthermia
- Hypothermia
- Renal failure/dialysis
- Severe thermal injury
- Thyrotoxicosis
- Cushing syndrome
- Mesenteric thrombosis

MEDICATIONS

- Calcium-channel blockers
- β -Blockers
- Chlorpromazine
- Cimetidine
- Diazoxide
- Diuretics
- Ethacrynic acid
- Phenytoin
- Steroids
- Total parenteral nutrition

SUBSTANCE ABUSE

- Alcohol
- Cocaine

UNDIAGNOSED DIABETES MELLITUS

the life-threatening signs and symptoms. The body's response is a further increase in CRH, and the cycle is perpetuated.

Presentation and Diagnosis

- The presentation and diagnosis of DKA is typically straightforward and relies on a thorough patient history, focused physical examination, and appropriate laboratory analysis.
- Patients typically report a history of poor glucose control and symptoms associated with hyperglycemia, such as polyuria, polydipsia, weight loss, and lethargy that may progress over the course of days to weeks.
- **Nausea, vomiting, and abdominal pain** are also common presenting complaints and frequently signify the progression from symptomatic hyperglycemia to overt DKA.
- Physical examination may reveal evidence of dehydration—for example, tachycardia, hypotension, prolonged capillary refill time, poor skin turgor, dry mucous membranes, and weight loss.
- Additionally, **Kussmaul respirations** (very deep, gasping breaths taken in response to severe metabolic acidosis), an acetone or fruity breath odor, depressed mental status, and even focal neurologic deficits or coma may also be seen.

TABLE 114.2

DIAGNOSTIC CRITERIA FOR DIABETIC KETOACIDOSIS (DKA) AND HYPEROSMOLAR HYPERGLYCEMIC NONKETOTIC SYNDROME (HHS)

Parameter	Normal range	DKA	HHS
Plasma glucose (mmol/L)	<6.7	>13.9	>33
Arterial pH	7.35–7.45	<7.30	>7.30
Serum bicarbonate (mmol/L)	22–28	<15	>15
Anion gap	>10	>12	<12
Serum osmolality (mOsm/kg)	Variable	Variable	>320
Serum ketones	Negative	Moderate to high	None
Urine ketones	Negative	Moderate to high	None

Adapted from Kitabchi AE, Umpierrez GE, Murphy MB, et al. Management of hyperglycemic crises in patients with diabetes. *Diabetes Care*. 2001;24:131–153; and Chiasson JL, Aris-Jilwan N, Belanger R, et al. Diagnosis and treatment of diabetic ketoacidosis and the hyperglycemic hyperosmolar state. *CMAJ*. 2003;168:859–866.

- **Laboratory analysis** is usually confirmatory of DKA in these patients (Table 114.2). A complete blood count, blood glucose, serum electrolytes, serum osmolality, blood urea nitrogen, serum creatinine, arterial or venous blood gas, serum ketones, and urinalysis should be ordered in patients with suspected DKA.
- Caution should be exercised when using the **serum sodium levels** in patients with DKA, as the reported laboratory value can be artificially low, normal, or elevated, depending on the spurious effects of glucose and triglycerides in these patients and the relative loss of water compared to sodium.
- In the presence of hyperglycemia, serum sodium measurement can be corrected by adding **1.6 mg/dL** to the measured serum sodium for **each 100 mg/dL increase** of glucose above normal.
- Appropriate cultures should be requested if infectious triggers of DKA are suspected.
- Other tests, such as serum lactate, β -human chorionic gonadotropin (β -HCG), electrocardiography, chest radiography, and computed tomography may be indicated, depending on the clinical scenario.
- A plasma anion gap–associated metabolic acidosis, due to the high ketone concentration, is typically seen in laboratory analysis of patients with DKA. However, in up to 11% of patients, a nongap hyperchloremic metabolic acidosis may occur instead.
- Other causes of anion gap–associated metabolic acidosis, which must be excluded during DKA evaluation, include alcoholic ketoacidosis, starvation ketoacidosis, and lactic acidosis, as well as methanol, ethylene glycol, paraldehyde, and salicylate ingestion.
- Ketonemia and ketonuria can both be assessed semiquantitatively with the nitroprusside reaction test. This test estimates the relative levels of acetoacetate and acetone in the blood, but does not detect the presence of β -OHB, potentially underestimating the degree of ketosis.
- Because the ratio of β -OHB to acetoacetate may increase from 1:1 to as much as 5:1 during the development of DKA, β -OHB may represent the predominant ketone during illness. Of note, β -OHB monitoring may significantly improve the diagnostic specificity in DKA patients with euglycemia or only mild hyperglycemia—as with prolonged vomiting, starvation, pregnancy, hepatic insufficiency, or follow-

ing insulin administration—where blood glucose levels can be misleading.

Management

- Management of DKA includes the phases of initial resuscitation, correction of hyperglycemia and resolution of ketosis, and treatment of any precipitating causes.
- As with all resuscitations, evaluation and treatment of airway and breathing dysfunction should be done first. DKA can cause loss of protective airway reflexes, hypoxia, and hyperventilation.
- If the patient's **Glasgow Coma Scale** is **8 or less**, or in situations that require sedation and transport away from the acute care environment for further evaluation, tracheal intubation may be necessary to ensure adequate **airway protection** and ventilation.
- Because these patients have a high incidence of **gastroparesis**, the placement of a decompressive gastric tube may also be warranted in the presence of an altered level of consciousness, and elevation of the head of bed to between 30 and 40 degrees may serve to prevent passive regurgitation.
- Mechanical ventilation, if utilized, should be set to maintain respiratory compensation of the accompanying severe metabolic acidosis initially and adjusted appropriately as the acidosis corrects.
- Following airway and respiratory care, initial therapy should be directed at restoring adequate **blood volume and organ perfusion** with intravascular volume resuscitation.
- In addition to correcting the hemodynamic insults associated with severe hypovolemia, appropriate volume administration can also decrease CRH levels and plasma glucose concentration.
- The goal during this phase is to replace the fluid deficit over the first 24 hours, half of which should be replaced in the first 6 to 8 hours. Typically 1 to 2 L of isotonic saline in the first 1 to 2 hours is sufficient for initial resuscitation; however, in more severe cases the resuscitation may require larger volumes, and some prefer to add colloids.
- The following clinical estimations of volume deficit using orthostatic blood pressure and heart rate may also be used

to guide initial fluid replacement, although these criteria may be less reliable in patients with neuropathy and/or impaired cardiovascular reflexes:

- An **increase in pulse** without change in blood pressure with orthostatic position change indicates approximately a **10% decrease** in extracellular volume (i.e., 2 L).
- A **decrease in blood pressure** ($> 15/10$ mm Hg) with position change indicates approximately a **15% to 20% decrease** in extracellular volume (i.e., 3–4 L).
- Supine hypotension indicates a decrease of $> 20\%$ in extracellular fluid volume (i.e., > 4 L).
- Invasive monitoring should be provided as necessary; patients with mild to moderate DKA may require only noninvasive blood pressure monitoring, continuous electrocardiography, pulse oximetry, and a urinary catheter, whereas patients with the most severe disease states and comorbidities may, in addition, require arterial and central venous catheterization.
- Additionally, patients with oliguria or hypotension refractory to initial rehydration, mental obtundation, sepsis, respiratory insufficiency, pregnancy, or significant comorbidities or precipitating events, such as myocardial infarction or decompensated congestive heart failure, should be managed in a critical care environment.
- After the initial resuscitation phase, both the rate of infusion and type of intravenous fluid must be adjusted. Current recommendations are to decrease the infusion rate to 250 mL/hour or to **4 to 14 mL/kg/hour**, depending on the patient's hydration status and goal replacement volume.
- Depending on the patient's corrected serum sodium, isotonic saline is continued or changed to hypotonic saline. If the patient's corrected serum sodium is low, 0.9% saline solution should be continued as the replacement fluid.
- Once plasma glucose levels reach 250 mg/dL, either 5% or 10% dextrose solution should be added to the replacement fluids to maintain serum glucose levels between 150 and 200 mg/dL, to allow the insulin infusion to continue until ketosis is reversed, and to prevent the too rapid correction of serum glucose levels.
- Concomitant with aggressive fluid resuscitation, insulin therapy to decrease glucose production and increase glucose utilization with subsequent improvements in ketosis, acidosis, and hyperglycemia should be instituted.
- Most experts recommend **low-dose insulin infusion** over intermittent intravenous or subcutaneous administration, as the former is more physiologic and more therapeutically reliable and decreases the risk of hypoglycemia and hypokalemia.
- Continuous insulin infusion is the preferred route of insulin in all but the mildest cases of DKA.
- For continuous insulin infusion, many experts recommend an **initial bolus** of regular insulin of 0.1 to 0.15 U/kg followed by an infusion at 0.05 to 0.1 U/kg/hour, with a goal of decreasing plasma glucose levels by **no more than 50 to 75 mg/dL/hour**.
- If the plasma glucose level does not respond appropriately in the first few hours, and if the intravascular volume status is adequate, the infusion rate may be doubled every hour until a constant decline in plasma glucose level is achieved.
- In addition to serum glucose and bicarbonate levels, the American Diabetic Association recommends evaluation of β -OHB levels as the preferred method of monitoring DKA, which may become the preferred method for rapid diagnosis.
- Typically, β -OHB concentrations are < 1 mmol/L; however, in patients with DKA, plasma β -OHB concentration can be elevated to concentrations in excess of 4 to 12 mmol/L (mean 7 mmol/L). Adequate DKA treatment should prompt a decrease in β -OHB concentration by approximately 1 mmol/L/hour, and should return to baseline (< 1 mmol/L).
- Despite massive potassium losses (3–5 mEq/kg) in patients presenting with DKA, the serum potassium concentration may be normal due to intravascular volume contraction and intracellular electrolyte shifts. The addition of potassium to the fluids, once adequate renal function is ensured, can help prevent hypokalemia during DKA treatment.
- In patients with significant hemodynamic compromise or severe hypokalemia (i.e., with a serum potassium level < 3.3 mEq/L), insulin should be temporarily withheld as resuscitation occurs, because the reduction in plasma glucose levels and acidosis can cause significant intracellular fluid and potassium shifts that may worsen cardiovascular function to the point of collapse.
- Severe hypokalemia may occur with resuscitation and insulin therapy and potentially cause life-threatening cardiac dysrhythmias and respiratory muscle weakness. **Potassium replacement** should begin once the serum potassium concentration falls **below 5.5 mEq/L**, assuming adequate urine output, using the following guidelines:
 - If the serum potassium is 4 to 5 mEq/L, 20 to 30 mEq of potassium should be added to each liter of intravenous fluid.
 - If the serum potassium is 3 to 4 mEq/L, 30 to 40 mEq of potassium should be added to each liter of intravenous fluid.
 - If the serum potassium is < 3 mEq/L, 40 to 60 mEq of potassium should be added to each liter of intravenous fluid.
- In addition to potassium, other electrolytes such as **magnesium, phosphate, and calcium** are also depleted in patients with DKA. Inadequate serum concentrations of these electrolytes may cause respiratory depression, cardiac dysfunction, and alteration of tissue oxygenation that can be avoided by aggressive monitoring and appropriate replacement.
- Measurement of these electrolytes should be done at presentation to identify significant abnormalities in order to facilitate appropriate correction as early as clinically indicated. And they should be repeated as necessary, depending on the clinical scenario.
- Of note, hypocalcemia may become problematic in the face of overaggressive phosphate replacement.
- Adequate treatment of DKA—intravascular volume repletion with reversal of hyperglycemia and ketosis—is generally associated with improvements in both physiologic and laboratory parameters. Criteria for resolution of DKA include plasma glucose < 200 mg/dL, serum bicarbonate concentration ≥ 18 mEq/L, venous pH > 7.3 , anion gap < 12 mEq/L, and, recently, β -OHB < 1 mmol/L.
- After resolution of the DKA episode, when the patient is able to tolerate enteral nutrition, a multidose subcutaneous insulin regimen that includes a combination of short- and intermediate- or long-acting insulin should be instituted.
- To allow for sufficient insulin plasma levels, intravenous insulin should be continued for 1 to 2 hours following the first dose of subcutaneous insulin.
- Following these acute phase, it is essential to also provide chronic therapy to prevent repeated episodes and secondary sequelae of diabetes mellitus.

TABLE 114.3

COMPLICATIONS OF DIABETIC KETOACIDOSIS AND HYPEROSMOLAR HYPERGLYCEMIC NONKETOTIC SYNDROME TREATMENT

- Hyperglycemia
- Hypoglycemia
- Electrolyte disturbances (hypokalemia, hyperkalemia)
- Hyperchloremic metabolic acidosis
- Cerebral edema
- Intravascular volume overload
- Hypoxemia
- Noncardiogenic pulmonary edema
- Acute respiratory distress syndrome
- Rhabdomyolysis
- Thromboembolism
- Pancreatitis

Complications

- Common **complications** encountered during DKA treatment include hypoglycemia and hyperglycemia, various electrolyte disturbances, lactic acidosis, intravascular volume overload, cerebral edema, acute respiratory distress syndrome, coagulopathy, rhabdomyolysis, and thromboembolism (Table 114.3).
- **Hypoglycemia** and hyperglycemia are common complications of DKA treatment. While intensive intravenous insulin therapy decreases blood glucose levels, reverses ketone body formation, and improves insulin sensitivity, it also places the patient at significant risk for hypoglycemia and its associated serious complications, including significant cognitive dysfunction, coma, and death.
- The incidence of serious hypoglycemic episodes associated with DKA treatment can be substantially decreased with the institution of low-dose insulin protocols, the addition of **dextrose-containing solutions** to intravenous fluid management when the blood glucose concentration reaches **250 to 300 mg/dL**, and the institution of frequent blood glucose monitoring with frequent insulin infusion rate titration.
- Additionally, hyperglycemia—with the potential for DKA to recur—can be seen following the resolution of DKA, due in large part to abrupt termination of the intravenous insulin infusion without adequate overlap of nonintravenous therapies, including subcutaneous insulin.
- Hypokalemia may be responsible for associated dysrhythmias, skeletal muscle weakness, and ileus. Treatment of the acidemic state with bicarbonate and inadequate potassium replacement predisposes patients to hypokalemia.
- **Cerebral edema** is a rare, but devastating, complication of DKA therapy. It occurs more commonly in pediatric populations and may be seen in up to 1% of the patients treated for DKA. The exact reason for the development of cerebral edema during DKA treatment remains unproven; however, it is felt to be related to an overly **rapid correction** of the hyperosmolar state. For this reason, current recommendations state that the change in serum osmolality resultant from therapy should not exceed 3 mOsm/kg/hour, and, in patients with concomitant cardiac and renal compromise, serum osmolality should be monitored frequently.

- With worsening cerebral edema, intracranial pressure may significantly increase—occasionally to the point of brainstem herniation with associated respiratory arrest and cardiovascular derangements. For this reason, careful monitoring should be done during DKA treatment for signs of cerebral edema and brainstem herniation such as the acute onset of headache, changes in the level of consciousness, the development of papilledema, or the onset of seizures.
- Sodium and water deficits are slowly corrected, and rapid decreases in blood glucose levels are avoided. Treatment of this condition is largely supportive and may be improved with the use of mannitol as an osmotic diuretic to decrease the amount of cerebral edema.
- Acute respiratory distress syndrome is also a rare but potentially fatal complication that may occur at any time during the process of DKA. The disorder may be linked to the underlying cause of DKA as a source of infection or the treatment phase with associated fluid resuscitation, fluid shifts, and changing osmotic gradients.

HYPEROSMOLAR HYPERGLYCEMIC NONKETOTIC SYNDROME

- HHS is a medical emergency that develops in response to one of many **precipitating conditions** (see Table 114.1) in patients with type 2 DM.
- Among adults in the United States, the incidence of HHS is approximately 17.5 cases per 100,000 persons per year and results in significant morbidity and mortality. The mortality rate from HHS is related directly to patient age, considering that mortality is, for example, <10% in patients younger than 75 years of age compared to 35% in patients older than 84 years of age.
- In approximately 20% of patients presenting with HHS, this diagnosis is their initial presentation with type 2 diabetes. Additionally, the diagnosis is usually made after significant delay and is made more complex because HHS can coexist with DKA in approximately 30% of patients.

Pathophysiology

- The basic pathophysiologic abnormality in HHS is a **relative insulin deficiency** caused by both an increase in peripheral insulin resistance and an increase in blood levels of the counter-regulatory hormones glucagon, cortisol, and growth hormone.
- Various catecholamines increase hepatic and renal glucose production and further worsen peripheral tissue glucose utilization.
- Together, the above defects cause an insidious but dramatic rise in serum glucose concentration, typically over days to weeks.
- With increasing serum glucose concentration, an **osmotic gradient** develops between the intravascular and extravascular compartment. Because water moves from the extravascular compartment down this osmotic gradient, both intracellular dehydration and a transiently increased intravascular volume with relative serum hyponatremia can occur.
- As the serum glucose concentration continues to rise, osmotic diuresis causes profound decreases in intravascular volume,

coupled with losses of vital electrolytes such as sodium, potassium, phosphate, and magnesium.

- This **large intravascular volume loss** can result in life-threatening end-organ hypoperfusion and nonketotic metabolic acidosis.
- Compared to DKA, ketones are minimally produced in patients with HHS likely due to the ability of the pancreas to secrete insulin. The amount of insulin, while not sufficient to prevent hyperglycemia in these patients, does prevent fatty acid lipolysis and the formation of ketone bodies and development of ketoacidosis.

Presentation and Diagnosis

- Because patients with HHS typically fail to develop ketoacidosis, the time from onset to diagnosis and treatment can be significantly longer than in patients with DKA. The clinical diagnosis of these patients, therefore, requires a high index of clinical suspicion.
- Patients with suspected HHS may initially exhibit nausea/vomiting, visual disturbances, muscle weakness, and leg cramps. Left untreated, these patients eventually develop confusion, lethargy, hemiparesis, seizures, and coma.
- Physical examination may reveal both signs of profound dehydration—such as decreased skin turgor and dry mucous membranes—as well as abdominal distension from gastroparesis.
- Initial laboratory evaluation in patients with suspected HHS should include serum glucose, ketones, electrolytes, and creatinine concentration; serum measured and calculated osmolality; urinalysis; and appropriate empiric bacterial and fungal cultures (see Table 114.2).
- Because these patients can have significantly elevated serum glucose concentrations—as $\geq 1,000$ mg/dL—the serum osmolality can be quite high and seems to correlate with neurologic symptoms.

Management

- The treatment goals for HHS include aggressive intravascular fluid replacement, insulin administration to correct hyperglycemia, appropriate electrolyte replacement, and, if indicated, respiratory system support. Ultimately, effective patient education and long-term patient support are also important.
- First, treatment of the triggering disorder should be started.
- HHS treatment is typically undertaken in two phases. The first is the acute—emergency—phase and consists of rapid **restoration of circulatory volume and electrolyte deficits** with concomitant insulin administration to correct serum hyperglycemia, hyperosmolality, and metabolic acidosis.
- The second phase is a transitional phase centered on changing insulin replacement to appropriate chronic diabetes therapy (i.e., subcutaneous or oral hypoglycemic regimen), as well as patient education and support.
- In patients with HHS, the total body water deficit can be as high as 100 to 200 mL/kg in adults; thus, fluid replacement is the mainstay therapy for intravascular collapse and poor organ perfusion.

- Initially, 0.9% saline solution should be infused at **15 to 20 mL/kg total body weight per hour** to restore extracellular fluid volume deficit. Normal saline infusion should continue until blood pressure and end-organ perfusion have been normalized. The intravenous solution should then be changed to 0.45% saline solution at a reduced rate to restore the intracellular fluid deficit.
- The overall fluid resuscitation goal should be replacement of one-half of the estimated fluid deficit over the first 8 hours, and the other half of the estimated fluid deficit over the next 16 hours. Care should be taken to ensure that the serum osmolality does **not decrease more than 3 mOsm/kg/hour** to reduce the risk of acute cerebral edema.
- The cornerstone of therapy for HHS is intravenous insulin given to restore normal peripheral glucose uptake, suppress lipolysis, and decrease hepatic gluconeogenesis.
- **Insulin** should be initially given as an intravenous **bolus of 0.15 units/kg**, followed by a continuous infusion of **0.1 unit/kg/hour** with a goal glucose decrease of 50 to 75 mg/dL/hour. While the patient is receiving intravenous insulin, the glucose should be **monitored every 1 to 2 hours** via either capillary or serum samples.
- Once the serum glucose decreases to 250 mg/dL, dextrose should be added to the intravenous fluid administration and the insulin infusion should be decreased to 0.05 to 0.1 U/kg/hour.
- Complications of insulin therapy include hypoglycemia, hypokalemia (insulin infusion should not begin with serum potassium <3.5 mEq/dL), and hypophosphatemia.
- Electrolyte replacement is also an important component to the management of HHS. **Hypokalemia** can develop during HHS due to intracellular shift of potassium ions from the extracellular compartment and losses due to the osmotic diuresis. For this reason, electrocardiographic monitoring should be utilized during this phase of therapy, and aggressive potassium replacement—with up to 40 mEq/hour—may be necessary.
- **Hypophosphatemia** may also develop secondary to the ongoing osmotic diuresis. Replacement of phosphate during HHS treatment seems prudent; however, several prospective randomized studies have failed to show a definitive benefit to phosphate replacement in the absence of decreased cardiac or respiratory function and anemia.

Complications

- In addition to the electrolyte abnormalities discussed above, complications from HHS include pancreatitis, rhabdomyolysis, thromboembolism, hyperchloremic metabolic acidosis, cerebral edema, acute gastric dilatation, and acute respiratory distress syndrome (see Table 114.3).
- Patients with HHS are at increased risk for **thromboembolism**, and thus, subcutaneous heparin administration may be warranted to prevent thromboembolic complications.
- Complications of HHS treatment include intravascular volume overload and acute cerebral edema from overaggressive intravenous fluid administration. Intravascular volume overload is seen as hypoxemic respiratory failure—often with pulmonary edema—and lower extremity pitting edema.
- **Acute cerebral edema** is manifested by headache, lethargy, and depressed levels of consciousness that can rapidly progress to brainstem herniation. Treatment of this

TABLE 114.4

RELATION BETWEEN INTENSIVE INSULIN THERAPY AND OUTCOME IN CRITICALLY ILL PATIENTS

Study	DIGAMI	Leuven I	Portland	Stamford	Leuven II
Patient population	Acute MI (N = 620)	Surgical (N = 1,548)	CABG (N = 3,554)	Medical ICU (N = 1,600)	Medical ICU (N = 767)
Diabetes	100%	13%	100%	17%	15%
Decrease in mortality rate	30%	34%	53%	29%	18%
Reason for reduced mortality rate	N/K	Sepsis	HF, VT, VF	N/K	Multiple
Hypoglycemia (%) (glucose level, mmol/L) ^a	17 (<3.0)	5.2 (<2.2)	0.8 (<3.3)	1.3 (<3.3)	25 (<2.2)
Mean glucose (mmol/L):					
Intensive treatment	9.2	5.7	9.8	7.3	5.8
Conventional treatment	12.0	8.5	11.8	8.4	8.6

CABG, coronary artery bypass graft; HF, heart failure; ICU, intensive care unit; MI, myocardial infarction; VF, ventricular fibrillation; VT, ventricular tachycardia; N/K, unknown.^a 1 glucose mmol/L = 18 mg/dL.

potentially devastating complication consists of administering an osmotic diuretic such as mannitol and supportive care.

GLYCEMIC CONTROL AND INSULIN THERAPY IN THE INTENSIVE CARE UNIT

- Over the past decade, multiple published studies (Table 114.4) suggested that intensified glycemic control of intensive care unit (ICU) patients by using intravenous insulin infusion results in improved outcomes, including decreased mortality rate. Although these observations led to dramatic changes in the management of ICU blood glucose control in both Europe and North America, concerns have been raised about the optimal range of glycemic control for ICU patients and the clinical implication of the increased risk of iatrogenic hypoglycemia.
- Although there were significant differences in design, blood sugar target, and patient population among all studies listed in Table 114.4, the results were, for the most part, fairly similar. Intensive therapy with intravenous insulin produced a consistent decrease in mortality rate in a variety of patient populations.
- In contrast, two recent multicenter randomized control trials (RCTs) of intensive insulin therapy—one focused on patients with severe sepsis (VISEP) and the second on medical and surgical ICU patients—failed to demonstrate improvement in mortality.
- The benefit of intensive insulin therapy may be a result of decreased infection rates with improving glycemic control.
- A higher rate of hypoglycemia was observed in the intensive insulin groups. This finding is particularly important for ICU patients who are commonly sedated and mechanically ventilated since aggressive lowering of serum glucose levels may

carry the risk of hypoglycemia, which is potentially more difficult to detect.

- In the case of sepsis, the most current Surviving Sepsis Campaign (Table 114.5) provides recommendations for glycemic control in the ICU.
- Until the full results of the ongoing studies become available, intensive insulin therapy to *all ICU patients* remains unsupported, and should be viewed with a healthy degree of scientific skepticism.

TABLE 114.5

THE SURVIVING SEPSIS CAMPAIGN 2008 CONSENSUS RECOMMENDATION ON GLUCOSE CONTROL DURING SEVERE SEPSIS

- Following initial stabilization, intensive care unit patients with severe sepsis and hyperglycemia to receive intravenous insulin therapy to reduce blood glucose levels (grade 1B)
- Validated protocol to be used for insulin dose adjustments and targeting glucose levels to the <150 mg/dL range (grade 2C)
- All patients receiving intravenous insulin to receive a glucose calorie source in addition to monitoring blood glucose values every 1–2 h until glucose values and insulin infusion rates are stable, then every 4 h thereafter (grade 1C)
- Caution taken if using point-of-care testing for capillary blood glucose as it may overestimate arterial blood or plasma glucose values (grade 1B)

Adapted from Dellinger P, Levy MM, Jean M, et al. Surviving Sepsis Campaign: international guidelines for management of severe sepsis and septic shock: 2008. *Crit Care Med*. 2008;36(1):296–327.

CHAPTER 115 ■ THE ADRENAL GLAND IN CRITICAL ILLNESS

- The most important adrenal problem affecting the intensivist is impaired production of adrenal steroids. Individuals with impaired capacity to produce adrenal steroids can become critically ill with illnesses that are otherwise trivial and are unlikely to improve in the absence of steroid replacement. Critically ill patients may also develop adrenal insufficiency in the course of an intensive care unit (ICU) admission secondary to the effects of the underlying disease, or its treatment, on either the pituitary or adrenal gland.
- Furthermore, it has been suggested that conditions such as septic shock and acute respiratory distress syndrome (ARDS) might frequently be associated with a relative deficiency of adrenal steroids and, thus, patients with these conditions might benefit from steroid treatment, even in the absence of preexisting adrenal disease.

STRESS POINTS

- The most important hormones synthesized by the adrenal gland are cortisol (the main glucocorticoid) and aldosterone (the main mineralocorticoid). Cortisol production is regulated by adrenocorticotropin hormone (ACTH) secretion, whereas aldosterone secretion is primarily regulated by the renin–angiotensin system.
- Corticosteroid insufficiency (hypoadrenalism) is the most important clinical problem involving the adrenal gland in the ICU setting. It can occur as a result of diseases that directly affect the adrenal gland (primary adrenal insufficiency) or those that impair ACTH production from the pituitary (secondary adrenal insufficiency). Corticosteroid insufficiency can be difficult to recognize since its clinical features are similar to those of other severe illnesses, and some features are masked by ICU interventions. Unrecognized, corticosteroid insufficiency is associated with a high mortality. The **clinical findings** associated with adrenal insufficiency are shown in Table 115.1.
- The diagnosis of adrenal insufficiency is difficult in critically ill patients due to the insensitivity of clinical features and the dramatic and variable changes that occur normally in the **hypothalamic–pituitary–adrenal (HPA) axis** during severe illness. The interpretation of biochemical tests is difficult and will depend on the clinical context. Where there is uncertainty, empiric glucocorticoid replacement is indicated.
- When the possibility of adrenal insufficiency during critical illness has been raised, definitive testing to determine whether it is present, persistent, and its nature (e.g., pituitary vs. Adrenal) will be needed, but only when the patient's condition has improved so as to safely allow the studies.

ESSENTIAL DIAGNOSTIC TESTS AND PROCEDURES

- The symptoms, physical signs, and laboratory findings traditionally associated with hypoadrenalism are not sufficiently sensitive to be reliable in making the diagnosis of adrenal insufficiency. Rather, these may suggest the need for biochemical testing.
- The diagnosis will usually be made on either a random serum **cortisol level**, the level of cortisol achieved after a **short ACTH test**, or (in the specific situation of septic shock) a poor **increment** in cortisol across a short ACTH test (Figs. 115.1 and 115.2).

PHYSIOLOGY OF THE ADRENAL GLAND

- The adrenal cortex is the site of synthesis of adrenal corticosteroids, whereas the medulla synthesizes catecholamines.

Anemia
Eosinophilia
Vasopressor insensitivity
Systemic inflammatory response in absence of infection

^aFeatures usually present in primary adrenal insufficiency but not secondary adrenal insufficiency.

Diagnostic algorithm in ICU patients without septic shock (only if features suggesting AI)

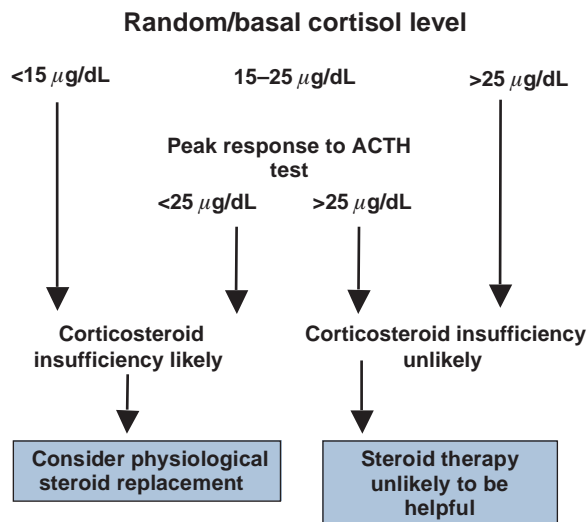

FIGURE 115.1. The combination of basal values and peak responses to ACTH tests is intended to avoid missing corticosteroid insufficiency of either central or adrenal origin.

- The cortex is structurally and functionally divided into layers (zones) that secrete mineralocorticoids, glucocorticoids, and adrenal androgens.

Adrenal Hormones

- The main hormones synthesized by the adrenal cortex are aldosterone (the main mineralocorticoid), cortisol (the main glucocorticoid), and dehydroepiandrosterone (the main adrenal androgen).
- **Aldosterone**, in conjunction with cortisol, regulates salt and water balance. The main action is to **increase sodium resorption** within the distal nephron; it also regulates sodium excretion from the skin (in sweat), the pancreas, and the colon.
- Cortisol action affects almost all tissues in the body and is important in maintaining homeostasis under resting and stress conditions. Cortisol in the circulation is **heavily bound** to serum proteins—**corticosteroid-binding globulin (CBG)** and **albumin**—such that only a small fraction is available in a tissue in free form.
- Adrenal androgens are the most abundantly produced adrenal steroids, but their clinical significance is minor compared to the other adrenal steroids, and they are not routinely substituted in patients with adrenal insufficiency.
- Adrenaline is the main catecholamine secreted from the adrenal medulla. Although this hormone may modify some aspects of the stress response, the relative normality of individuals who have had both adrenal medullas removed suggests that this action is of limited importance in most situations.

Regulation of Adrenal Hormone Synthesis

- Cortisol is synthesized in response to ACTH, which is released from the anterior pituitary.

Diagnostic algorithm in septic shock

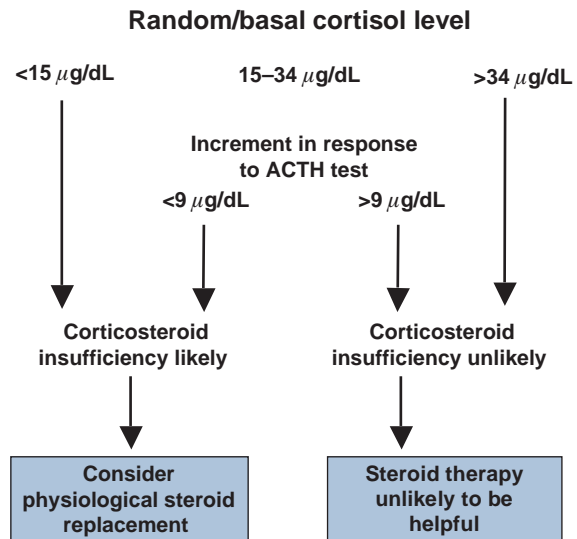

FIGURE 115.2. An adequate basal response is required to rule out central causes of corticosteroid insufficiency, whereas an adequate increment has been reported to be needed to exclude relative adrenal insufficiency. The use of an incremental response outside of the setting of septic shock is not recommended. (Adapted from Cooper MS, Stewart PM. Corticosteroid insufficiency in acutely ill patients. *N Engl J Med.* 2003;348:727–734.)

- ACTH release is controlled by hypothalamic **corticotrophin-releasing hormone (CRH)** secretion. Central activation of the HPA axis occurs with all physiologic stressors and also entrains the diurnal rhythm of cortisol secretion.
- ACTH has an important trophic action on the adrenal cortex, and continued ACTH secretion is essential to maintain the structural integrity of the cortex and the capacity to generate cortisol.
- Impairment of ACTH secretion leads to a prolonged reduction in the capacity of the adrenal to respond to exogenous ACTH.
- During severe illness, factors such as hypotension, pain, anxiety, and endotoxin substantially increase ACTH and cortisol secretion. The level of CBG also decreases rapidly due to a combination of reduced synthesis and increased breakdown. These combined effects lead to increased **free cortisol levels** and increase cortisol levels within target tissues.
- Aldosterone synthesis is under control of **both ACTH and angiotensin II (AngII)** with the rate-limiting step regulated by AngII.
- The activity of the renin–angiotensin system is thus the most important factor in regulating aldosterone synthesis.

Glucocorticoid Action

Metabolic Effects

- Glucocorticoids strongly influence most of the metabolic pathways involved in energy homeostasis. The effects ensure that **glucose is readily available** as a fuel.
- Glucocorticoids induce enzymes responsible for hepatic gluconeogenesis and antagonize the anabolic actions of insulin on glycogen deposition.

- Glucocorticoids also increase the production of fuels for gluconeogenesis by stimulating muscle amino acid generation and adipose tissue fatty acid synthesis.
- Prolonged glucocorticoid stimulation may result in adverse outcomes. Increased gluconeogenesis increases the risk of glucose intolerance and hyperglycemia. Continued breakdown of protein leads to myopathy, skin thinning, easy bruising, and poor wound healing. Increased peripheral lipolysis leads to loss of fat on limbs but accumulation of central fat.

Cardiovascular Effects

- Glucocorticoids have important effects on salt and water balance, which are likely to be an important part of the stress response protecting against hemorrhage or sepsis.
- Glucocorticoids contribute to renal **sodium reabsorption**, even though the dominant regulatory pathway is via aldosterone, and also have a major impact on the capacity to excrete water through the kidneys.
- A deficiency of glucocorticoids can result in excessive water retention and **hyponatremia**.
- In the absence of glucocorticoids, the vasculature can become **insensitive** to the pressor effects of **catecholamines**.

Immunologic Effects

- Glucocorticoids impact the development, migration, and survival of leukocytes, reduce the synthesis of proinflammatory cytokines by immune cells, and block tissue production of eicosanoids such as prostaglandins and leukotrienes.
- While excessive glucocorticoid action can lead to immunosuppression, glucocorticoid deficiency states are also associated with impaired resistance to microbial infection.

Other Effects

- Glucocorticoids can alter bone metabolism, leading to osteoporosis and fractures.
- Glucocorticoids may also induce a range of neuropsychiatric symptoms ranging from sleep disturbance to frank psychosis.

CORTICOSTEROID INSUFFICIENCY

- Corticosteroid insufficiency can occur with diseases or interventions that involve the adrenal gland directly (**primary adrenal insufficiency**) or occur from impaired ACTH production due to hypothalamic or pituitary disease (**secondary adrenal insufficiency**).

Causes of Corticosteroid Insufficiency

- Worldwide, the most common cause of permanent hypoadrenalism is tuberculous adrenalitis.
- In the general population, adrenal insufficiency is most frequently encountered in patients who have developed hypoadrenalism secondary to recent oral glucocorticoid usage.
- During critical illness, reversible adrenal insufficiency may develop secondary to many factors, including the use of anesthetic agents and antibiotics, central nervous system (CNS) disease, and adrenal insults that may comprise hemorrhage, infection, and hypoperfusion (see Table 115.1).

- Increased proinflammatory cytokine production during sepsis can also induce systemic glucocorticoid resistance such that normal adrenal responses may be insufficient to control systemic inflammation.
- Secondary hypoadrenalism due to recent exogenous glucocorticoid therapy may suppress the HPA axis, with consequent adrenal atrophy that may last for months after cessation of glucocorticoid treatment.
- Adrenal atrophy and subsequent deficiency depends on both the dose and duration of treatment but should be anticipated in any patient taking (or having recently stopped) more than 30 mg hydrocortisone per day or equivalent for more than 3 weeks.
- In such subjects, hypoadrenalism may be precipitated by failure to give adequate glucocorticoid replacement for intercurrent stress.

Clinical Presentation

- The clinical presentation of adrenal insufficiency differs greatly between the endocrine outpatient setting and the ICU. In critically ill patients, **classical features may be masked**.
- In the outpatient setting, clinical features depend on the rate of onset and severity of adrenal deficiency. The onset may be insidious, with presenting symptoms such as weakness, weight loss, nausea, abdominal pain, arthralgia, and postural syncope, and the diagnosis being made only with the development of an acute crisis during an intercurrent illness.
- Skin pigmentation usually differentiates primary from secondary hypoadrenalism, reflecting the persistently high circulating ACTH concentrations in the former condition. In autoimmune Addison disease, there may be associated vitiligo.
- In secondary adrenal insufficiency due to hypopituitarism, the presentation may relate to symptom complexes due to deficiency of hormones other than ACTH, notably leuteinizing hormone (LH)/follicle-stimulating hormone (FSH)—presenting with infertility, oligomenorrhea/amenorrhea, and/or poor libido—and thyroid-stimulating hormone (TSH)—presenting with weight gain and cold intolerance.
- Rarely, presentation may be more acute in patients with pituitary apoplexy.
- In critically ill patients, these features may be masked, and the only signs may be **hemodynamic instability** despite adequate fluid resuscitation, usually with a **hyperdynamic circulation** and decreased systemic vascular resistance, or ongoing evidence of inflammation without an obvious source or response to empiric treatment.
- Acute adrenal insufficiency (Addisonian crisis) is a medical emergency manifesting as hypotension and circulatory failure.

Laboratory Findings

- In established primary hypoadrenalism, hyponatremia is present in 90% of cases and hyperkalemia in 65%.
- **Hyperkalemia** occurs due to aldosterone deficiency and is therefore usually absent in secondary hypoadrenalism.
- **Hyponatremia** may be depletion in Addisonian crisis, but elevated vasopressin levels can cause dilutional hyponatremia in secondary adrenal insufficiency.

- Usually, free thyroxine concentrations are low or normal, but TSH values are frequently elevated. This is a direct effect of glucocorticoid deficiency and reverses with glucocorticoid replacement. Thyroxine levels may also be low in secondary hypoadrenalism. Thyroid hormone administration without glucocorticoids in these situations can precipitate adrenal insufficiency and should be avoided.
- **Eosinophilia** may be seen and can occasionally alert the astute clinician to the diagnosis.

Biochemical Diagnosis

- The biochemical diagnosis of hypoadrenalism can be straightforward in an outpatient setting but is often much more difficult in the critical care unit.
- Clinical suspicion of hypoadrenalism should be confirmed biochemically and, in the outpatient setting, the gold standard stimulation test is the **insulin tolerance test (ITT)**.
- In the critical care unit setting, the ITT is problematic as it cannot be performed in patients with ischemic heart disease, epilepsy, or severe cortisol deficiency (a 0900 hr or early morning cortisol <7 $\mu\text{g/dL}$).
- The cortisol response to hypoglycemia obtained during the ITT can be reliably predicted by the ACTH stimulation test—a safer, quicker, and less expensive study.
- The **ACTH stimulation test (Table 115.2)** involves intramuscular (IM) or intravenous (IV) administration of 250 μg tetracosactrin. In critically ill patients, the IV route is preferred.
- In critically ill patients, plasma cortisol levels are measured at 0 and 30 minutes and an additional sample 60 minutes after baseline is often used, with the peak value defined as the higher of the 30- and 60-minute values.
- The peak value is unaffected by the time of day, but the basal value varies with the diurnal rhythm.
- The use of the 60-minute sample is not standard practice when basing decisions on peak levels but is reasonable when an increment is being used (e.g., septic shock).
- The ACTH test should not be used after a recent pituitary insult (surgery, apoplexy), as it may take 2 to 3 weeks for the adrenal cortex to readjust to the reduced level of ACTH secretion.
- The test can be performed in patients who have recently commenced corticosteroid replacement therapy with dexamethasone, as it does not cross-react in the cortisol assay.
- In a critically ill patient, the testing regimen is more complex and more difficult. The use of the short ACTH is controversial in critical illness but remains the test that is most useful to intensivists.
- In patients with suspected primary adrenal insufficiency, the **peak value** obtained during an ACTH test should be at least 20 $\mu\text{g/dL}$, but in patients with hypotension or sepsis, it would be reasonable to expect values to exceed 25 $\mu\text{g/dL}$.
- In patients found to have abnormal responses to the 250- μg study, further tests may be required to determine the cause, for example, studies for adrenal autoantibodies, abdominal imaging for primary adrenal failure, and/or pituitary magnetic resonance imaging and other anterior pituitary function tests for secondary adrenal failure.
- Clinical improvement with hydrocortisone replacement is good evidence for adrenal insufficiency when the diagnosis is uncertain.
- A general scheme for investigating adrenal insufficiency in critical illness, combining basal and stimulated tests, is given in Figure 115.1.
- In vasopressor-dependent septic shock, the **incremental response** (<9 $\mu\text{g/dL}$) post-ACTH administration is associated with increased mortality.

Management

- In addition to measurement of plasma electrolytes and blood glucose, samples for ACTH and cortisol should be taken before initiating corticosteroid therapy.
- If the patient is not critically ill, an ACTH stimulation test can be performed. In critically ill patients, intravenous

TABLE 115.2

ACTH STIMULATION TEST

Short Adrenocorticotropin Hormone (ACTH) Stimulation Test

Procedure. Serum samples are obtained just before and 30 (and/or 60) minutes after an IV injection of 250 μg of tetracosactrin (Synacthen, Cosyntropin, 1-24 ACTH).

INTERPRETATION

Unstressed patient:	Peak cortisol value <20 $\mu\text{g/dL}$ suggests AI
During critical illness:	Peak cortisol <20 $\mu\text{g/dL}$ suggests AI (patients without sepsis or hypotension)
	Peak cortisol <25 $\mu\text{g/dL}$ suggests AI (patients with sepsis or hypotension)
	Cortisol increment <9 $\mu\text{g/dL}$ indicates relative AI (of use <i>only</i> in vasopressor-dependent septic shock)

Comments. The diagnosis of adrenal insufficiency (AI) in the intensive care unit usually depends on the short ACTH stimulation test, but its interpretation is difficult and depends on clinical context. Peak cortisol values of either 20 or 25 $\mu\text{g/dL}$ have been proposed and should be used depending on the severity of the illness. In septic shock, the use of the increment has been proposed for diagnosing relative adrenal insufficiency and may identify patients likely to benefit from glucocorticoid replacement; however, it should *not* be used outside this setting without evidence. The test does not differentiate between primary and secondary hypoadrenalism and is unreliable in recent-onset secondary AI.

TABLE 115.3

RELATIVE POTENCY OF GLUCOCORTICOIDS AND APPROXIMATE DOSE EQUIVALENTS WHEN USED FOR GLUCOCORTICOID REPLACEMENT

	Relative glucocorticoid potency ^a	Replacement dose (mg)
Hydrocortisone ^b	1	30 ^d
Cortisone ^{b,c}	0.8	37.5
Prednisolone	4.5	5–7.5
Prednisone ^c	4.5	5–7.5
Methylprednisolone	5	4
Dexamethasone	35	0.75

^aRelative glucocorticoid potency varies with the parameter studied so is only approximate and refers predominantly to glucocorticoid replacement in Addison disease.

^bPhysiologic glucocorticoids that are preferred for replacement purposes.

^cThese steroids are inactive prodrugs so are used only via the oral route.

^dThis is the standard initial replacement dose in patients with possible adrenal insufficiency but can often be reduced to 15–20 mg when needed long term.

hydrocortisone should be given in a dose of 100 mg every 6 hours either as a bolus dose or a continuous infusion.

- Clinical improvement, especially in blood pressure, should be evident within 6 hours if the diagnosis is correct.
- After 24 hours, the hydrocortisone dose can be reduced, usually to 50 mg every 6 hours and subsequently, if possible, to oral hydrocortisone, 40 mg in the morning and 20 mg at 6:00 p.m. This can then be rapidly reduced to standard replacement doses of 20 mg on waking and 10 mg at 6:00 p.m.
- Although synthetic glucocorticoids have been used in adrenal replacement—their relative potencies and dose equivalents are given in Table 115.3—they have no advantage over hydrocortisone.
- Mineralocorticoid replacement is not required during high-dose hydrocortisone therapy, but patients with adrenal disease will also require fludrocortisone when daily hydrocortisone dose drops below 50 mg/day.
- In septic shock, the recommended replacement is 50 mg of hydrocortisone every 6 hours.

ADRENAL HORMONE EXCESS (CUSHING SYNDROME)

- States of endogenous corticosteroid excess are rare. Cushing disease is due to an ACTH-secreting pituitary adenoma and has an incidence of approximately 1 per 1 million of population.
- Endogenous *Cushing syndrome* is otherwise from a cortisol-secreting adrenal adenoma or ectopic ACTH secretion, often from a benign or malignant pulmonary tumor.
- The diagnosis of Cushing disease/syndrome and the determination of the site of the lesion are difficult to make, involving dynamic suppression tests, imaging, and venous sampling.
- Much more common is iatrogenic Cushing syndrome caused by therapeutic glucocorticoids. Patients with this disorder are likely to have the classic features of Cushing syndrome—namely, central obesity, myopathy, skin fragility, glucose intolerance, osteoporosis, and hypertension.
- The main clinical issue in this situation is to ensure that a **physiologic replacement dose** of steroid is maintained during intercurrent stress.
- In any patient on long-term oral steroid doses above 5 to 7.5 mg prednisolone or its equivalent, intravenous steroid replacement should be administered if the patient is unable to continue the oral dose, since it is likely that he or she will have a variable degree of adrenal atrophy secondary to prolonged ACTH suppression.

OTHER ADRENAL DISEASES

Hyperaldosteronism

- Primary hyperaldosteronism was previously thought to be uncommon, but is increasingly recognized as a major cause of hypertension.
- This form of mineralocorticoid-mediated hypertension is associated with **hypokalemia and a raised aldosterone-to-renin ratio**.
- The use of this ratio has increased the number of diagnoses of primary hyperaldosteronism, mainly due to an increased incidence of bilateral adrenal hyperplasia.
- Treatment is with surgery or with long-term **spironolactone**.

CHAPTER 116 ■ PHEOCHROMOCYTOMA

IMMEDIATE CONCERNS

Major Problems

- Pheochromocytoma is a rare catecholamine-secreting tumor with a wide spectrum of presentations ranging from minimal symptoms to sudden death. Although early diagnosis can lead to a curative treatment course, outcomes are often fatal when the condition is unrecognized. Critical care physicians should

be familiar with pheochromocytoma crisis, as it is a medical emergency requiring the highest level of specialty care.

Stress Points

- The diagnosis of pheochromocytoma should be considered in any patient who presents with **severe hypertension** or the classic symptoms of episodic **headache, palpitations, and diaphoresis**.

- Furthermore, pheochromocytoma should be included in the differential diagnosis in any patient with an **unexplained cardiovascular event**, including congestive heart failure, myocardial infarction, or stroke.
- Fractionated **plasma metanephrines** or **24-hour urine metanephrines** are the initial laboratory studies to rule out pheochromocytoma.
- **α -Blockade** with phenoxybenzamine should be started as soon as the biochemical diagnosis of pheochromocytoma is established.
- After adequate α -blockade is established, **β -blockers** can be used as an adjuvant means of controlling tachycardia.
- Pheochromocytoma crisis is a medical emergency requiring immediate α -blockade and invasive hemodynamic monitoring; additional pharmacologic agents, such as β -blockers, calcium channel blockers, and intravenous nitrates, are often needed to control heart rate and blood pressure.
- The only curative therapy for pheochromocytoma is surgical resection; however, this should be attempted only on an elective basis after several weeks of adrenergic blockade.

PATHOPHYSIOLOGY

- Intermittent and unregulated catecholamine release is the hallmark pathophysiologic feature of pheochromocytoma.
- The morbidity of pheochromocytoma is primarily related to the cardiovascular impact of unregulated systemic catecholamine excess.
- Pheochromocytomas originate from chromaffin cells and, by definition, are located in the adrenal medulla.
- Approximately 90% of pheochromocytomas are histologically benign.
- There are three sequential products synthesized in the adrenal medulla from the precursor L-tyrosine—dopamine (DA), norepinephrine (NE), and epinephrine (EPI).
- The rate-limiting step in catecholamine synthesis is the production of the precursor peptide L-DOPA. By decarboxylation, L-DOPA is converted to DA, which is then converted to NE by β -hydroxylase. Ultimately, NE is converted to EPI by phenylethanolamine-N-methyltransferase (PNMT).
- Although NE is the predominant catecholamine secreted by most pheochromocytomas, there are reports of rare tumors that secrete DA, adrenocorticotrophic hormone, vasoactive intestinal peptide, and calcitonin gene-related peptide.
- Because PNMT is found only in the adrenal medulla and the organ of Zuckerkandl, EPI-secreting tumors are typically located in these two locations.

EPIDEMIOLOGY OF PHEOCHROMOCYTOMA

- Pheochromocytoma is a rare tumor with an incidence ranging from 0.1% to 0.25% in large autopsy studies.
- The prevalence in hypertensive patients is in the range of 0.1% to 1%.
- Pheochromocytoma can occur sporadically or in association with several familial syndromes. Approximately 84% of cases are estimated to be sporadic.
- Up to 24% of nonsyndromic pheochromocytoma patients have specific germ line mutations, including RET (MEN-2),

VHL (von Hippel-Lindau), and succinate dehydrogenase subunit D (SDHD) and B (SDHB).

- Approximately 40% of MEN-2 patients develop pheochromocytoma. Because of the relatively high incidence, patients with the RET proto-oncogene mutation should be routinely screened for elevation in serum or urine metanephrines.
- Bilateral and multicentric tumors are more common in MEN-2 patients, while extra-adrenal and malignant lesions are uncommon.
- VHL disease is inherited in an autosomal dominant fashion and is characterized by retinal hemangiomas, pancreatic tumors, cerebellar hemangioblastoma, kidney lesions, and epididymal cystadenoma.
- Pheochromocytoma can be found in up to 20% of people with VHL disease. As in MEN-2, bilateral disease is more common than in sporadic cases.
- SDHB and SDHD are susceptibility genes for pheochromocytoma associated with extra-adrenal lesions. Whereas SDHD mutation carriers are more likely to have multifocal extra-adrenal pheochromocytomas, SDHB mutation carriers are more likely to develop malignancy and may be associated with kidney and thyroid cancer.
- Other rare familial disorders that are associated with pheochromocytoma include von Recklinghausen disease and Carney syndrome.

CLINICAL PRESENTATION

Signs and Symptoms

- Symptoms are highly variable but classic symptoms include episodic headache, palpitations, diaphoresis, and visual blurring.
- Other complaints may include tremors, anxiety, dizziness, nausea, diarrhea, abdominal discomfort, Raynaud phenomenon, and weight loss.
- **Hypertension** is the most common feature and occurs in up to 90% of patients. Less commonly, some present with diastolic hypertension and postural hypotension, in the absence of antihypertensive therapy.
- Patients may be normotensive between episodes of catecholamine excess, and **postural tachycardia and hypotension** is another commonly seen feature of pheochromocytoma.
- Conversely, some patients can be normotensive for many years and only suffer a hypertensive crisis after being stressed.
- Up to 23% of all “incidentalomas” are discovered during abdominal imaging in trauma patients, further underscoring the significance of this tumor in the critical care setting.
- On specific questioning, many of these patients with incidentalomas report symptoms referable to the hyperadrenergic state.
- Moreover, among patients with a known history of another malignancy, up to a fourth of radiologically discovered adrenal tumors are pheochromocytomas and not metastatic disease.

ESSENTIAL DIAGNOSTIC TESTS

Biochemical Identification

- The biochemical diagnosis of pheochromocytoma is dependent on the detection of the metabolic products of the

catecholamines. Monoamine oxidase catalyzes the conversion of catecholamines into **vanillylmandelic acid** and **homovanillic acid**. Furthermore, carboxyl-O-methyl transferase converts NE, EPI, and DA to **normetanephrine**, **metanephrine**, and **methoxytyramine**, respectively.

- Because functional pheochromocytomas release catecholamines heterogeneously and intermittently, spot checks of NE, EPI, or DA are often within a normal range and cannot reliably exclude the diagnosis of pheochromocytoma.
- Conversely, free metanephrines are continuously elevated in patients with functional pheochromocytomas. Total metanephrine measurement is less sensitive than determining the fractionated amount of normetanephrine, metanephrine, and methoxytyramine.
- **Fractionated plasma metanephrine** measurement is more sensitive than 24-hour urinary total metanephrines and catecholamines but is less specific.
- In the critically ill patient with clinical characteristics that are highly suspicious for pheochromocytoma, measurement of fractionated plasma metanephrines is the most appropriate test. Conversely, when low-risk patients are screened, 24-hour urinary studies will yield the lowest proportion of false-positive results.
- Certain medications and radiographic contrast agents can interfere with the laboratory results and should be withheld before the draw. The list of medications that can affect the biochemical testing for pheochromocytoma is long and includes: **acetaminophen**, **β -blockers**, **vasodilators**, **α -blockers**, **stimulants**, **antipsychotics**, **antidepressants**, and **calcium channel blockers**.
- Provocative tests with agents such as histamine, glucagon, and naloxone are no longer recommended, as they can be dangerous and are ineffective in patients with normal urinary studies.

Tumor Localization

- Tumor localization will not likely change the therapeutic plan for patients in the intensive care unit. However, localization studies are important for surgical planning and can confirm the diagnosis.
- Ultrasound is particularly useful in critically ill patients, as it can be done at the bedside without exposing them to nephrotoxic contrast agents or ionizing radiation. Although ultrasound can accurately rule out a large adrenal lesion, it is also highly user dependent.
- **Magnetic resonance imaging (MRI)** can identify pheochromocytoma lesions and delineate the anatomy important for surgical planning. Pheochromocytomas have a characteristic high-intensity signal on **T2-weighted images**.
- **Computed tomography (CT) scanning** from the chest to pelvis is recommended to evaluate for extra-adrenal lesions. Drawbacks to consider include (1) the possibility of exacerbating a pheochromocytoma crisis from contrast injection; (2) the exposure to ionizing radiation, which may be important in some obstetric or pediatric patients; and (3) the obscuring artifacts that can occur from implanted devices and surgical clips.
- **Meta-¹³¹Iodobenzylguanidine (MIBG)** is particularly useful in patients at risk for multiple or extra-adrenal tumors, such as in young children, and in patients with a family history

or familial syndrome associated with pheochromocytoma. MIBG is less sensitive than CT or MRI.

Workup of Incidental Lesions

- The finding of an adrenal “incidentaloma” should prompt the biochemical workup described above, as well as the measurement of plasma aldosterone, renin activity, and 24-hour urine cortisol. These studies will rule out aldosteronoma and Cushing syndrome.
- Although many clinicians continue to perform fine-needle aspiration biopsy and selective venous sampling for patients with adrenal tumors, these interventional studies may precipitate a pheochromocytoma crisis and are relatively contraindicated.
- All functioning adrenal lesions, including pheochromocytoma, should be resected electively.

MANAGEMENT

Treatment of Nonemergent Pheochromocytoma

- Pheochromocytoma is a potential cause of cardiovascular emergencies such as heart failure, myocardial infarction, and stroke. When pheochromocytoma is the cause of these events, appropriate therapy to control the hyperadrenergic state can often reverse or minimize disability.
- Although surgical intervention remains the only curative therapy for pheochromocytoma, the tumor should be resected only after appropriate preoperative steps are undertaken.
- Preoperative preparation for elective resection includes **α -blockade** to control hypertension, prevent cardiac arrhythmias, and allow adequate volume resuscitation before resection.
- Effective preoperative preparation and **α -blockade** reduces operative mortality. Even in the normotensive patient, complete **α -blockade** will prevent hemodynamic instability caused by operative stress and tumor manipulation during elective resection.
- **Phenoxybenzamine** is an ideal **α -blocker** for preoperative patients because it has a relatively long half-life. The starting dose is 10 mg every 12 hours and should be titrated upward, as tolerated. Dose escalation can be halted when the patient has postural hypotension.
- **β -Blockers** are sometimes needed to control heart rate and should be given only after adequate **α -blockade**, to avoid severe hypertension from unopposed **α -stimulation**.
- **Metyrosine**, an inhibitor of tyrosine hydroxylase, reduces catecholamine production and can be added to the preoperative regimen.
- Narcotics should generally be avoided, as they may stimulate **histamine release**, which may in turn trigger a crisis.

Managing the Postoperative Patient

- Perioperative complications are either related to inadequate adrenergic blockade, lack of appropriate intravascular volume expansion, or to a technical problem. Surgical

complications include bleeding, infection, and damage to nearby structures, such as the spleen or renal vessels.

- Most pheochromocytomas smaller than 6 cm can be resected using the laparoscopic technique. Larger tumors may require laparotomy or thoracoabdominal access for safe resection.
- Despite preoperative α -blockade, many patients have either arrhythmias or some form of hemodynamic instability during adrenalectomy. Some compensatory hypotension often results after tumor extirpation. Typically, this drop in blood pressure is minimized when blood volume is restored appropriately and when α -blockade is adequate preoperatively.
- Although many patients are hyperglycemic due to chronic catecholamine excess before resection, they may be profoundly **hypoglycemic** in the early postoperative period. Intravenous glucose and frequent blood sugar checks are required in many of these patients.
- Essential hypertension may persist after resection. Disease may recur from the contralateral adrenal gland or metastases years after surgery. Reoperative resection is the treatment of choice when complete extirpation is feasible.
- Palliative debulking is often desirable in patients with disease that cannot be completely resected, as it can improve symptoms and the effectiveness of medical therapy.
- An uncommon surgical complication of adrenalectomy is renovascular hypertension, a result of injury to, or thrombosis of, the renal artery or vein.

Treatment of Pheochromocytoma Crisis

- Pheochromocytoma crisis is uncommon but requires prompt diagnosis and emergent medical intervention. The clinical presentation of pheochromocytoma crisis includes (1) multisystem **organ failure**; (2) **fever**, often exceeding 40°C; (3) **encephalopathy**; and (4) **hemodynamic instability**.
- A common error is the **misdiagnosis of sepsis** in patients whose condition continues to decline despite empiric antibiotic therapy.
- Episodes of pheochromocytoma crisis are typically precipitated by traumatic stress, which is often iatrogenic.
- Patients in pheochromocytoma crisis should be transferred urgently to an **intensive care unit** or to the highest level of care available.
- **Phentolamine**, an intravenous α -blocker, should be given in 2-mg boluses. **Phenoxybenzamine** and **prazosin** can be used but can be more difficult to titrate.
- β -Blockade, without α -blockade, can precipitate hemodynamic instability. However, after initial α -blockade is started, β -blockade can effectively control heart rate and blood pressure. **Labetalol**, which has both α - and β -blocker effects, can be given intravenously during crisis situations.
- **Nitrates**, such as **sodium nitroprusside** and nitroglycerine, result in prompt venodilation, which can decrease cardiac

preload and cause an immediate decline in blood pressure. Side effects from sodium nitroprusside include cyanide accumulation after long-term use. These agents should be used as adjuvant therapies after α -adrenergic blockade is achieved.

- Monitoring should include real-time arterial pressure and measurement of urinary output with a bladder catheter. Central venous monitoring is not essential, and placement should not delay pharmacologic treatment. Central venous catheters are useful for monitoring volume status, and many pharmacologic agents require central venous delivery.
- Emergent adrenalectomy should be avoided in patients with pheochromocytoma crisis. After the patient is stabilized and α -blockade instituted, planning should begin for elective adrenalectomy with curative intent. This can be performed during the same admission after preoperative planning, including the completion of localization studies and at least 2 weeks of α -blockade.

Pregnancy and Pheochromocytoma

- The stress of pregnancy and labor can prompt pheochromocytoma crisis and elicit symptoms in patients with unrecognized pheochromocytoma.
- On rare occasions, symptoms are minimal during gestation and manifest only after delivery.
- Obstetric outcomes are exceptionally poor when maternal pheochromocytoma is unrecognized; fetal and maternal mortality rates exceed 50% in such cases. However, others have reported favorable results when the diagnosis is established and the mother is adequately treated antenatally.
- In obstetric patients, maternal hypertension is often **erroneously attributed to pre-eclampsia or eclampsia**. Because of the grave consequences related to this missed diagnosis, pheochromocytoma should be considered in any hypertensive gravid woman.
- The localization of pheochromocytoma lesions in pregnant women should avoid fetal exposure to ionizing radiation. **Ultrasound** and **MRI** are safe, but CT and MIBG scanning result in some fetal exposure to radiation.
- Both α - and β -blockade can be given safely to the obstetric patient. The timing of surgical resection should be carefully planned.
- Emergent adrenalectomy is not required and should be delayed until delivery, which should be accomplished by cesarean section, or thereafter.
- If the diagnosis is made early in the gestational period and medical therapy is poorly tolerated, the second trimester is the ideal time period for elective laparoscopic resection. Surgery in the first trimester is associated with fetal loss, and resection in the third trimester can be technically challenging because of the larger uterus and can cause premature labor.

CHAPTER 117 ■ THYROID DISEASE IN THE INTENSIVE CARE UNIT

THYROID FUNCTION TESTS

- The purpose of this section is to provide an overview of the most commonly ordered labs. A later section will delineate how to interpret these values in the critically ill patient.

Serum Thyroid-Stimulating Hormone/Free Thyroxine

- Measurement of serum thyroid-stimulating hormone (TSH) and free thyroxine (FT₄) is sufficient to diagnose most thyroid disorders.
- The ultrasensitive TSH test is recommended. Currently, the most widely accepted range of **0.45 to 4.12 mIU/L** is based on values from the NHANES III (National Health and Nutrition Examination Survey) database.

Total T₄ Measurement

- Total T₄ (TT₄) includes both bound and free thyroxine. Therefore, conditions or medications that affect serum levels of thyroid-binding globulin (TBG) will also affect the total T₄ value.
- The use of FT₄ value can eliminate this shortcoming. If FT₄ is not available, this level can be estimated by looking at the FT₄ index, FTI.

Serum Tri-iodothyronine (T₃)

- Serum tri-iodothyronine (T₃) may be measured in the free and bound fractions, although it is generally recommended that the **total T₃** be used, as only a minute fraction of T₃ is free.

- T₃ levels should be measured in patients suspected of having **hyperthyroidism**, as some patients may have excess secretion of only T₃ early in the course of thyrotoxicosis.
- Measurement of this hormone is not helpful in hypothyroidism as the elevated TSH stimulates preferential formation of T₃ to typically maintain the level in the normal range.

T₃ Resin Uptake

- T₃ resin uptake (T₃RU) is an indirect, inverse test to estimate the number of **unoccupied serum protein-binding sites**.
- T₃RU (the binding of ¹²⁵I-T₃ to an adsorbent) is increased if the number of unoccupied binding sites on TBG is decreased. This may be due to either low TBG levels such as in nephrotic syndrome or chronic liver disease, or increased thyroid hormone levels as in hyperthyroidism.
- In contrast, the T₃RU is low if the number of unoccupied binding sites is increased. Low thyroid hormone concentrations (hypothyroidism or high TBG concentrations), estrogen therapy, or pregnancy may lead to a low T₃RU.

Reverse T₃

- Reverse T₃ (rT₃) differs from T₃ in that the iodine is missing from the inner ring instead of the outer ring of T₄. It is largely bound to proteins in the serum.
- Its half-life in the serum is quite short, and furthermore, the biologic function of rT₃ is not completely understood in humans.
- The clinical utility of measuring these levels is chiefly in the setting of **sick euthyroidism**.
- Table 117.1 details the interpretation of thyroid function tests.

TABLE 117.1

INTERPRETATION OF THYROID FUNCTION TESTS

	TSH	Free T ₄	Total T ₃	T ₃ U	rT ₃
Hypothyroidism					
Primary	High	Low	Normal	Low	Low/normal
Secondary	Low/normal	Low	Normal	Low	Low/normal
Hyperthyroidism	Low	High/normal	High	High	Low/normal
Sick euthyroid	Low/normal	Low/normal	Low	High	High

TSH, thyroid-stimulating hormone; T₄, thyroxine; T₃, tri-iodothyronine; T₃U, T₃ resin uptake; rT₃, reverse T₃.

DRUGS AND THYROID FUNCTION

- The vast majority of the effects of pharmacologic agents on thyroid hormone homeostasis may be divided into four categories:
 - Agents that alter the synthesis or secretion of thyroid hormones
 - Agents that alter hormone concentration by changing serum levels of binding proteins or by competing for their binding sites
 - Agents that modify the cellular uptake and metabolism of thyroid hormones
 - Agents that interfere with thyroid hormone action at the tissue level
- Typically these effects on thyroid hormone metabolism are transient, but they may complicate the interpretation of the thyroid function tests.
- Commonly used compounds that interfere with thyroid function and their mechanisms of action are listed in Table 117.2.

Thyrotoxicosis

Clinical Presentation

- In the intensive care unit (ICU), patients with thyrotoxicosis may have an atypical presentation, with tachyarrhythmias or central nervous system disturbance as the primary sign.
- It is important to consider thyroid dysfunction in the differential diagnosis of such patients, since treatment with

TABLE 117.3

SIGNS AND SYMPTOMS OF THYROTOXICOSIS

Symptoms	Signs
Anxiety	Goiter
Hyperdefecation	Lid lag/lid retraction
Sweating/heat intolerance	Proximal muscle weakness
Palpitations	Tremor
Weight loss	Tachycardia/arrhythmias
Weakness	Hyperreflexia
Increased appetite	Thyroid bruit
Scant/absent menses	Dermopathy

β -blockers and antithyroid medications can rapidly improve the clinical course.

- Table 117.3 lists the symptoms and signs that may be seen in a patient with thyrotoxicosis.

Cardiovascular Manifestations

- Sinus **tachycardia** and **atrial fibrillation** are the most commonly seen cardiovascular disorders in hyperthyroidism. Since atrial fibrillation may be the only indication of thyrotoxicosis, it is important to screen such patients with a TSH and FT₄.
- Congestive **heart failure** typically occurs only in patients with underlying heart disease, but may also manifest as a result of chronic tachycardia-induced cardiomyopathy.

TABLE 117.2

COMMONLY USED DRUGS THAT AFFECT THYROID FUNCTION

Drug	Mode of action	Thyroid function abnormality
<i>Amiodarone</i>	Inhibits cellular hormone uptake Alters hormone secretion Alters intracellular metabolism	Hyperthyroidism Hypothyroidism
<i>Lithium</i>	Reduced hormone secretion (acute) Autoantibody immune response (chronic)	Hypothyroidism (acute) Hyperthyroidism (chronic)
<i>Dopamine</i> <i>Cholestyramine</i> <i>Ferrous sulfate</i> <i>Charcoal</i> <i>Sucralfate</i> <i>Propranolol</i> <i>Phenobarbital</i> <i>Sodium ipodate</i> <i>Iopanoic acid</i>	Reduced hormone secretion	Reduced TSH, T ₄
<i>Glucocorticoids</i>	Reduced absorption from gut Altered hormone synthesis Alters intracellular metabolism	Elevated TSH, reduced T ₄ Reduced T ₄ -to-T ₃ conversion Reduced total T ₄
<i>Heparin</i> <i>Lasix</i> <i>Salicylates</i>	Reduced hormone secretion Altered hormone synthesis Reduced TSH secretion Altered hormone synthesis	Reduced T ₄ -to-T ₃ conversion
<i>Carbamazepine</i> <i>Radiographic contrast agents</i>	Inhibits T ₄ binding to TBG Inhibits T ₄ binding to TBG Inhibits T ₄ binding to TBG	Reduced total T ₄ Reduced T ₄ -to-T ₃ conversion Transient increase in fT ₄ Reduced total T ₃ , total T ₄ Reduced total T ₃ , total T ₄ Increased free T ₃ , free T ₄ Reduced total T ₄ Increased free T ₄ Decreased free T ₃
<i>Cytokines</i>	Alters intracellular metabolism Alters hormone secretion Autoantibody immune response	Transient hypothyroidism or hyperthyroidism

TSH, thyroid-stimulating hormone; T₄, thyroxine; T₃, tri-iodothyronine; TBG, thyroid-binding globulin.

- Physical examination findings in a thyrotoxic patient include widened pulse pressure, hyperdynamic precordium, tachycardia, and systolic ejection murmur.
- The typical electrocardiographic changes seen in thyrotoxicosis are sinus tachycardia and atrial fibrillation. Patients may also present with complete heart block, and cases have been reported that showed reversal with treatment of the underlying thyroid disorder.

Pulmonary Manifestations

- Dyspnea on exertion is a common presenting symptom of patients with hyperthyroidism. **Respiratory muscle strength** is significantly reduced in thyrotoxicosis and improves with reduction of thyroid hormone levels.
- Several studies have also shown that thyrotoxicosis is a risk factor for the development of **pulmonary hypertension**.
- Pulmonary emboli may be seen in patients with atrial fibrillation who are not on anticoagulation therapy.
- Pulmonary edema has been described in uncontrolled thyrotoxic patients.

Laboratory Findings

- The laboratory findings in hyperthyroidism are the combination of a low TSH and a high FT₄ (see Table 117.1).
- If the FT₄ is normal and TSH suppressed in a patient suspected of having thyrotoxicosis, it is important to check the T₃ level, as this may be elevated in early Graves disease or in T₃-secreting toxic adenomas.
- In the event that the patient presents with an elevated T₄ or T₃ and a detectable or “normal” TSH, the clinician should consider the effects of **nonthyroidal illness** or drugs (see Table 117.2) on thyroid function testing.
- Rarely, the patient may have a TSH-secreting pituitary tumor or thyroid hormone resistance.
- Consultation with an endocrinologist may be warranted if the patient has unusual thyroid function tests that cannot be readily corroborated with the entire clinical picture.

Etiology

- The two most common causes of thyrotoxicosis in the outpatient setting are **Graves disease** and **toxic multinodular goiter**.
- Young women are more likely to present with the classic stigmata of Graves disease: thyroid bruit, ophthalmopathy, and diffuse goiter.
- Elderly patients tend to have a solitary or multiple nodules that become autonomously functioning and lead to hypersecretion of thyroid hormone.
- In the ICU it is important to consider other causes of hyperthyroidism. **Factitious** thyrotoxicosis is rare but should be considered in a patient with a history of taking herbal supplements or over-the-counter weight loss medications.
- Surreptitious use of thyroid hormone may be diagnosed by measurement of serum **thyroglobulin levels**. If low, this would indicate that the patient is self-medicating. Typically, the thyroglobulin levels are high in patients with true thyroid disorders.
- Patients with a history of Graves disease, multinodular goiter, or even subclinical hyperthyroidism may develop frank thyrotoxicosis several days after the administration of iodinated contrast media. However, patients with normal thyroid function are, in general, not at risk of this complication.

Treatment

- The treatment of thyrotoxicosis is based on the underlying pathophysiology. Patients with Graves disease, toxic multinodular goiter, or toxic adenoma should be started on a **thionamide**, such as methimazole (MMI) or propylthiouracil (PTU).
- The dosage of antithyroid medication should be tailored to the degree of thyrotoxicosis; hence, consultation with an endocrinologist is advisable.
- Patients with peripheral manifestations of hyperthyroidism may also benefit from the addition of a β -adrenergic antagonist drug. **Propranolol** is the drug most commonly used in the United States.
- Patients who have overdosed on thyroid hormone or are taking a supplement with thyroid hormone extract should be counseled regarding the complications of taking thyroid hormone supplements in excess, and the offending agent should be discontinued.
- If the patient requires treatment, β -adrenergic antagonists and bile acid sequestrants may be used.

Thyroid Storm

- Thyroid storm is a rare but life-threatening syndrome of exaggerated clinical manifestations of thyrotoxicosis. The clinical picture is one of decompensation of one or more **organ systems**.
- It is a medical emergency typically caused by exacerbation of hyperthyroidism following a precipitating event or illness; Table 117.4 lists the precipitants of thyroid storm.
- There are no universally accepted criteria for its diagnosis, and consequently, the incidence is unknown. However, four main features noted in thyroid storm are tachycardia, fever, central nervous system (CNS) disturbances, and gastrointestinal symptoms.
- The CNS symptoms vary from marked hyperirritability and anxiety to confusion and coma.
- Laboratory testing is unreliable in distinguishing patients with thyrotoxicosis and thyroid storm; thus the diagnosis of thyroid storm is primarily a clinical one.

TABLE 117.4

PRECIPITANTS OF THYROID STORM

Infection
Parturition
Nonthyroid surgery
Radioactive iodine therapy
Postthyroidectomy
Vigorous palpation of the thyroid
Iodine therapy/radiographic contrast agents
Diabetic ketoacidosis
Hypoglycemia
Withdrawal of antithyroid drug therapy
Myocardial infarction
Cerebrovascular accident
Pulmonary embolus
Trauma
Medications
Thyroxine
Haldol
Pseudoephedrine

TABLE 117.5

SUMMARY OF TREATMENT FOR THYROID STORM

Medication	Dose and route of administration	Action
Propranolol	0.5–1 mg IV over 10 min, then 1–3 mg IV as needed 80–120 mg PO every 6 h	β -Adrenergic blockade and inhibition of T_4 -to- T_3 conversion
Thionamides		
PTU	200–400 mg PO/NG/PR every 4 h	Inhibit hormone synthesis and block conversion of T_4 to T_3
Methimazole	20 mg PO/NG every 4 h	Inhibits hormone synthesis
Iodine ^a		
SSKI	5 drops POo/NG every 6 h	Blocks release of thyroid hormone
Lugol solution	10 drops PO/NG every 8 h	
Iodinated contrast agents ^a		
Sodium ipodate or iopanoic acid	0.5 g PO/NG every 12 h	Blocks release of thyroid hormone and conversion of T_4 to T_3
Glucocorticoids		
Hydrocortisone	200 mg IV load, then 100 mg IV every 8 h	Stress-dose steroids and blocks conversion of T_4 to T_3
Dexamethasone	2 mg PO/NG/IV every 6 h	
Lithium	300 mg PO/NG every 6 h titrate to lithium level of 1 mEq/L	Inhibits hormone synthesis
Cholestyramine	4 g PO/NG every 6 h	Lowers serum T_3 and T_4

IV, intravenously; PO, orally; PTU, propylthiouracil; NG, nasogastrically; SSKI, saturated solution of potassium iodide.

^aEither iodine or iodinated contrast agents should be used, but not both. Administration of iodine should be preceded by PTU by 2–3 hours to avoid enhancement of thyroid hormone synthesis.

- Mortality rates range from 20% to 100%, so prompt, multifaceted therapy is essential.

Management

- The treatment of thyroid storm takes a four-pronged approach (Table 117.5).
 - First, an antithyroid drug must be given to reduce thyroid hormone production and peripheral conversion of T_4 to T_3 .
 - Second, supportive care must be administered against the systemic disturbances of fever, hypovolemia, and cardiovascular compromise.
 - Third, the peripheral actions of thyroid hormone should be blocked.
 - Finally, any precipitating factors should be addressed.
- A thionamide is given to block synthesis of T_3 and T_4 . PTU is the favored agent because it also inhibits peripheral conversion of T_4 to T_3 . By reducing T_3 concentrations in the serum, it is postulated that the manifestations of thyrotoxicosis are more rapidly improved with PTU than with MMI.
- Neither of these drugs is available parenterally, so administration is typically by mouth or nasogastric (NG) tube. In patients with altered mental status, or in whom an NG cannot be placed, rectal administration of PTU has been reported to be used successfully in a few patients.
- It is conventional to use high doses of antithyroid drugs, such as 200 to 400 mg PTU every 4 hours or 20 mg MMI every 4 hours.
- Thionamides do not inhibit the release of preformed T_3 and T_4 from the thyroid. Inorganic iodide, however, can accomplish this goal. It may be administered orally as Lugol solution

(10 drops every 8 hours) or as saturated solution of potassium iodide (SSKI, 5 drops every 6 hours).

- Oral radiographic contrast agents, sodium ipodate or iopanoic acid, may be substituted for iodine. These drugs block the release of preformed thyroid hormone from the gland and inhibit the extrathyroidal conversion of T_4 to T_3 .
- It is critical to administer **thionamide therapy about an hour before the iodide** or contrast agent is given, because the sudden influx of iodide into the thyroid can lead to increased thyroid hormone production and thereby prolong the thyrotoxicosis.
- When the iodide or contrast agent is given after the antithyroid drug, serum T_3 and T_4 levels are substantially reduced in 2 to 3 days and may reach the normal range in 5 to 7 days.
- If the patient has an allergy to iodide or cannot tolerate thionamides, lithium may be substituted to inhibit T_3 and T_4 synthesis. It may be given initially at a dose of 300 mg every 6 hours and titrated to maintain serum lithium concentrations around 1 mEq/L.
- Fever is preferentially treated with acetaminophen. **Salicylates should not be used** as they inhibit T_3 and T_4 binding to serum proteins and thereby increase serum free T_3 and T_4 levels.
- The patient's fluid losses should be appropriately replaced, bearing in mind the insensible losses from high fever and, if present, diarrhea.
- Hypercalcemia, if present, will usually be reversed by adequate hydration.
- High-dose **glucocorticoids** have been given historically for empiric treatment of relative adrenal insufficiency. Such

TABLE 117.6

FEATURES OF AMIODARONE-INDUCED THYROTOXICOSIS

	Iodine-induced thyrotoxicosis (type I)	Destructive thyrotoxicosis (type II)
Underlying thyroid abnormality	Yes	No
Goiter	Diffuse or multinodular usually present	Occasionally small, firm goiter
RAIU	Low/normal/high	Low
Serum IL-6 concentrations	Slightly elevated	Markedly elevated
Pathogenic mechanism	Excessive thyroid hormone synthesis	Excessive hormone release (destructive thyroiditis)
Treatment	Thionamides and KClO ₄	Glucocorticoids
Subsequent hypothyroidism	Unlikely	Possible
Color flow Doppler sonography	Normal or increased blood flow	Decreased blood flow

RAIU, radioactive iodine uptake; IL-6, interleukin-6; KClO₄, potassium perchlorate.

treatment also has the added benefit of inhibition of peripheral conversion of T₄ to T₃.

- In patients with Graves disease, glucocorticoids also directly inhibit secretion of thyroid hormone. A loading dose of hydrocortisone 200 mg may be given initially followed by 100 mg every 8 hours; this therapy can be tapered rapidly after 2 to 3 days.
- Dexamethasone or methylprednisolone at equivalent doses may be substituted for hydrocortisone if preferred.
- β -Adrenergic antagonist drugs can provide rapid amelioration of many of the symptoms of thyroid storm and should be dispensed immediately.
- In the thyrotoxic state, drug clearance is increased and higher-than-usual doses are necessary to achieve the desired effect. If rapid β -blockade is necessary to reduce heart rate, or if the patient's mental status precludes oral drugs, intravenous (IV) administration is preferred.
- In extreme cases, it may be beneficial to use a method to remove T₃ and T₄ from the patient's serum. The simplest approach is to administer oral **cholestyramine**. This drug binds the hormones in the gastrointestinal tract, interrupting the enterohepatic circulation. Plasmapheresis has also been used successfully to lower T₃ and T₄ levels.
- Patients treated with the above regimen usually recover in 12 to 24 hours if the syndrome is recognized and treated in a timely fashion.
- Long-term treatment of hyperthyroidism is required if the patient has Graves disease or toxic multinodular goiter. In patients with Graves disease, it may be preferable to treat with thionamides, as there is a chance of remission of the autoimmune condition. However, others advocate total thyroidectomy in cases that progress to thyroid storm.
- Radioiodine ablation is not an option for several months because the inorganic iodide used in treatment of the thyroid storm saturates the gland and precludes further uptake of iodide.

- The drug has a half-life of several months, and, during that time, it releases approximately 9 mg of inorganic iodine per day.
- In euthyroid patients, chronic administration of the drug results in increased serum TT₄, FT₄, and rT₃ levels; lower T₃ concentrations; and normal TSH.
- Most patients remain euthyroid while on amiodarone despite the hormonal derangements that may be seen; on the other hand, about 14% to 18% of patients develop either **hypothyroidism or hyperthyroidism** while on amiodarone.
- On discontinuation of the amiodarone, most patients return to euthyroidism, although it may take several months because of the prolonged half-life of the drug.
- Hypothyroidism is more commonly encountered in iodine-replete areas, such as the United States. Treatment is aimed at normalization of the TSH with levothyroxine replacement while the amiodarone therapy is continued.
- In iodine-deficient regions, it is more common to see hyperthyroidism as a result of amiodarone therapy. There are two mechanisms (Table 117.6) of amiodarone-induced thyrotoxicosis (AIT).
 - Type I AIT occurs in glands with an underlying abnormality. Areas of autonomy, such as a toxic nodule or autoimmune disease in the thyroid, produce increased levels of hormone in response to the excess iodine released from the amiodarone.
 - Type II AIT develops as a result of a direct cytotoxic effect of amiodarone on the thyrocyte.
- Treatment of type I AIT is difficult because most patients do not respond to thionamides, as these drugs have decreased efficacy in states of iodine excess. If possible, it is important to discontinue the amiodarone.
- Use of potassium perchlorate (KClO₄) blocks further iodine entry into the thyrocyte and may enhance the efficacy of thionamides.
- It is important to note that both thionamides and KClO₄ may cause agranulocytosis, so serial monitoring of blood counts is advisable.
- The treatment of type II AIT is primarily with glucocorticoids and by discontinuation of the amiodarone, although in some cases it is reasonable to continue the antiarrhythmic medication. In patients in whom chronic therapy with amiodarone is essential, thyroidectomy is a potential option for treatment of AIT.
- Radioiodine ablation is not an option given the low iodine uptake as a result of the iodine excess from the amiodarone.

Drug-Induced Alterations in Thyroid Function

Amiodarone

- Amiodarone is a lipophilic drug that contains 75 mg iodine per 200-mg tablet.

CONTRAST MEDIA AND THYROID FUNCTION

- Another potential source of excess iodine is radiographic contrast media. The oral cholecystographic agents, iopanoic acid and sodium ipodate, may be used short term in thyrotoxic patients for their side effect of decreasing peripheral conversion of T_4 to T_3 and blocking hormone secretion from the thyroid. Used over a longer period of time, however, such agents will only exacerbate the underlying hyperthyroidism.
- Many other agents are available that have variable effects on the thyroid gland. Typically, patients with no underlying thyroid disease will not be affected by the use of these agents, but patients with Graves disease, multinodular goiter, or the elderly are at risk to develop **thyrotoxicosis** after their use.
- The lipid-soluble agents used for myelography, bronchography, and uterosalpingography are cleared slowly and release inorganic iodine for months to years.
- Newer water-soluble preparations used in arteriography and computed tomography are cleared from the plasma more quickly, but the iodine they release during these procedures can still affect thyroid function.
- The degree of thyroid dysfunction can range from mild transient subclinical hyperthyroidism to thyroid storm. Most patients experience only transient thyrotoxicosis, and the syndrome resolves when the excess iodine is cleared. If treatment is required, thionamides and β -adrenergic blockade may be used until the thyrotoxicosis resolves.

THYROTOXIC PERIODIC PARALYSIS

- Thyrotoxic periodic paralysis (TPP) is a complication of hyperthyroidism characterized by localized or generalized attacks of weakness or flaccid paralysis and hypokalemia.
- Although it has been reported in Western countries and in women, it is more common in Asian men, where the incidence is 1.9% in thyrotoxic patients.
- The clinical presentation is identical to familial hypokalemic periodic paralysis, but the pathophysiology is distinct. Although the mechanism of the syndrome is not clearly defined, hypokalemia alone is not enough to elicit the paralysis.

Clinical Presentation

- The clinical presentation is one of flaccid weakness that is symmetrical; lower extremities are generally affected more than the upper extremities.
- Breathing may be impaired if the patient has a more generalized weakness.
- The onset of the attacks is usually sudden and may be preceded by cramping.
- Ingestion of alcohol or carbohydrates and strenuous physical exercise commonly precipitate the episodes of weakness.
- Patients have decreased or absent deep-tendon reflexes. The symptoms may last from a few hours to several days.

Treatment

- Treatment is aimed at correction of the hyperthyroidism. If hypokalemia is present, replacement should be given.

- Some patients are given a potassium-sparing diuretic in addition to the potassium supplementation until euthyroidism is achieved. β -Adrenergic antagonists also decrease the frequency of attacks in these patients.

Preoperative Management

- Adequate preparation for surgery in thyrotoxic patients is critical to the successful outcome of the procedure. Surgery in a hyperthyroid patient can precipitate thyroid storm, with high morbidity and mortality if preoperative care is inadequate.
- The type of treatment will depend on the amount of time before the surgery. Elective procedures should be postponed until the T_3 and T_4 levels are normalized with thionamides and β -adrenergic blockade. This can usually be achieved within approximately 2 weeks.
- TSH may not normalize for months, and this value should not be used as the criteria to assess the thyroid status.
- Urgent or emergent procedures may be safely done after initiation of PTU and a β -adrenergic antagonist. Inorganic iodide should also be administered to block release of thyroid hormone and decrease peripheral conversion of T_4 to T_3 .
- Finally, a glucocorticoid should also be used if the patient is suspected of having concomitant adrenal insufficiency, or additional inhibition of T_4 to T_3 conversion is needed.

HYPOTHYROIDISM

- Hypothyroidism is a common clinical problem, affecting approximately 4.6% of the population in the United States.
- Hypothyroidism is most often caused by autoimmune thyroiditis, also known as *Hashimoto thyroiditis*. Other common causes of hypothyroidism are noted in Table 117.7.
- Nonthyroidal illness, surgery, or diagnostic testing can lead to metabolic decompensation in patients with undiagnosed or untreated hypothyroidism.
- Untreated hypothyroidism may slow the metabolism of certain drugs, thereby increasing the risk of problematic side effects.

TABLE 117.7

CAUSES OF HYPOTHYROIDISM

Autoimmune, Hashimoto thyroiditis
Postthyroidectomy
Postradiation
^{131}I treatment
External beam radiation
Iodine deficiency
Drugs
Lithium
Iodine-containing drugs (amiodarone, radiocontrast agents)
Secondary hypothyroidism
Pituitary tumor, irradiation, empty sella syndrome, infiltrative disorders
Hypothalamic disease
Transient disorders
Silent, subacute thyroiditis

TABLE 117.8**CLINICAL MANIFESTATIONS OF HYPOTHYROIDISM**

Symptoms	Signs
Fatigue and weakness	Delayed relaxation of tendon reflexes
Cold intolerance	Bradycardia
Weight gain	Hypoventilation
Constipation	Diastolic hypertension
Dyspnea on exertion	Reduced pulse pressure
Depression	Pericardial and pleural effusions
Menorrhagia	Generalized and periorbital edema
Myalgia	Macroglossia
Dry skin and hair	Loss of eyebrows

- The clinical manifestations of hypothyroidism are manifold. Most of the symptoms are nonspecific, which can lead to a delay in the diagnosis.
- In elderly patients, the diagnosis may be missed because the patient may be asymptomatic or the signs attributed to aging.
- Patients in the ICU may present with severe CNS disturbances, cardiovascular derangements, hyponatremia, or respiratory failure.
- Table 117.8 notes the signs and symptoms of hypothyroidism.

Cardiovascular Manifestations

- The symptoms of cardiovascular dysfunction are much less pronounced in patients with hypothyroidism compared to their thyrotoxic counterparts.
- Cardiovascular hemodynamics are affected by hypothyroidism in several ways. In particular, patients have **decreased cardiac output**, mediated by reduced contractility and heart rate.
- These patients also have increased systemic vascular resistance, predisposing them to hypertension.
- Diastolic filling and compliance are reduced, leading to diastolic dysfunction. Elevation of diastolic pressure, out of proportion to systolic pressure, may lead to a decreased pulse pressure.
- Although congestive heart failure can occur with hypothyroidism, it is rare for hypothyroidism to be the sole causative agent. Typically, patients have underlying cardiac disease that is exacerbated by hypothyroidism.
- Pericardial effusion associated with hypothyroidism may also compromise cardiac function.
- Angina may also worsen in patients with hypothyroidism.
- Patients without preexisting cardiac dysfunction typically do not manifest symptoms and signs of congestive heart failure or coronary artery syndrome unless the hypothyroidism is profound.

Pulmonary Manifestations

- **Dyspnea on exertion** is a common presenting complaint in patients with hypothyroidism, in part due to the impaired cardiac function and reduced pulmonary function. Respiratory muscle weakness also appears to play a role in this dyspnea.

- There is a reduction in central pulmonary drive in response to hypoxia and hypercapnia, leading to hypoventilation.
- Upper airway obstruction may occur as a result of goiter (see below: Acute Airway Obstruction). Additionally, sleep apnea may occur as a result of macroglossia.
- Finally, a restrictive pattern of disease may be seen in the presence of a pulmonary effusion.

Gastrointestinal Manifestations

- **Peristalsis** is slowed in patients with hypothyroidism. Most patients have normal bowel motility, but a small proportion with hypothyroidism requires laxative use.
- Patients may report vague abdominal pain and distention. Rarely, severe cases may present with ileus.
- Severely hypothyroid patients may also have **malabsorption**. The mechanism of this abnormal absorption is not clearly defined; theories include myxedematous infiltration of the mucosa, associated autoimmunity, and decreased intestinal motility.

Metabolic Manifestations

- Hypothyroidism may lead to decreased free water clearance and subsequent **hyponatremia**. The magnitude of sodium derangement is directly related to the severity of hypothyroidism.
- Hyperlipidemia is more commonly seen than hyponatremia. Lipid clearance is decreased in patients with hypothyroidism, resulting in elevated levels of free fatty acids, low-density lipoprotein (LDL), and total cholesterol.
- Treatment of the hypothyroidism results in improvement of the lipid panel.

Treatment

- Thyroid hormone is preferentially replaced with T₄. In adults, the starting dose of T₄ is typically 1.7 μg/kg/day (based on ideal body weight). Elderly patients or those with coronary disease should be started at lower doses and titrated based on TSH levels every 6 weeks.

Complications**Myxedema Coma**

- Myxedema coma is a rare but life-threatening complication of hypothyroidism. It may occur after severe longstanding hypothyroidism or after an acute precipitating event such as surgery or infection. It is more likely to occur in elderly women during the winter months.
- Any of the usual causes of hypothyroidism (see Table 117.6) may induce myxedema coma. Prompt recognition and treatment are essential, even before laboratory results are available.
- Mortality rates are improving due to early diagnosis and treatment, but mortality remains at 30% to 40%. Patients with cardiac complications and the elderly are at greatest risk.

Clinical Presentation

- Most patients with myxedema coma have had symptoms of hypothyroidism for many months. There is a gradual onset of lethargy, progressing to stupor, which is precipitated by cold exposure, infection, or medications. Other precipitating events are stroke, congestive heart failure, trauma, or gastrointestinal bleeding.
- The patient is typically an obese elderly woman with yellow discoloration of the skin. The principal features of myxedema are hypothermia, bradycardia, and decreased mental status or coma.
- Patients also characteristically have a **decreased respiratory rate** as a result of reduced hypoxic ventilatory drive. The resultant hypercarbia can exacerbate the altered mental status.
- **Hypothermia** is present in nearly all patients with myxedema coma. Temperature may be quite low ($<80^{\circ}\text{F}$, $[20^{\circ}\text{C}]$); values below 90°F (32°C) predict a poorer prognosis.
- The severity of hypothermia may go unrecognized if the proper thermometer is not used; many thermometers may not be able to measure below 93°F (34°C).
- The diagnosis of myxedema coma should be considered in any unconscious patient with infection who does not have a fever. Warming should be gradual, using ordinary hospital blankets. Electric heating blankets should not be used, as they may cause peripheral vasodilation and subsequent hypotension.
- The cardiovascular abnormalities seen in myxedema coma are similar to those associated with severe hypothyroidism. Patients can present with **bradycardia**, **reduced cardiac output**, and decreased cardiac contractility, which may lead to hypotension.
- Signs of congestive heart failure may be found. In patients with diminished heart sounds, low-voltage electrocardiogram, or cardiomegaly on chest radiograph, an investigation for pericardial effusion should be performed.
- This profound level of hypothyroidism may lead to impaired free water excretion. As a result, over half of patients can have **hyponatremia**.
- Patients should be managed by free water restriction; the condition will improve with thyroid hormone replacement.
- Bladder atony may occur, so patients should be monitored for residual volumes postvoiding.
- Hypoglycemia is a common feature that is the result of the hypothyroidism or concomitant adrenal insufficiency.

Diagnosis

- The diagnosis of myxedema coma is initially made based on historical and clinical clues. It is important to investigate other causes of altered mental status, such as cerebrovascular accident and infection.
- Serum should be obtained for measurement of TSH, free T_4 , and cortisol.
- If the clinical picture is consistent with myxedema coma, treatment should be initiated before laboratory confirmation of the diagnosis.

Treatment

- Because of the high mortality rate of this endocrine emergency, patients with myxedema coma should be treated aggressively.
- Patients should be presumed to have adrenal insufficiency and treated with **stress-dose steroids** (hydrocortisone, 100 mg IV every 8 hours) until laboratory data exclude the diagnosis.

- The administration of levothyroxine prior to glucocorticoids in such patients can provoke an adrenal crisis.
- The optimal replacement strategy for levothyroxine is unknown because of the rarity of the condition. Clinical judgment must be used to weigh the risk of rapid administration of thyroid hormone—with the possibility of precipitation of myocardial infarction—against the risk of not replacing the thyroid hormone fast enough in light of the high mortality of undertreated myxedema coma.
- It is preferable to administer both T_3 and T_4 intravenously to patients with myxedema because of the possibility of impaired gastrointestinal absorption.
- Supportive care should be directed to the coexisting medical conditions. Hyponatremia can usually be managed with free water restriction, but 3% saline may be given in extreme circumstances.
- Hypotension will usually improve with initiation of levothyroxine. Refractory hypotension should be treated with vasopressor agents until the thyroid hormone has had time to act.
- Patients may require mechanical ventilation because of respiratory muscle weakness, depressed mental status, or decreased hypoxic ventilatory drive.
- Finally, it is important to address the underlying medical illness that precipitated the myxedema coma.

Preoperative Management of Hypothyroidism

- Patients with mild to moderate hypothyroidism may proceed to surgery, as no convincing evidence exists to show that there is an adverse effect on outcomes; if the procedure is elective, it is optimal to begin replacement with thyroid hormone and delay the surgery until the patient is euthyroid.
- The exception to this rule is a patient with coronary artery disease awaiting bypass or stenting. Such patients should have their **coronary vasculature addressed first**, and then have their thyroid hormone replaced postoperatively.
- Evidence suggests that replacement of thyroid hormone before restoring coronary blood flow could tax an already ischemic myocardium.
- A patient with severe hypothyroidism—for example, very low levels of thyroid hormone, or myxedema coma, or clinical symptoms of chronic thyroid hormone deficiency such as altered mentation, pericardial effusion, or heart failure—who requires urgent surgery should be given a loading dose of intravenous T_4 and possibly T_3 .
- In addition, stress-dose glucocorticoids should be given if adrenal or pituitary function is uncertain, as replacement of thyroxine in a patient with adrenal insufficiency can precipitate adrenal crisis.

THYROID FUNCTION IN NONTHYROIDAL ILLNESS

- Aberrations in thyroid function during illness occur along a continuum, with wider deviations from the mean as the patient becomes more severely ill. Several names have been ascribed to the condition, including euthyroid sick syndrome, low T_3 syndrome, low T_4 syndrome, and nonthyroidal illness.

- Interpretation of thyroid function tests in critically ill patients is complex. For this reason, thyroid function should not be measured in this setting unless a thyroid disorder is strongly suspected.
- When it is deemed appropriate to evaluate the hypothalamic—pituitary—thyroid axis, the clinician should check a TSH, total T_4 , free T_4 , and total T_3 .
- The most commonly seen change in thyroid hormone function tests in hospitalized patients is a low serum T_3 concentration. Most T_3 in the serum is produced by deiodination of T_4 to T_3 in the peripheral tissues.
- Many commonly used medications in the ICU may also decrease the peripheral conversion of T_4 to T_3 , further lowering the circulating T_3 levels.
- Glucocorticoids and β -adrenergic antagonists are the most common offending agents. In addition, free fatty acids inhibit the deiodinase activity.
- Cytokines have also been shown to have a role in the development of the sick euthyroid syndrome by their role in decreasing the conversion of T_4 to T_3 .
- Concomitant with the decline in T_3 levels is a rise in rT_3 (reverse T_3) in nonthyroidal illness. Fasting may produce this clinical picture within 24 to 36 hours and is reversed as quickly with refeeding.
- This pattern of low T_3 /high rT_3 is found in many patients with various acute and chronic illnesses such as infection, surgery, cancer, cardiovascular diseases, pulmonary processes, burns, or trauma.
- The metabolic rate of formation of rT_3 is unchanged in the setting of illness. The increase in this value is, instead, a reflection of the attenuated rates of clearance of rT_3 .
- The complicating factor with measuring the rT_3 levels in patients suspected of having nonthyroidal illness is that it may take up to a week to process the test in the laboratory.
- T_4 levels may also be reduced in up to 20% of hospitalized patients and 50% of critically ill patients. These low T_4 levels are correlated with a higher mortality rate.
- The reduction in T_4 can, in part, be attributed to decreased concentrations of one of the three thyroid hormone-binding proteins: TBG, transthyretin, and albumin.
- Serum TSH levels are typically normal in most patients with nonthyroidal illness, although during the recovery phase of the illness, thyrotropin concentrations may rise.
- In more critically ill patients, the TSH may simultaneously fall with the decline in T_4 levels. Such findings have led some to suggest that some patients may have an acquired transient central hypothyroidism during the nonthyroidal illness.
- Thyroid hormone replacement has not been shown to improve outcomes in critically ill patients. Medications may also alter TSH levels (see Table 117.2). Dopamine infusions are frequently associated with a reduction in serum thyrotropin concentration.
- When measuring TSH levels in the ICU, it is important to use a high-sensitivity assay with a lower detection limit of at least 0.01 mU/L. The vast majority of hospitalized patients with low, but detectable, TSH by this assay have sick euthyroid syndrome.
- In contrast, patients with undetectable thyrotropin are more likely to be hyperthyroid.
- Finally, those patients with high TSH (up to 20 mU/L) are likely recovering from a nonthyroidal illness and should be reassessed 6 weeks after the hospitalization.

Acute Airway Obstruction and Goiter

- Acute airway obstruction is a life-threatening complication of an enlarged thyroid gland.
- Fortunately quite rare, but important to consider, is anaplastic **thyroid cancer**. Patients with this disease may present with considerable growth of the thyroid within a few weeks.
- Thyroid **lymphoma** can also show a rapid growth pattern but will quickly respond to appropriate chemotherapy and/or radiation therapy.
- **Riedel thyroiditis**, also rare, with a prevalence of 0.06% to 0.3%, may present with a rapidly enlarging, hard neck mass that must be differentiated from thyroid cancer or lymphoma. The fibrous tissue may invade soft tissue and muscle and lead to tracheal compression.
- The more common scenario is a patient who presents with a nodule that rapidly increases in size over several minutes to hours. In these cases, the patient has underlying nodular disease that has encroached on a nearby blood vessel and **bled into a cystic compartment** of the nodule. Typically, patients have regression of such a nodule over the ensuing weeks.
- The clinical presentation of a compressive goiter is varied. Patients may present with complaints of a pressure sensation in the neck, particularly with movement of the head. Difficulty swallowing and vocal cord paralysis also may be encountered.
- The **Pemberton sign**, facial flushing and jugular venous distention on raising the arms over the head, is an indication of obstruction of venous outflow from the head.
- Many patients with a goiter have a mild degree of airway obstruction when screened with pulmonary function tests.
- It is critical to recognize that a patient presenting with new-onset wheezing or stridor may have a substernal goiter.
- The management of acute airway compromise is primarily surgical. If airway collapse is imminent, it is critical to protect the airway with intubation.
- The type of surgery necessary depends on the size of the goiter and whether there is an associated malignancy. Radioiodine treatment can take months to years to shrink the goiter.

Postthyroidectomy Hypocalcemia

Hypoparathyroidism

- The most common cause of hypoparathyroidism is surgery on the neck, with resultant removal of, or injury to, the parathyroid glands. This is typically seen after cancer surgery, total thyroidectomy, or parathyroidectomy.
- It is most often a transient condition with symptoms occurring 1 to 2 days postoperatively. Symptoms may vary from subtle perioral numbness and tingling to profound fatigue to tetany.
- Table 117.9 lists the symptoms and signs that may be seen in patients with hypocalcemia.
- Risk of hypocalcemia is dependent on the extent of surgery, localization and preservation of the parathyroids, and skill of the surgeon. Incidence rates of postoperative, transient hypocalcemia range from 1.6% up to >50%, but most of these patients will regain parathyroid function over the ensuing months.
- The risk of permanent hypoparathyroidism is variable, between 0% and 10%. During nonparathyroid neck surgery,

TABLE 117.9

SYMPTOMS AND SIGNS OF ACUTE HYPOCALCEMIA

Symptoms	Signs
Perioral numbness and tingling	Chvostek sign
Tingling paresthesias in distal extremities	Trousseau sign
Muscle cramps	Hypotension
Hyperreflexia	Bradycardia
Carpopedal spasm	Prolonged QT interval
Seizures	Arrhythmias

it is critical for the surgeon to recognize a compromised parathyroid gland and autotransplant the gland into the adjacent neck muscle to ensure the gland will regain function.

Treatment

- Treatment is aimed at normalization of the serum calcium. Many surgeons begin thrice-daily prophylactic oral calcium supplementation the night of the surgery.
- If the patient develops progressive symptoms, tetany, or seizures, the use of IV **calcium gluconate** is warranted. In life-threatening situations, 10 mL of calcium gluconate may be administered intravenously over a 5- to 10-minute period and repeated as necessary.

- In less acute situations, a continuous calcium infusion may be used by mixing 10 ampules of calcium gluconate in 500 mL of 5% dextrose in water. The infusion rate may vary between 0.3 mg/kg/hour to 2 mg/kg/hour, depending on the clinical setting.
- The goal of therapy is to reverse hypocalcemic symptoms and restore calcium levels to the low-normal range.

Hungry Bone Syndrome

- Hungry bone syndrome (HBS) is a well-recognized complication of surgical correction of severe hyperparathyroidism.
- Patients with very high levels of parathyroid hormone (PTH) may develop significant hypocalcemia after surgical removal of the offending parathyroid adenoma(s). The mechanism of this metabolic derangement is rapid skeletal mineralization.
- Less commonly seen is HBS after thyroidectomy for thyrotoxicosis. Patients with hyperthyroidism may develop secondary osteoporosis and resultant hypercalcemia from the increased bone resorption. After surgical removal of the thyroid gland, patients have a reversal of the thyrotoxic osteodystrophy and, instead, have a net flux of calcium and phosphorous deposition into bone.
- In extreme thyrotoxicosis, the patient may develop hypocalcemia. This condition typically resolves within a few days to weeks with treatment of the hypocalcemia.

SECTION XVIII ■ HEMATOLOGIC AND ONCOLOGIC DISEASE AND DYSFUNCTION

CHAPTER 118 ■ COAGULATION DISORDERS IN THE INTENSIVE CARE UNIT

- Coagulopathic conditions frequently encountered in the intensive care unit (ICU) arbitrarily divided (Table 118.1):
 - Those associated with serious bleeding or a high probability of bleeding
 - Thrombotic syndromes or conditions associated with higher probability of thrombosis
 - Systemic diseases associated with acquired selective coagulation factor deficiencies
 - A few conditions associated with abnormal coagulation screening tests that represent laboratory phenomena not associated with increased bleeding risk

OVERVIEW OF COAGULATION

- For years teaching was that process of blood clotting divided into the intrinsic, extrinsic, and common pathways (Fig. 118.1)

TABLE 118.1

OVERVIEW OF COAGULATION DISORDERS SEEN IN THE ICU

Conditions Associated with Serious Bleeding or a High Probability of Bleeding

Disseminated intravascular coagulation (DIC)
Liver disease/hepatic insufficiency
Vitamin K deficiency/depletion
Massive transfusion syndrome
Anticoagulant overdose (heparin, warfarin)
Thrombocytopenia (drug-induced, immunologic)
Acquired platelet defects (drug-induced, uremia)

Thrombotic Clinical Syndromes

Thrombotic thrombocytopenia purpura/hemolytic uremic syndrome
Deep venous thrombosis
Pulmonary embolism
Coronary thrombosis/acute myocardial infarction

Laboratory Abnormalities Not Associated with Clinical Bleeding

Lupus anticoagulant
Reactive hyperfibrinogenemia

Other Selected Clinical Syndromes

Hemophilia (A and B)
Specific factor deficiencies associated with specific diseases
Amyloidosis, factor X; Gaucher, factor IX; nephrotic syndrome, factor IX, antithrombin III
Cyanotic congenital heart disease (polycythemia, qualitative platelet defect)
Depressed clotting factor levels (newborns)

- Students come away with thought that clotting occurs as result of orderly sequential process
- Obscure fact that once initiated, clot production and clot destruction (fibrinolysis) occur simultaneously
 - Minimizes role that platelets and the endothelium play in overall process
- Previously thought that intrinsic pathway, beginning with activation of factor XII (fXII) to activated factor XII (fXIIa) in contact with some biologic or foreign surface, was physiologically most important in initiation of clot formation
 - Now know that the activation of fX to fXa through action of fVIIa/tissue factor (TF) complex paramount
 - Also evident that various elements of clotting cascade frequently act in concert
 - Use of term *tenase* to describe the action of fVIIa/TF complex along with the fIXa/fVIIIa complex on activation of factor X to Xa
 - Use of term *prothrombinase* to describe factor Xa/Va complex, which cleaves prothrombin (factor II) to form thrombin (factor IIa)
 - There is cross talk between two arms of the clotting cascade, with fVIIa being able to enhance the activation of fIX (to fIXa) and fXI (to fXIa), further pointing out the central role that fVIIa and TF play *in vivo* (Fig. 118.2)
 - There are various positive feedback loops principally involving thrombin that enhance the upstream activation of clotting process
- TF for activation of coagulation present in subendothelial matrix
 - Found circulating freely in plasma as soluble TF and contained on cellular elements such as monocytes
 - Clotting does not occur in free-flowing blood but rather on surfaces
 - Platelets, endothelial cells, subendothelial matrix, and biologic polymers, for example, catheters, grafts, stents, and so on, provide these surfaces for clot formation
- Platelets initiate clot formation through formation of platelet plug
 - More significantly bring specialized proteins that regulate clotting response, for example, fVIII, inhibitors of fibrinolysis, and so on, to area of bleeding
 - Provide surface for colocalization of clotting factors for efficient clot formation (Fig. 118.3)
 - Do not ordinarily adhere to vascular endothelium unless mechanically disrupted (e.g., cut) or activated by inflammation
 - Then platelets bind to endothelial cells or subendothelial matrix via a von Willebrand factor (vWf)-dependent mechanism
 - Once adherent platelets become activated and secrete various molecules, that further enhances platelet

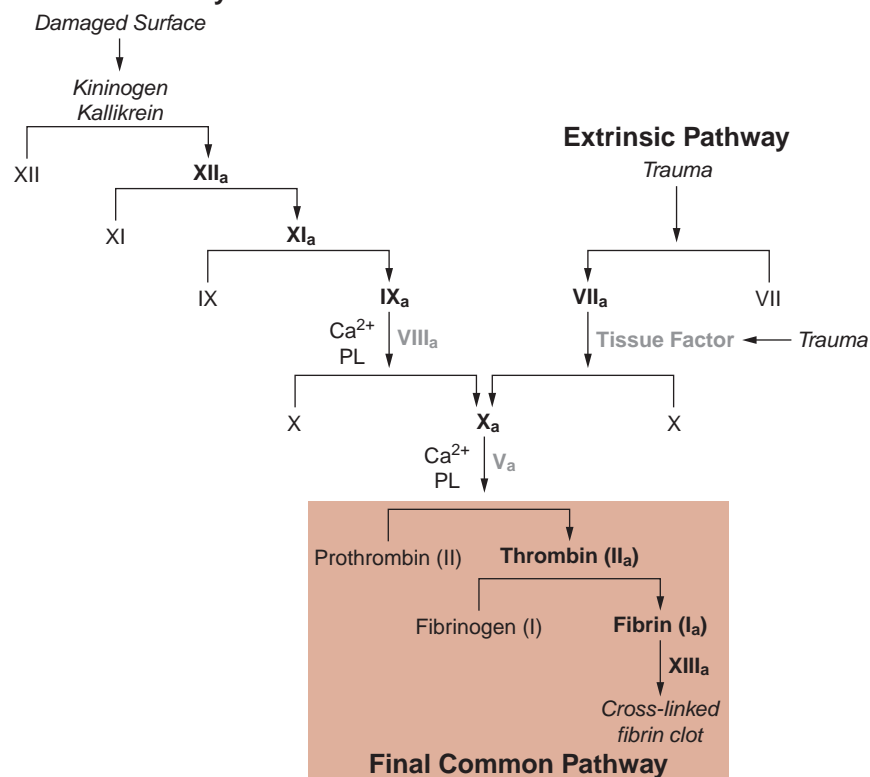

Intrinsic Pathway

FIGURE 118.1. Coagulation is initiated either through the intrinsic pathway by activation of factor XII by the generation of high-molecular-weight kininogen and kallikrein, or through activation of the extrinsic pathway by tissue factor. Roman numerals indicate zymogen clotting factors; “a” indicates activated forms of the clotting factors.

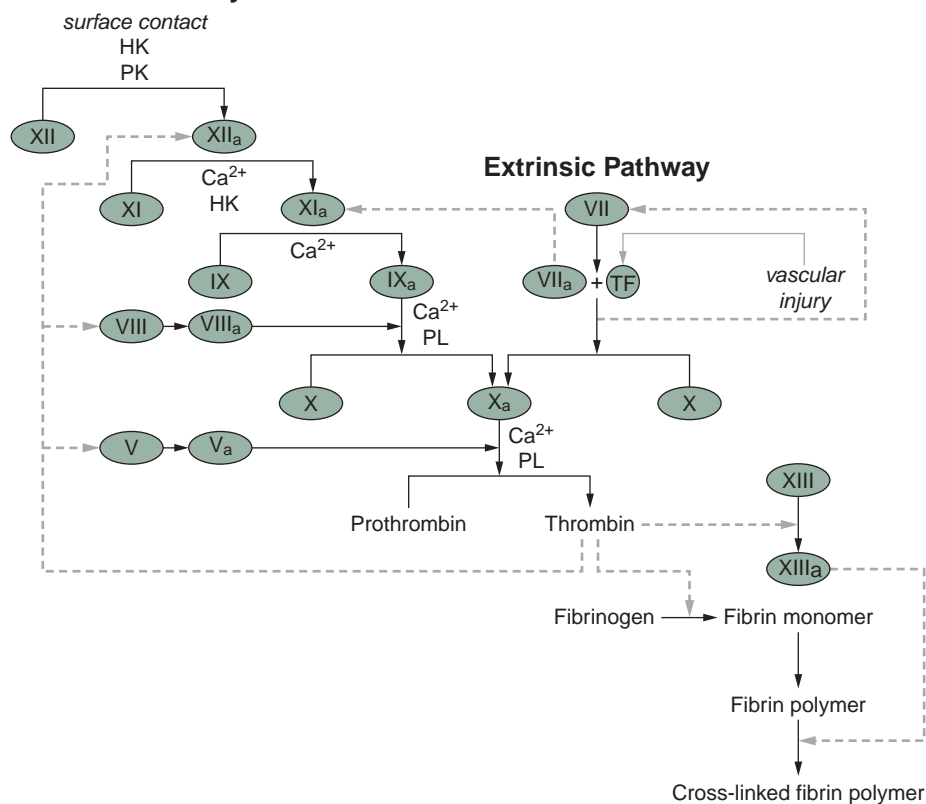

Intrinsic Pathway

FIGURE 118.2. Modified clotting cascade indicating cross talk between the intrinsic and extrinsic pathways by the action of VII_a/tissue factor (TF) enhancing the conversion of factor XI to activated factor XI (XI_a) (dotted lines). Ca²⁺, calcium; HK, high-molecular-weight kininogen; PK, prekallikrein; PL, phospholipids.

FIGURE 118.3. The role of platelets in mediating primary hemostasis at sites of vascular injury. Platelets are initially activated and express specific adhesion receptors on their surface, followed by adhesion to activated endothelial cells and exposed subendothelial components (e.g., collagen, von Willebrand factor). Subsequent platelet aggregation occurs with the development of a primary platelet plug. Coagulation occurs on the developing platelet plug with the creation of a fibrin clot.

adherence and aggregation, vascular contraction, clot formation, and wound healing

- Endothelium a specialized organ that plays central role in regulation of clot formation (i.e., hemostasis) by presenting a nonthrombogenic surface to flowing blood and by enhancing clot formation when disrupted by trauma or injured by infection or inflammation (Fig. 118.4)
- Normal endothelium produces inhibitors of blood coagulation and platelet activation, and modulates vascular tone and permeability
- Endothelial cells synthesize and secrete components of subendothelial extracellular matrix, including adhesive glycoproteins, collagen, fibronectin, and vWf
- When disrupted, bleeding occurs
- When *injured*, endothelium often becomes *prothrombotic* rather than *antithrombotic*, and unwanted clot formation may occur

INTERACTION OF COAGULATION AND INFLAMMATION

- Many inflammatory cytokines have been identified as promoters of a procoagulant milieu
 - Interconnection of TF and tumor necrosis factor- α (TNF- α) may potentially be most important of these
 - During sepsis, TF expression is up-regulated in activated monocytes and endothelial cells as a response to endotoxin
 - Consequence being both secretion of proinflammatory cytokines, interleukin-6 (IL-6), and TNF- α from activated mononuclear cells, and the activation of coagulation
 - Results in increased thrombin production, which plays a central role in coagulation and inflammation through the induction of procoagulant, anticoagulant, inflammatory, and mitogenic responses

FIGURE 118.4. The interaction of the protein C system with the endothelium: thrombin bound to thrombomodulin (TM) modifies protein C bound to the endothelial protein C receptor (EPCR) on the cell surface to generate activated protein C (APC). APC acts as a natural anticoagulant by inactivating activated factors V (fVa) and VIII (fVIIa), modulates inflammation by down-regulating the synthesis of proinflammatory cytokines, leukocyte adherence, and apoptosis and enhances fibrinolysis by inhibiting thrombin-activatable fibrinolysis inhibitor (TAFI) and plasminogen activator inhibitor type-1 (PAI-1). sTM, soluble thrombomodulin; sEPCR, soluble endothelial protein C receptor; PS, protein S; C4bbp, C_{4b} binding protein; PAI-1, plasminogen activator inhibitor type 1.

- Thrombin results in activation, aggregation, and lysis of leukocytes and platelets, and activation of endothelial cells, with resultant increase in proinflammatory cytokines IL-6 and TNF- α expression
- Net result of thrombin generation is to produce a proinflammatory and procoagulant state
 - Leading to formation of fibrin and microvascular thrombosis
 - These proinflammatory effects of thrombin are counterbalanced by the anti-inflammatory effects of activated protein C (see Fig. 118.4)
- Second important point of connection of coagulation and inflammation is through protein C (PC) system
 - Anticoagulant effects of activated protein C (aPC) and its cofactor, protein S, well known; only recently have anti-inflammatory roles of these proteins been appreciated
 - Experimentally, aPC increases secretion of anti-inflammatory cytokines, reduces leukocyte migration and adhesion, and protects endothelial cells from injury
 - Balance between anticoagulant and anti-inflammatory roles of aPC may be mediated by relative distribution of free and complement factor C_{4b}-bound protein S
 - *In vitro*, aPC inhibits TNF- α elaboration from monocytes and blocks leukocyte adhesion to selectins, as well as having an influence on apoptosis
 - Protein C pathway is engaged when thrombin binds to thrombomodulin on surface of endothelial cell
 - Binding of PC to the endothelial cell protein C receptor (EPCR) augments protein C activation by thrombin-TM complex more than 10-fold *in vivo*
 - EPCR is shed from the endothelium through the action of inflammatory mediators and thrombin, thereby down-regulating aPC generation in sepsis and inflammation
- Third important link between inflammation and coagulation occurs at level of fibrinolysis and also involves PC system
 - aPC capable of neutralizing fibrinolysis inhibitors, *plasminogen activator inhibitor type-1* (PAI-1) and *thrombin activatable fibrinolysis inhibitor* (TAFI)
 - Consequently, depressed levels of aPC promote clot formation by reducing *inactivation* of procoagulant molecule-activated factors V and VIII (fVa, fVIIIa), leading to increased generation of thrombin and fibrin clots and by limiting fibrinolytic response needed to degrade clots
 - TAFI (also known as carboxypeptidase R) also shown to inactivate inflammatory peptides, such as complement factors C3a and C5a, which play role in contact activation of coagulation
 - Polymorphisms of promoter region of the PAI-1 gene that lead to differences in PAI-1 production have been demonstrated to affect prognosis in meningococcal sepsis and multiple trauma

AN APPROACH TO THE PATIENT WITH AN ACTUAL OR SUSPECTED COAGULATION DISORDER

Clinical History

- Diagnostic assessment begins at the bedside
 - Specific questions regarding bleeding should investigate occurrence of any of following:
 - Spontaneous, easy, or disproportionately severe bruising
 - Intramuscular hematoma formation (either spontaneous or related to trauma)
 - Spontaneous or trauma-induced hemarthrosis
 - Spontaneous mucous membrane bleeding
 - Prior problems with bleeding related to surgery (including dental extractions, tonsillectomy, and circumcision)
 - The need for transfusions in the past
 - Menstrual history
 - Current medications
 - Innumerable aspirin-containing medications available, all of which can potentially interfere with platelet-mediated primary hemostasis
- Prior history of significant thrombosis, deep vein thrombosis (DVT), pulmonary embolus, or stroke, suggests possibility that hypercoagulable condition may be present
- Occurrence of thrombotic events, particularly early cardiovascular events such as myocardial infarction, in young adult relatives should cause consideration of:
 - Deficiencies of antithrombin-III, protein C, or protein S
 - Presence of factor V Leiden R506Q mutation, prothrombin G20210A (or the newly described A19911G) polymorphism or mutation
 - C677T mutation or polymorphism of the MTHFR (methylenetetrahydrofolate reductase) gene
 - Vasculitis associated with autoimmune disorder such as systemic lupus erythematosus (SLE) must always be considered in evaluation of an individual with unexplained pathologic clot

Physical Examination

- Generalized bleeding in critically ill ICU patients presents a special problem
 - Often associated with severe underlying multiple organ system dysfunction
 - Correction of coagulopathy usually requires improvement in patient's overall clinical status
 - Supportive evidence or physical findings of other concurrent organ system dysfunction, such as oliguria or anuria, respiratory failure, or hypotension, often are readily apparent
 - Bleeding in critically ill patients is often caused by sepsis-related disseminated intravascular coagulation (DIC)
 - Must also consider coagulopathy of severe liver dysfunction, undiagnosed hemophilia, or, in elderly or debilitated, vitamin K deficiency in differential diagnosis
 - Physical examination of patient with bleeding disorder should answer basic questions:
 - Is process localized or diffuse?
 - Is it related to an anatomic or surgical lesion?
 - Is there mucosal bleeding?
 - Are there signs of either arterial or venous thrombosis?
 - During the course of the examination, attention paid to presence of specific physical findings:
 - Enlarged spleen coupled with thrombocytopenia suggests that splenic sequestration may be a contributor to the observed thrombocytopenia
 - Evidence of liver disease, such as portal hypertension and ascites, points to decreased factor synthesis as a possible cause of a prolonged prothrombin time (PT) or activated partial prothrombin time (aPTT)

- If lymphadenopathy, splenomegaly, or other findings suggestive of disseminated malignancy detected, acute or chronic DIC should be suspected as the cause of prolonged coagulation times, hypofibrinogenemia, and/or thrombocytopenia
- Purpura that are palpable suggest capillary leak from vasculitis
 - Purpura associated with thrombocytopenia or qualitative platelet defects generally not elevated and cannot be distinguished by touch
- Venous and arterial telangiectasia may be seen in von Willebrand disease and liver disease, respectively
 - Selective pressure centrally applied to arterial telangiectasia, whole lesion fades
 - Venous telangiectasia requires confluent pressure across entire lesion, as with a glass slide, for blanching to occur

Diagnostic Laboratory Evaluation

- Importance of correct specimen collection for hemostatic evaluation must be emphasized
 - In ICU, common for laboratory samples to be drawn through an indwelling arterial or central venous cannula
 - Heparin-containing solution commonly present
 - In cannula flush medium to transduce a waveform
 - As a component of intravenous infusion
 - Depending on heparin concentration
 - Fibrin degradation products (FDPs) can be falsely elevated
 - Fibrinogen can be falsely low
 - PT, aPTT, and thrombin time (TT) can be spuriously prolonged
 - Minimum of 20 mL of blood in adolescents and adults, and 10 mL of blood in younger children, should therefore be withdrawn through the cannula and either discarded or used for other purposes before obtaining a specimen for laboratory hemostasis analysis
 - Should minimize any influence of heparin on results
 - May not be reasonable to withdraw this volume of blood, and a peripheral venipuncture may be necessary
 - aPTT sensitive to presence of small amounts of heparin
 - Unexpected prolonged aPTT obtained through a heparinized catheter should raise suspicion of sample contamination
 - TT will also be prolonged but will normalize if heparin neutralized (e.g., with toluidine blue or HEPA sorb)
 - Most suspected bleeding disorders confirmed using routine tests (Table 118.2):
 - Evaluation of peripheral blood smear, including an estimate of the platelet count and platelet and red blood cell (RBC) morphologic features
 - Measurement of PT, aPTT, and TT
 - Assays for fibrinogen or presence of fibrin degradation products or the d-dimer fragment of polymerized fibrin
 - Latter test more specific for fibrinolytic fragment produced when polymerized fibrin monomer, produced

TABLE 118.2

HEMORRHAGIC SYNDROMES AND ASSOCIATED LABORATORY FINDINGS

Clinical syndrome	Screening tests	Supportive tests
DIC	Prolonged PT, aPTT, TT; decreased fibrinogen, platelets; microangiopathy	(+) FDPs, d-dimer; decreased factors V, VIII, and II (late)
Massive transfusion	Prolonged PT, aPTT; decreased fibrinogen, platelets ± Prolonged TT	All factors decreased; (–) FDPs, d-dimer (unless DIC develops); (+) transfusion history
Anticoagulant overdose Heparin	Prolonged aPTT, TT; ± prolonged PT	Toluidine blue/protamine corrects TT; Reptilase time normal
Warfarin (same as vitamin K deficiency)	Prolonged PT; ± prolonged aPTT (severe); normal TT, fibrinogen, platelets	Vitamin K-dependent factors decreased; factors V, VIII normal
Liver disease Early Late	Prolonged PT Prolonged PT, aPTT; decreased fibrinogen (terminal liver failure); normal platelet count (if splenomegaly absent)	Decreased factor VII Decreased factors II, V, VII, IX, and X; decreased plasminogen; ± FDPs unless DIC develops
Primary fibrinolysis	Prolonged PT, aPTT, TT; decreased fibrinogen and ± platelets decreased	(+) FDPs, (–) d-dimer; short euglobulin clot lysis time
TTP	Thrombocytopenia, microangiopathy with mild anemia; PT, aPTT, fibrinogen generally WNL/mildly abnormal	ADAMTS13 deficiency/inhibitor, unusually large vWf multimers between episodes; mild increase in FDPs or d-dimer
HUS	Microangiopathic hemolytic anemia, ± thrombocytopenia; PT, aPTT generally WNL	Renal insufficiency; FDPs and d-dimer generally (–)

DIC, disseminated intravascular coagulation; PT, prothrombin time; aPTT, activated partial thromboplastin time; TT, thrombin time; FDPs, fibrin degradation products; TTP, thrombotic thrombocytopenic purpura; WNL, within normal limits; vWf, von Willebrand factor; HUS, hemolytic uremic syndrome.

through the action of thrombin on fibrinogen, cleaved by proteolytic enzyme, plasmin

- D-dimer assay positive only if fibrinogen cleaved to fibrin by action of thrombin

Evaluation of Thrombosis

- Patients presenting with thrombotic event generally don't display abnormalities of usual clotting studies
- Hyperfibrinogenemia and persistent elevations of fVIII associated with increased risk of thrombosis
- Both elevated by acute inflammation
 - Finding of elevations of these clotting factors is generally not helpful in the evaluation of a thrombotic event in an acutely ill individual
- Several inherited or acquired abnormalities that increase risk for thrombosis identified:
 - Prior to initiation of anticoagulation, plasma levels of protein C (antigen and activity), protein S (antigen and activity), total and free, and antithrombin III (antigen and activity) should be obtained
 - Polymerase chain reaction (PCR) analysis for mutations in factor V (factor V Leiden; [Arg]R506Q[Gln]), prothrombin ([Gly]G20210A[Ala], and [Ala]A19911G[Gly]) and MTHFR ([Cys]C677T[Thr]) genes should be performed
 - Baseline serum homocysteine obtained as thrombosis risk of MTHFR mutation related to elevations of homocysteine caused by alterations in the metabolism of folic acid rather than the mutation *per se*
 - Acquired thrombotic risk factors include:
 - Presence of lupus anticoagulants, antiphospholipid, and anticardiolipin antibodies
 - In adult populations, approximately 40% of patients with thrombosis will not display known thrombophilic risk factors
 - Intensivist must look for confounding clinical conditions:
 - Severe dehydration with marked hemoconcentration

CONDITIONS ASSOCIATED WITH SERIOUS BLEEDING OR A HIGH PROBABILITY OF BLEEDING

Disseminated Intravascular Coagulation

Pathogenesis

- Often occurring in conjunction with more serious, life-threatening disorders, one of most serious hemostatic abnormalities seen in ICU
- Clinical syndrome results from activation of blood coagulation
- Then leads to excessive thrombin generation
- Final result of this process is the widespread formation of fibrin thrombi in the microcirculation, with resultant consumption of certain clotting factors and platelets
- Consumption generally results in development of significant bleeding due to rate of consumption outpacing rate at which clotting factors and platelets are produced (Table 118.3)

TABLE 118.3

UNDERLYING DISEASES ASSOCIATED WITH DIC

- | | |
|--------------------------------|--|
| • Sepsis | • Retained placenta |
| • Liver disease | • Hypertonic saline abortion |
| • Shock | • Amniotic fluid embolus |
| • Penetrating brain injury | • Retention of a dead fetus |
| • Necrotizing pneumonitis | • Eclampsia |
| • Tissue necrosis/crush injury | • Localized endothelial injury (aortic aneurysm, giant hemangiomas, angiography) |
| • Intravascular hemolysis | • Disseminated malignancy (prostate, pancreatic) |
| • Acute promyelocytic leukemia | |
| • Thermal injury | |
| • Freshwater drowning | |
| • Fat embolism syndrome | |

Clinical Presentation and Diagnosis

- Suspicion that DIC is present usually stems from one of two situations:
 - Unexplained generalized oozing or bleeding
 - Unexplained abnormal laboratory parameters of hemostasis
- Usually occurs in context of suggestive clinical scenario or associated disease (see Table 118.3)
- Infection and multiple trauma most common underlying conditions associated with development of DIC
- A list of laboratory studies in DIC is found in Table 118.4
- In addition to liver disease, several other conditions have presentations similar to DIC and must be considered in differential diagnosis:
 - Massive transfusion
 - Primary fibrinolysis
 - Thrombotic thrombocytopenic purpura/hemolytic uremic syndrome
 - Heparin therapy
 - Dysfibrinogenemia

Management

- Primary treatment for DIC is correction of underlying problem that led to its development
 - Specific therapy for DIC should not be undertaken unless:
 - Patient has significant bleeding or organ dysfunction secondary to DIC

TABLE 118.4

LABORATORY TESTS FOR THE DIAGNOSIS OF DIC

Test	Discriminator value
Platelet count	<80–100,000 cells/ μ L or a decrease of >50% from baseline
Fibrinogen	<100 mg/dL or a decrease of >50% from baseline
PT	>3 s prolongation above ULN
FDPs	>80 mg/dL
d-Dimer	Moderate increase

PT, prothrombin time; FDPs, fibrin degradation products; ULN, upper limit of normal.

- Significant thrombosis has occurred
- If treatment of underlying disorder—for example, acute promyelocytic leukemia—is likely to increase the severity of DIC
- Supportive therapy for DIC includes use of several component blood products
 - Packed RBCs are given according to guidelines in face of active bleeding
 - Fresh whole blood, <24 to 48 hours old, may be given to replete both volume and oxygen-carrying capacity
 - Additional potential benefit of providing coagulation proteins, including fibrinogen, and platelets
 - Cryoprecipitate contains higher concentration of fibrinogen than whole blood or fresh frozen plasma (FFP)
 - FFP of limited value for treatment of significant hypofibrinogenemia
 - May effectively replete other coagulation factors consumed with DIC such as protein C
 - Large volumes of FFP needed
 - Use of cryoprecipitate or FFP in treatment of DIC has been debated
 - Concern that products provide further substrate for ongoing DIC
 - Clinical (autopsy) studies failed to confirm this concern
- Goal of blood component therapy to produce clinical stability
 - Serum fibrinogen level <75 to 50 mg/dL, repletion with cryoprecipitate to raise plasma levels to 100 mg/dL or higher is goal
 - Starting dose is one bag of cryoprecipitate for every 10 kg body weight every 8 to 12 hours
 - Recheck fibrinogen level after infusion to document fibrinogen level
 - Amount and timing of next infusion adjusted according to results
 - Platelet transfusions when thrombocytopenia contributes to bleeding
 - Fibrin/fibrinogen fragments produced in DIC have potential to impair platelet function by inhibiting fibrinogen binding to platelets
 - May be clinically significant at the concentration of FDPs achieved with DIC
 - Platelet transfusions to maintain platelet counts up to 40,000 to 80,000 cells/ μ L
 - Pharmacologic therapy for DIC has two primary aims:
 - To “turn off” ongoing coagulation so that repletion of coagulation factors may begin
 - To impede thrombus formation and ensuing ischemic injury
 - Two new recombinant blood products have some usefulness
 - Recombinant-activated protein C
 - Results in 6% reduction in sepsis mortality in adults and possibly a reduction in the incidence of DIC
 - Recombinant-activated factor VII (rhFVIIa)
 - Potent agent for control of bleeding from several medical and surgical causes, including DIC and other consumptive coagulopathies
 - Other anticoagulant molecules such as heparin and antithrombin III and thrombolytic agents studied as therapy for DIC and sepsis

Liver Disease and Hepatic Insufficiency

Abnormal Hemostasis in Liver Disease

- Common cause of abnormal hemostasis in ICU patients
 - Abnormal coagulation studies or overt bleeding occurs in 15% of patients with clinical or laboratory evidence of hepatic dysfunction
 - Common cause of a prolonged PT or aPTT, often without any clinical sequelae
- Hemostatic defect associated with liver disease multifactorial
 - Synthesis of several plasma coagulation proteins impaired
 - Include factors II, V, VII, IX, and X
 - Fibrinogen synthesis usually maintained at levels that prevent bleeding until terminal liver failure supervenes
 - Function of fibrinogen synthesized by diseased liver may not be normal
 - Increased sialic acid content in structure
 - May result in a diminished ability to form clots (i.e., a dysfibrinogen)
 - Factor XIII activity often decreased in hepatocellular disease
 - Clinical significance of decrease in factor XIII uncertain
 - Levels as low as 3% provide normal fibrin clot stabilization
 - Although apparently synthesized by liver, factor VIII (i.e., factor VIII coagulant protein [VIII:C], antihemophilic factor A [AHF]) synthesis seems independent of state of hepatic function
 - Factor VIII levels may be increased in some types of liver disease
 - Plasma protein C and antithrombin III levels are low in hepatic insufficiency
 - Patients with liver disease, particularly cirrhosis, have increased fibrinolytic activity
 - Mechanism for heightened fibrinolytic state not clear
 - Related to increased amounts of plasminogen activator noted in these patients
 - Thrombocytopenia present to variable degree in patients with hepatic dysfunction
 - Usually ascribed to splenic sequestration
 - Rarely profound and generally does not produce clinically significant bleeding
 - *In vitro* platelet aggregation may be affected
 - Increased plasma concentrations of FDPs possible cause of qualitative platelet abnormalities
 - Thrombocytopenia in conjunction with other coagulation or hemostatic defects secondary to liver disease may result in difficult to manage bleeding
 - Patients with hepatocellular disease may exhibit decreased synthesis of:
 - Vitamin K-dependent anticoagulant proteins
 - Protein C and protein S
 - Antithrombin-III
 - Decreased levels of these natural anticoagulants may increase risk of thrombosis
 - Neither PT, aPTT, nor TT affected by levels of any of these naturally occurring anticoagulants

Presentation

- Factor VII activity levels usually first to decrease due to its short half-life—4 to 6 hours—and increased turnover
 - Results in prolonged PT

- Prolonged thrombin time in setting of liver disease may indicate:
 - Presence of dysfibrinogenemia as result of altered hepatic fibrinogen synthesis
 - An acquired defect in fibrin polymerization (e.g., increased FDPs)
- As severity of liver disease increases, aPTT also may be affected
 - Reflecting more severely impaired synthetic function
 - Plasma concentrations of vitamin K-dependent coagulation proteins decrease, as does factor V, which is not vitamin K dependent
 - Plasma levels of fibrinogen generally maintained until disease approaches end stage
 - Synthetic hypofibrinogenemia of liver disease not accompanied by marked increase in either FDPs or d-dimers
- Fibrinolysis may complicate clinical management
 - Differentiating between concomitant DIC and fibrinolysis attributable to liver disease alone may be difficult
 - D-dimer assay result should be negative in the patient with liver disease and elevated FDPs, but no active bleeding

Management

- If patient is not actively bleeding, with certain provisos, no specific therapy is required.
 - With prolonged PT, postoperative or preoperative patient, correction of PT may be attempted
 - FFP provides most immediate source of specific coagulation factors (i.e., factor VII)
 - Usually corrects isolated mild PT prolongation
 - Cryoprecipitate required if fibrinogen levels <50 to 100 mg/dL or if documentation of significant dysfibrinogenemia
- Vitamin K deficiency relatively common in patient population
 - Correction of PT in vitamin K-responsive critically ill patients typically requires longer than 12 to 24 hours
 - Patients with significant hepatic impairment may manifest partial response or may not respond
 - Immediate use of FFP is therefore appropriate when rapid correction is necessary.
- Recombinant human-activated factor VII (rhfVIIa) infusions shown to control bleeding in severe liver disease
 - Does not necessarily result in reduced mortality
- When synthetic capability of liver more profoundly impaired and aPTT prolonged
 - Greater volumes of FFP or more specific therapy needed
 - Use of factor IX concentrates (prothrombin complex concentrates) or rhfVIIa has been advocated
 - Particularly if bleeding present; however, use remains controversial
 - Products produced from plasma pooled from multiple donors carry a significant risk of both hepatitis B and C
 - May provoke DIC and actually worsen hemostasis
 - Use of prothrombin complex concentrates or rhfVIIa reserved for patients with poorly controlled bleeding unresponsive to other therapeutic modalities such as infusion of FFP
- Comprehensive therapeutic approach needed in patient with active bleeding as result of liver disease
 - Initially, FFP, 10 to 15 mL/kg body weight, given every 6 to 8 hours until bleeding slows significantly
 - Then continued at maintenance levels as dictated by clinical status and coagulation studies
 - Recombinant human-activated factor VII or prothrombin complex concentrates used in patients unresponsive to FFP infusions
 - Cryoprecipitate infused for fibrinogen levels <50 to 100 mg/dL
 - Platelet transfusions required if platelet count <40,000 to 80,000 cells/ μ L
 - Vitamin K empirically administered on presumption that part of synthetic defect results from a lack of cofactor
 - Anticipate poor response to vitamin K in presence of severe liver disease
 - Transfusions of packed red blood cells (PRBCs) given as deemed appropriate by the clinician

Vitamin K Deficiency

- Most common cause of prolonged PT in ICU is vitamin K deficiency
 - Necessary for the gamma-carboxylation of factors II, VII, IX, and X
 - Without which factors cannot bind calcium and are not efficiently converted into activated forms
 - Factor VII has shortest half-life of these coagulation proteins
 - PT is the most sensitive early indicator of vitamin K deficiency
- Differential diagnosis of isolated prolongation of PT, with or without bleeding, includes:
 - Vitamin K deficiency
 - Liver disease
 - Clinical presentation of these patients quite similar
 - Distinction sometimes made only on basis of response (or lack thereof) to empirical vitamin K therapy
 - Warfarin administration (overt or covert) should be excluded
 - Newer, long-acting vitamin K antagonist rodenticides (so-called *super-warfarin*) produce profound, prolonged, vitamin K-resistant reduction in vitamin K-dependent clotting factors
 - May produce an isolated prolongation of PT initially
 - Treatment of poisoning with these agents requires aggressive prolonged use of vitamin K and, in bleeding patient infusions of FFP or rhfVIIa
 - Confirmation of warfarin exposure as cause of prolonged PT possible by toxicologic methods
 - Laboratory findings of an isolated vitamin K deficiency
 - Prolonged PT, include a normal fibrinogen level, platelet count, and factor V level
 - Factor V not a vitamin K-dependent protein
 - Should therefore be normal except in cases of DIC (consumption) or severe liver disease (decreased production)
 - Prolongation of aPTT from vitamin K deficiency, warfarin therapy, or from liver disease a relatively late event
 - Occurs initially as result of factor IX depletion

Management

- Management of vitamin K deficiency consists primarily of its repletion
 - Usually by intravenous (IV) or subcutaneous routes in critically ill patients

- Should not await development of bleeding or oozing
- Should be administered when PT abnormality detected and vitamin K deficiency thought responsible
- Adequate blood pressure (BP) and subcutaneous perfusion needed to ensure reliable absorption
- Possibility of anaphylactoid reactions with IV use of vitamin K of concern
 - Risk markedly reduced when drug given as infusion over 30 to 45 minutes in small volume of fluid
 - Anaphylaxis still reported with this mode of infusion
- Usual dose of vitamin K in adults is 10 to 15 mg IV or subcutaneously
 - 1 to 5 mg in young children
 - Up to 10 mg in larger children
- PT should correct within 12 to 24 hours after this dose
- Serial dosing of critically ill patients often used and PT may require up to 72 hours to normalize
 - If PT does not correct within 72 hours after three daily doses of vitamin K, intrinsic liver disease suspected
 - Further administration of vitamin K is of no additional benefit in this setting
- When patient actively bleeding:
 - Not sufficient to only provide vitamin K
 - FFP used in this setting
 - To restore hemostasis to acceptable level, 30% to 50% of normal factor activity
 - 10 to 20 mL/kg body weight of FFP is typically required
 - Similar approach is used in patients previously given warfarin
 - rhfVIIa used with success to reverse bleeding noted in vitamin K deficiency and in warfarin overdose
- Development of washout coagulopathy directly dependent on volume of blood transfused relative to patient's blood volume
 - Generally residual plasma clotting activity after one blood volume exchange falls to 18% to 37% of normal
 - After two–blood volume exchange, residual activity is only 3% to 14%
 - After three–blood volume exchange, <5% of normal clotting function remains
- DIC may develop in many clinical settings
 - Including some associated with major hemorrhage or massive transfusion
 - In presence of hypotension associated with hypovolemia or hemorrhagic shock
 - Major trauma especially with release of tissue factors into plasma
 - Exsanguinating hemorrhage
 - May require blood replacement faster than type-and-crossmatch of each unit can be performed
 - Donor–recipient incompatibility, even when mismatch is minor blood group systems, can lead to DIC
 - Human error resulting in major incompatibility produces severe hemolysis and may be lethal
 - Microaggregates of blood cells formed within stored blood products can cause DIC
 - Smaller pore effective filtering systems for blood product administration has essentially eliminated this as a source of problems
- Patient bleeding as consequence of massive transfusion or washout presents with:
 - Diffuse oozing and bleeding from all surgical wounds and puncture sites
 - Laboratory abnormalities include:
 - Prolonged PT, aPTT, and TT
 - Fibrinogen levels and platelet counts are typically decreased
 - FDPs not usually increased unless concurrent DIC present (see Table 118.2)
 - Likelihood clinico-laboratory picture resultant from massive transfusion estimated from:
 - Amount of bleeding that has occurred
 - Blood volume administered relative to patient's blood volume
 - Number of blood volume exchanges given
 - The more PRBCs transfused relative to patient's blood volume
 - Greater the chance of coagulopathy development due to massive transfusion

Massive Transfusion Syndrome

- Transfusion of large quantities of blood can result in multifactorial hemostatic defect
 - Related to washout of plasma coagulation proteins and platelets
 - Exacerbated by development of DIC with consequent:
 - Factor consumption
 - Hypothermia
 - Acidosis
 - Rarely, by citrate toxicity or hypocalcemia
- Washout syndrome results from transfusion of large amounts of stored blood products devoid of clotting factors and platelets
 - Develops exclusively in patients receiving large volumes of PRBCs
 - Trauma victims
 - Patients with massive gastrointestinal hemorrhage or hepatectomy
 - Those undergoing cardiopulmonary bypass
 - Without also receiving FFP and platelets
 - Factors V and VII have short shelf half-lives
 - Often deficient in blood banked longer than 48 hours
 - Qualitative platelet defect noted in whole blood within hours of storage
 - Especially if acid–citrate–dextrose solution used
 - Transfusion of large quantities of stored whole blood may produce limited improvement of bleeding, resulting from decreased clotting factors and platelets.

Management

- Therapeutic approach to patients developing coagulopathy from massive transfusion is supportive
- Platelets and FFP given to replete components of coagulation typically lacking
 - Platelet administration may help stem bleeding from anatomic wounds
 - Severe bleeding associated with thrombocytopenia alone uncommon unless:
 - Counts fall below 20,000 to 30,000 cells/ μ L of blood
 - Nonetheless, patients may benefit from platelet transfusion at counts as high as 80,000 to 100,000 cells/ μ L

- FFP preferred over cryoprecipitate
 - More complete coagulation protein composition
 - Cryoprecipitate specifically given when fibrinogen depletion a major contributor to bleeding
- Prospective identification of those at risk of coagulopathy from massive transfusion critical:
 - Magnitude of insult and anticipated need for blood are large:
 - Both platelets and FFP given before coagulopathy develops
 - In most patients (weight ≥ 30 to 40 kg or body surface area [BSA] ≥ 1.0 m²):
 - 4 units of platelets (0.5 unit of apheresis-collected platelets) and 1 unit of FFP
 - Given for each 5 units of whole blood or PRBC transfused
 - Should prevent washout and attendant bleeding
 - If patient continues to bleed despite what should be adequate therapy for massive transfusion syndrome, other causes should be considered
 - Anatomic bleeding and possibility of DIC should be investigated
 - Therapy here may include rhfVIIa infusion

Anticoagulant Overdose

- Anticoagulant therapy usual in ICU
 - Possibility of administration error exists
 - Poorly standardized and can lead to overdose

Heparin

- A repeating polymer of two disaccharide glycosaminoglycans
 - Commercially prepared from either porcine intestinal mucosa or bovine lung
 - Currently found in two forms:
 - Unfractionated heparin (UH)
 - Low-molecular-weight heparin (LMWH)
- They have different mechanisms of action and associated precautions
 - UH
 - Has immediate effect on coagulation
 - Mediated primarily through interaction with antithrombin III
 - Resulting heparin–antithrombin III (AT-III) complex possesses greater affinity for thrombin than does AT-III alone
 - Inactivates thrombin
 - Damping-down clot formation
 - Additionally has direct inhibition of activated factor X (fXa)
 - This anticoagulant effect of UH relatively minor
 - Consequently, achieving therapeutic aPTT with UH very difficult in face of low levels of AT-III
 - Degree of anticoagulation produced by heparin monitored by prolongation of aPTT
 - LMWH
 - Produced by controlled enzymatic cleavage of heparin polymers
 - Produces anticoagulation almost exclusively through inhibition of fXa
 - Produces more stable degree of anticoagulation
 - Due to longer half-life (3 to 5 hours) and biologic activity (24 hours), allows for intermittent bolus therapy every 12 or 24 hours
 - Does not produce consistent prolongation of aPTT
- Requires assay of anti-Xa activity for monitoring, if desired
- Heparin hepatically metabolized by “heparinase” enzyme in dose-dependent fashion
 - Excess heparin renally excreted
 - As rate of heparin administration is increased
 - Half-life of drug prolonged due to increased percentage excreted by kidney
 - 10-unit/kg bolus of heparin infused IV, average half-life is 1 hour
 - If bolus increased to 400 or 800 units/kg half-life prolonged to 2.5 and 5 hours, respectively
 - Nonlinear response results in greater drug effects on coagulation with smaller dosage increments
 - Increases in heparin infusion rate in response to inadequate prolongation of aPTT results in point when further small infusion increments result in greater prolongation of aPTT
 - Risk of pathologic bleeding associated with heparin increases when aPTT is:
 - 1.5 to 2.5 times the patient’s baseline aPTT
 - Corresponds to plasma heparin concentration of 0.2 to 0.4 units/mL
 - Administration of heparin as continuous infusion rather than intermittent bolus dose less likely to be associated with bleeding
- **Management:** Serious bleeding associated with heparin overdose rapidly reversed by protamine sulfate
 - Protamine binds ionically with heparin to form complex lacking anticoagulant activity
 - 1 mg of protamine neutralizes approximately 100 units of heparin
 - Dose of protamine needed is calculated from number of units of active heparin remaining in patient’s system
 - Estimated from original heparin dose and typical half-life for infusion rate
 - aPTT used to gauge residual effects of heparin
 - Protamine itself potentially has anticoagulant effects
 - Drug given by slow IV push over 8 to 10 minutes
 - Single dose should not exceed 1mg/kg, with 50-mg maximum dose
 - Dose may be repeated
 - No more than 2 mg/kg, to a 100-mg maximum dose, given as cumulative dose without rechecking coagulation parameters
 - Dose of protamine always be monitored by coagulation studies
 - Significant side effects most commonly seen in overly rapid drug administration
 - Hypotension
 - Anaphylactoid-like reactions
 - LMWH not consistently neutralized by protamine
 - Invasive procedures should not be performed within 24 hours of administration
 - Bleeding following LMWH therapy treated effectively with rhfVIIa

Warfarin

- Warfarin and vitamin K structurally similar in respective 4-hydroxycoumarin nucleus and naphthoquinone ring
- Mechanism of action of warfarin through competitive binding at the vitamin K receptor site:

- Postribosomal γ -carboxylation of vitamin K-dependent coagulation proteins occurs:
 - Factors II, VII, IX, and X
 - Modification necessary to produce calcium-binding site on molecule
 - Allows for efficient activation of zymogen clotting factor into enzymatically active form
- When warfarin present in sufficient plasma concentrations, there is depletion of active forms of vitamin K-dependent factors
- PT/international normalized ratio (INR) calculated from PT, an accurate indicator of effects of warfarin when use continued beyond 2 or 3 days
- Factor VII has half-life of 4 to 6 hours and active form rapidly depleted after one or two doses of warfarin
- Remainder of vitamin K-dependent factors take up to a week to become depleted
- PT becomes prolonged and INR elevated with factor VII depletion alone
 - Does not reflect overall state of anticoagulation until equilibrium period of several days has passed
 - Over this time, other vitamin K-dependent factors depleted
- In severe cases of warfarin overdose, aPTT becomes prolonged
 - Resultant from depletion of active forms of factors II, IX, and X
- Several drugs and pathophysiologic conditions associated with potentiation of warfarin's effects on coagulation (Table 118.5)
- Aspirin has no direct effect on warfarin metabolism
 - So profoundly influences qualitative platelet function that is considered potentiator of warfarin's anticoagulant effects
 - Same true for clofibrate
- Conditions of acute and chronic hepatic dysfunction can alter warfarin metabolism and vitamin K-mediated γ -carboxylation
- Clinical syndrome termed warfarin (Coumadin) necrosis noted during initial stages of anticoagulation with vitamin K antagonist
- Characterized clinically by development of skin and subcutaneous necrosis
 - Particularly in areas of subcutaneous fat
- Pathologically by thrombosis of small blood vessels in fat and subcutaneous tissues
- Syndrome caused by rapid depletion of vitamin K-dependent anticoagulant protein C
 - Prior to achieving depletion of procoagulant proteins
 - Occurs predominantly in individuals heterozygous for protein C deficiency
 - Anticoagulation requires decrease in procoagulant protein levels to about 20% to 25%
 - Prothrombotic milieu created with protein C levels of 40% or less
 - Individuals heterozygous for protein C deficiency
 - With baseline protein C levels of 50% to 60% of normal
 - May develop prothrombotic environment during first few days of warfarin therapy
 - Risk of developing warfarin necrosis greater when initial dose of warfarin >10 to 15 mg administered
 - Development of syndrome avoided if heparin and warfarin therapy are overlapped until "Coumadinization" complete and if large loading doses of warfarin are avoided
- **Management:** When overanticoagulation with warfarin presents with bleeding
 - Immediate reversal usually mandated
 - Treatment of choice is FFP
 - Provides prompt restoration of deficient vitamin K-dependent coagulation proteins, along with restoration of hemostatic function
 - 10 to 15 mL/kg FFP sufficient to produce significant correction of PT
 - Repeat infusions of FFP may be needed to effect continued correction
 - Due to the short half-life of fVII
 - Vitamin K may be administered in less acute situations
 - For severe bleeding or bleeding not controlled by FFP infusions
 - rhfVIIa used successfully

TABLE 118.5**DRUGS THAT POTENTIATE THE ANTICOAGULANT EFFECTS OF WARFARIN****Antibiotics**

Broad-spectrum antibiotics (especially cephalosporins)
 Griseofulvin (oral)
 Metronidazole
 Sulfapyrazone
 Trimethoprim-sulfamethoxazole

Anti-inflammatory Drugs

Steroids (anabolic, in particular)
 Acetylated salicylates
 Phenylbutazone (oxyphenbutazone)
 Sulfonamides

Other Drugs

Cimetidine
 Clofibrate
 Disulfiram
 Phenytoin
 Thyroxine (both D- and L-isomers)
 Tolbutamide

Platelet Disorders

- Platelets necessary for efficient clot formation
- Produce physical barrier at site of vascular injury, the so-called *platelet plug*
- Also serve to focus clotting process at point of bleeding
 - Delivering vasoconstrictors, clotting factors, and surface on which clot development occurs
 - Quantitative and qualitative platelet disorders a common cause of clinical ICU bleeding (Table 118.6)

Quantitative Platelet Disorders

- Decreased number of circulating platelets reflects:
 - Increased peripheral destruction or sequestration
 - Decreased marrow production
 - Combination of these factors

TABLE 118.6

PLATELET DISORDERS SEEN IN THE ICU

Quantitative	Qualitative
Increased Destruction	Drugs
Immune	Anti-inflammatory agents
Idiopathic thrombocytopenic purpura	Aspirin (irreversible)
Systemic lupus erythematosus	Nonsteroidal anti-inflammatory agents
Acquired immunodeficiency syndrome	Corticosteroids
Drugs (gold salts, heparin, sulfonamides, quinidine, quinine)	Antibiotics
Sepsis	Penicillins (e.g., ampicillin, carbenicillin, ticarcillin, penicillin-G)
Nonimmune	Cephalosporins (e.g., cephalothin)
Thrombotic thrombocytopenic purpura/hemolytic uremic syndrome	Nitrofurantoin
Mechanical destruction (e.g., cardiopulmonary bypass, hyperthermia)	Chloroquine, hydroxychloroquine
Consumption (i.e., DIC)	Phosphodiesterase inhibitors
Decreased Production	Dipyridamole
Marrow suppression	Methylxanthines (e.g., theophylline)
Chemotherapy	Other drugs
Viral illness (e.g., cytomegalovirus, Epstein-Barr virus, herpes simplex, parvovirus)	Antihistamines
Drugs (thiazides, ethanol, cimetidine)	Alpha-blockers (e.g., phentolamine)
Marrow replacement	Beta-blockers (e.g., propranolol)
Tumor	Dextran
Myelofibrosis	Ethanol
Other conditions	Furosemide
Splenic sequestration	Heparin
Dilution (see Massive Transfusion Syndrome)	Local anesthetics (e.g., lidocaine)
	Phenothiazines
	Tricyclic antidepressants
	Nitrates (e.g., sodium nitroprusside, nitroglycerin)
	Metabolic Causes
	Uremia
	Stored whole blood
	Disseminated intravascular coagulation (i.e., FDP-mediated inhibition)
	Hypothyroidism

DIC, disseminated intravascular coagulation; FDP, fibrin degradation product.

- Examples of increased peripheral destruction include:
 - Immune-mediated processes (both autoimmune and drug-induced)
 - Abnormal consumption (as in DIC)
 - Mechanical destruction (e.g., cardiopulmonary bypass, hyperthermia)
 - Autoimmune processes such as idiopathic thrombocytopenic purpura (ITP), SLE, acquired immunodeficiency syndrome (AIDS), lymphocytic leukemia, or lymphoma
 - Result in increased peripheral destruction and splenic sequestration
 - Drug-induced, immune-mediated platelet destruction a cause of thrombocytopenia frequently considered in thrombocytopenic ICU patient
 - Usually reversible with withdrawal of offending drug
 - Exact mechanism related to binding of drug to platelet membrane
 - Subsequent binding to platelet, platelet–drug complex, or both, of a specific antibody
 - Resulting platelet–drug–antibody complexes cleared by RES
- Drugs in the ICU commonly associated include:
 - Quinidine and quinine
 - Heparin
 - Gold salts
 - Various penicillin and cephalosporin antibiotics
 - Sulfonamide antibiotics
 - Anticonvulsant valproic acid (Depakote, Depakene) (in part, is immunologic in nature)
- Various drugs associated with nonimmune mechanism of thrombocytopenia by bone marrow suppression:
 - Most cancer chemotherapeutic agents
 - Thiazide diuretics
 - Cimetidine
 - Ethanol
 - Several of the cephalosporin and penicillin antibiotics
 - Generalized infection, bacterial sepsis, and many viral illnesses
 - Gaucher disease
- Consumption of platelets also can cause thrombocytopenia
 - Mechanical destruction occurs during cardiopulmonary bypass

- Not uncommon to note a 50% drop in platelet count postbypass
- Platelet counts may decrease for 48 to 72 hours after bypass before recovering
- May also be destroyed by high body temperatures
 - Severe hyperthermic syndromes
- Consumed during microvascular coagulation in DIC

Qualitative Platelet Disorders

- Drugs frequently used in ICU have the potential to impair platelet function
 - The sicker the patient, the greater the likelihood of exposure to one of these drugs (see Table 118.6)
 - Terminating offending drugs usually results in restoration of normal function
 - Aspirin the notable exception
 - It irreversibly inhibits platelet cyclo-oxygenase
 - Resulting in defect lasting for duration of platelet lifespan, 8 to 9 days
 - Effect is profound: single 325-mg aspirin results in qualitative platelet defect remaining in 50% of circulating platelets 5 days after ingestion
 - Prefer to avoid aspirin ingestion for at least 7 days prior to an elective invasive procedure
 - Nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen or naproxen sodium inhibit platelet cyclo-oxygenase
 - Effects are reversible
 - Normal platelet function usually restored within 24 hours of last dose
 - Degree of platelet inhibition produced by NSAIDs is not clinically significant
 - Patients can receive these drugs for analgesia and fever control
 - Reasonable to minimize use of NSAIDs in bleeding, severely thrombocytopenic patient
 - Clopidogrel (Plavix) or dipyridamole (Persantine) produce platelet inhibition that remains evident for several days after discontinuing drug
 - β -lactam antibiotics sterically hinder binding of platelet aggregation agonist adenosine diphosphate (ADP) to specific platelet receptor, resulting in impaired platelet aggregation
 - Reversed on removal of the drug
 - In ICU one must also always consider possibility that patient with bleeding suggestive of a platelet defect may have an inherited disorder of platelet function
 - Rare but encountered from time to time and include:
 - Glanzmann thrombasthenia (abnormal platelet GP IIb/IIIa)
 - Bernard-Soulier syndrome (abnormal GP Ib/IX)
 - Wiskott-Aldrich syndrome, platelet storage pool deficiency (abnormal platelet dense bodies)
 - Gray platelet disorder (abnormal platelet granules)
 - **Management:** Unnecessary medications *always* discontinued when platelet function impaired
 - Never acceptable to leave nonessential agent on patient's medication list because it is benign
 - More controversial issue is deciding whether platelet transfusions warranted
 - Relationship of thrombocytopenia to clinical bleeding is relative

- Massive transfusion syndrome and DIC may respond to empirical platelet transfusion at counts as high as 80,000 to 100,000 platelets/ μ L
- Although bleeding with platelet count of 80,000 cells/ μ L (or greater) unlikely to be a result of thrombocytopenia
- With cancer chemotherapy and bone marrow aplasia
 - Therapy not required until counts <10,000 to 20,000 cells/ μ L
 - rhfVIIa used to reverse hemostatic defect caused by aspirin or clopidogrel
- Administration of platelets limits both morbidity and mortality
 - Finding generalized to all patients with platelet counts in this range
 - Appropriateness of this approach unclear
 - Major concern is development of alloimmunization
 - Potentially negating future benefit from platelet transfusion in time of need
 - Patients with acute leukemia have self-limited marrow aplasia resulting from chemotherapy
 - Need for platelet transfusion is limited
 - Patients with aplastic anemia have ongoing need for platelet transfusion
 - Risk of alloimmunization high
 - Autoimmune disorders associated with increased peripheral platelet destruction, disorders of splenic sequestration, and drug-related thrombocytopenia unlikely to benefit from platelet transfusion
 - Exception related to planned invasive procedure associated with increased risk of bleeding
 - Transfusions in presence of type II HIT contraindicated

Uremia

- Commonly seen in ICU and associated with increased risk of bleeding
 - Shown to cause reversible impairment of platelet function
 - “Toxin” responsible for defect not well defined
 - Some studies have demonstrated an impairment of platelet-vessel wall interactions and suggest defects in vWf
 - Degree of platelet impairment related to severity of uremia for given patient
 - Thrombotic events are also increased with uremia
 - Appear to be multifactorial in cause but reflect increased renal loss of antithrombin III and protein S in nephrotic-range proteinuria
 - Therapeutic approaches may modulate the qualitative platelet defect
 - Dialysis
 - Cryoprecipitate
 - 1-deamino-8-D-arginine vasopressin (DDAVP) 0.3 μ g/kg, maximum dose 21 mg
 - Conjugated estrogens (10 mg/day in adults)
 - Benefit derived by treatment with cryoprecipitate or DDAVP related to increase in plasma concentration of large multimeric forms of vWf
 - Greatly improving platelet adhesion
 - Duration of action of these agents is limited
 - Reaching their zenith between 2 and 6 hours
 - Additional doses of DDAVP during same 24-hour period may result in a diminished response to the drug (tachyphylaxis) with little or no further benefit

- May require 48 to 72 hours before again responding to this agent
- Mechanism of action of conjugated estrogens not known
 - Effect of estrogen more protracted and does not diminish with repeat dosing
 - Benefit is not noted for 3 to 5 days after starting therapy

THROMBOTIC SYNDROMES

- Often the cause of admission to an ICU
 - Particularly if acute coronary syndromes included in this category
 - Noncardiac thrombotic syndromes encountered in ICU include:
 - DVT (specifically in association with a central venous catheter)
 - Heparin-induced thrombocytopenia
 - Pulmonary embolism syndrome
 - Thrombotic thrombocytopenic purpura (TTP) or hemolytic uremic syndrome (HUS)
 - Thrombotic DIC
 - Stroke
 - Central nervous system (CNS) venous sinus thrombosis
 - Most commonly in infants and elderly associated with dehydration
 - Many conditions, particularly venous thromboembolic events, develop while patient in ICU
 - May be preventable
 - Assess risk of DVT and risks of thromboprophylaxis in all patients and institute appropriate therapy on a case-by-case basis
 - Postoperative patients and those immobilized for long periods of time are at risk
 - Candidates for some sort of thromboprophylaxis
 - Approximately 10% of ICU patients will develop DVT while in ICU
 - *Despite* receiving thromboprophylaxis
 - Up to 15% of these experience symptomatic pulmonary embolism (PE)
 - Not all patients at same risk
 - Not all respond to prophylactic measures equally

Management

- Initial management approach for patient with documented or highly suspected thrombotic event:
 - Anticoagulation with either UH or LMWH
 - Efficacy of either appears equivalent
 - Some studies suggest incidence of severe bleeding less with LMWH
 - LMWH may produce a more stable level of anticoagulation
 - May result in fewer laboratory tests and dose adjustments
 - Choice of which agent to use is at discretion of intensivist
 - If repeated invasive procedures anticipated UH may be preferred agent
 - Owing to shorter half-life
 - Most patients started on UH with bolus dose of 50 units/kg

- Followed by a continuous infusion of 10 units/kg/hour
 - Doses may be reduced for elderly or frail patient
- Once initiated adjust to keep aPTT 1.5 to 2.5 times baseline
 - Corresponds to plasma heparin concentration of 0.2 to 0.4 units/mL
- Dosing of LMWH weight related
- Dose of warfarin titrated to maintain INR of the PT between 1.5 and 4.0

SELECTED DISORDERS

Systemic Diseases Associated with Factor Deficiencies

- Amyloidosis, Gaucher disease, and nephrotic syndrome occasionally seen in ICU
- Each may have one or more associated factor deficiencies
 - Amyloidosis or Gaucher disease develop factor IX deficiency
 - Factor X deficiency also associated with amyloidosis
 - Deficiencies generally result from absorption of specific clotting factor onto abnormal proteins present with each disorder
 - In nephrotic syndrome, factor IX deficiency may develop
 - Originally thought proteinuria responsible for development of factor IX deficiency
 - May not be the case
 - Deficiency typically remits with corticosteroid therapy
 - Antithrombin III deficiency seen along with nephrotic syndrome and may lead to thrombosis
 - Loss of antithrombin III DOES appear related to proteinuria

Laboratory Disorders Not Associated with Bleeding: Lupus Anticoagulants

- Lupus anticoagulant received much attention as potential cause of bleeding
 - By virtue of name and associated laboratory abnormalities
 - As isolated hemostatic defect thrombosis more likely a problem
 - 25% incidence rate
 - Bleeding in one series occurred in only 1 of 219 patients
- PT and aPTT assays depend on interaction of various coagulation factors with either lipoprotein or phospholipid to activate coagulation efficiently
- Lupus anticoagulant is an antiphospholipid antibody directed against phospholipids or lipoproteins
 - Produces prolongation of the PT, aPTT, or measured recalcification time of platelet-rich plasma
 - Prolongation of aPTT more common than prolongation of PT
 - Although isolated prolongation of PT seen
 - 25% of patients with active SLE and lupus anticoagulant also have associated:
 - Thrombocytopenia or hypoprothrombinemia
 - Therefore at risk for bleeding
 - In contrast to those patients with lupus anticoagulant alone

- Lupus anticoagulant originally described in patients with SLE
 - Not limited to this class of diseases
 - Lupus anticoagulants or anticardiolipin antibodies, or both demonstrated in:
 - Large percentages of patients with human immunodeficiency virus (HIV) infection
 - Hemophilia A
 - Both HIV and hemophilia A
 - Also observed chronic and acute inflammatory disorders
- Thrombotic events in patients who exhibit lupus anticoagulant may occur independent of underlying disorder and be directly related to lupus anticoagulant itself
- Likelihood of thrombosis associated with lupus anticoagulant appears greatest when:
 - Lupus anticoagulant has specificity for:
 - β_2 -glycoprotein I or
 - Phosphatidylserine
- Some forms of disorder, such as associated with pregnancy, respond to anti-inflammatory drugs such as aspirin or prednisone
- Thrombosis equally likely to be venous or arterial
 - Venous thrombosis more common in extremities
 - Arterial thrombosis more common in CNS
 - Placental infarcts frequently seen in placental specimens in patients with repeated fetal wastage
 - Stroke, myocardial infarction (MI), and PE are well described in patients with the lupus anticoagulant

Reactive Hyperfibrinogenemia

- Defined as plasma fibrinogen concentration >800 mg/dL
- In clinical laboratory, fibrinogen measured using functional assay
 - Time to fibrin clot formation is end point in presence of excess thrombin
 - Time to clotting proportional to amount of fibrinogen present in sample
 - When excessive amounts of fibrinogen present, clotting is incomplete
 - Fibrin fragments formed inhibit further fibrin clot formation
- Other hematologic parameters, the aPTT, PT, and TT, consequently prolonged
 - Suggesting potential, although artifactual, risk for bleeding
 - Can be evaluated by diluting plasma to normal fibrinogen concentration using saline or defibrinated plasma
 - Clotting studies will now be normal
 - Bleeding not seen unless fibrinogen also is dysfibrinogen
 - Even in these patients bleeding remains uncommon problem
 - In patients with dysfibrinogenemia:
 - Clotting studies fail to correct when saline or defibrinated plasma dilutions undertaken
 - Distinguishes from patients with reactive hyperfibrinogenemia

CHAPTER 119 ■ ANTITHROMBOTICS AND THROMBOLYTIC THERAPY

- Venous (VTE) and arterial (ATE) thromboembolism major causes of morbidity and mortality
- Arterial thromboembolism commonly implicated in:
 - Myocardial infarctions
 - Stroke
 - Limb ischemia
 - Responsible for more deaths yearly than next seven leading causes combined
- Venous thrombosis may lead to:
 - Pulmonary embolism
 - Right heart dysfunction
 - Venous insufficiency
 - Postthrombotic syndrome
 - Incidence of intensive care unit (ICU) patients developing VTE ranges from 5% to 33%
 - Estimated 2 million cases of VTE yearly in United States alone
 - Annual estimated mortality of about 60,000 from pulmonary embolism

- Ability to rapidly diagnose and initiate effective therapy paramount

ANTIPLATELET AGENTS

- Platelets play key role in inflammatory and thrombotic cascade
 - Integral in pathogenesis of arterial thrombosis
 - Particularly in regions of high fluid shear stress:
 - Coronary, cerebrovascular, peripheral circulations
 - Aggregation leading to disruption of blood flow can have devastating outcomes

Aspirin (ASA)

- ASA most widely used antiplatelet drug in the world
 - Used as antipyretic agent since the mid-1800s
 - Antiplatelet effect recognized only about 50 years ago

- Activated platelets cleave phospholipids to generate arachidonic acid
 - Converted to thromboxane-A₂ through a series of reactions
 - Mediated by cyclo-oxygenase-1 (COX-1) and thromboxane-A₂ synthase
 - Three isoforms of COX enzyme
 - COX-1 being the major type
 - COX-3 being a variant of COX-1
 - COX-2 the inducible form present in cells at site of inflammation
- ASA an irreversible inhibitor of COX-1 and COX-3 at low concentrations
 - Rapid onset of action, approximately 30 minutes
 - Exerts its effect by acetylating serine 529 site of platelet COX-1 enzyme
 - Anucleate platelets unable to synthesize new enzyme
 - Single daily ASA dose sufficient to inhibit function for platelet lifespan
 - Restoration of normal aggregation on cessation of ASA therapy results from newly released, nonacetylated platelets replacing ASA-treated ones
- ASA dose required to inhibit platelet function relatively low
 - Antithrombotic effect of ASA saturates at doses of approximately 100 mg
- Efficacy of ASA in acute coronary syndrome established
 - For acute myocardial infarction (MI) ASA alone reduced mortality to similar extent as streptokinase alone
 - No additive benefit when using both agents
 - Meta-analysis found ASA reduced risk of MI, stroke, or death from 13.3% to 8.0% in patients with unstable angina
 - Greatest risk reduction occurred with dose of 75 to 150 mg/day
 - Higher doses such as 325 mg/day conferred no added benefit
- Risk reduction of ischemic strokes in atrial fibrillation associated with oral vitamin K-inhibiting anticoagulant therapy is greater than that provided by ASA

Aspirin Resistance

- ASA efficacy in inhibition of platelet function differs between patients
 - Cardiovascular events occur preferentially in patients with low responses to ASA therapy
 - Low response is referred to as *aspirin resistance*
 - Prevalence varies between 5% and 60%, depending on laboratory studies used
 - ASA-resistant patients noted to have a 24% risk of death, MI, or stroke
 - Compared with a 10% risk for ASA sensitive patients
 - Two aspects of resistance: biochemical and clinical
 - Biochemical resistance refers to ASA inability to initiate platelet inhibition
 - Clinical resistance indicates an increased risk of cardiovascular events in patients receiving ASA treatment
 - Platelet receptor polymorphism is thought to be responsible for resistance
- Risk of hemorrhage, especially from the gastrointestinal tract, a major concern when doses higher than 325 mg/day used
 - Local effect of ASA on gastric mucosa more prevalent with higher doses
 - Patients with vascular malformations or mucosal lesions may bleed at lower doses
- Risk of cerebral hemorrhage in patients with prior stroke or uncontrolled hypertension
 - In event of hemorrhage discontinue ASA and measure bleeding time
 - If needed, treat with fresh platelet transfusion
- For elective surgical procedures ASA stopped 5 days before surgery
- ASA not recommended for VTE prophylaxis
 - Other forms of standard VTE prophylaxis preferred
 - Subcutaneous heparin
 - Pneumatic compression devices

Clonidogrel

- Clonidogrel a member of the thienopyridine family
 - A potent platelet inhibitor
 - Irreversibly binds to low-affinity adenosine diphosphate (ADP) receptors
 - Rapidly absorbed and metabolized by hepatic cytochrome P-450 enzyme system
 - Active metabolite selectively and irreversibly inhibits ADP-induced platelet aggregation
 - Metabolite also impairs activation of glycoprotein (GP) IIb/IIIa complex
 - Prevents fibrinogen binding to platelets
 - Platelets exposed to drug affected for remainder of their lifespan
- Dose-dependent platelet inhibition can be seen within 2 hours after a single oral dose
 - Maximum effect, patients given loading dose of 300 to 600 mg
 - Followed by 75 mg/day
 - Repeated doses of 75 mg/day (no load)
 - Maximum platelet inhibition can be achieved within 3 to 7 days
- When steady state achieved, platelet aggregation inhibited by 40% to 60%
 - Prolongation of bleeding time independent of age, renal impairment, or gender
 - Platelet aggregation and bleeding time return to baseline about 5 days after discontinuation
- Clonidogrel more effective than ASA in reducing atherosclerotic events by 8.7%
 - Peripheral vascular disease
 - Myocardial infarction
 - Stroke
- Efficacy and safety of clonidogrel evaluated in acute coronary syndrome patients
 - Shows 20% relative risk reduction in composite triple end points:
 - Nonfatal myocardial infarction
 - Death
 - Stroke
- Clonidogrel, like ticlopidine, prolongs bleeding time
 - Incidence of neutropenia reported at 0.1%
 - Rare case reports of clonidogrel-associated thrombotic thrombocytopenic purpura
 - Incidence of gastrointestinal bleeding is less when compared to ASA
 - Incidence of bleeding is higher among patients taking clonidogrel, requiring urgent surgical procedures

- Clopidogrel effect can be reversed by transfusion of fresh platelets

Ticlopidine

- An older thienopyridine compound
 - Inhibits platelet aggregation irreversibly
 - Interferes with ADP-induced binding of fibrinogen to platelet receptors
 - Fallen out of favor because of two major side effects: neutropenia and thrombotic-thrombocytopenic purpura
 - Rare case reports of severe bone marrow toxicity limit ticlopidine use to patients intolerant or unresponsive to ASA

Cilostazol

- A newer platelet aggregation inhibitor with vasodilatory activity
 - Causes platelet inhibition by inhibiting phosphodiesterase (PDE) type III activity
 - Has greater vasodilatory effect on femoral arteries than on vertebral, carotid, or superior mesenteric arteries
 - Approved U.S. Food and Drug Administration for reduction of symptoms related to intermittent claudication in severe peripheral vascular disease

Glycoprotein IIb/IIIa Antagonists

Abciximab

- The most successful GPIIb/IIIa antagonist
 - A human-murine Fab chimeric monoclonal antibody (Ab) fragment to GPIIb/IIIa binding site
 - Large protein with rapid and prolonged response
 - Causes bleeding time to remain elevated for 12 hours after injection
 - Used in combination with ASA and heparin in patients with unresponsive unstable angina or undergoing percutaneous coronary intervention
 - Delivers 60% relative risk reduction in triple end points: myocardial infarction, emergent revascularization, or cardiovascular deaths
- Major complications—reported as frequently as 10.5%—of agent include:
 - Intracranial bleeding
 - Decrease in hemoglobin of more than 15%,
 - High incidence of thrombocytopenia
 - May be spurious in 4% of cases due to platelet clumping
 - True and severe thrombocytopenia may also develop, resulting in profound bleeding
 - In the event of profuse bleeding, platelet transfusions required to normalize platelet count
 - Desmopressin has been shown to normalize the bleeding time

Eptifibatide

- A disintegrin derived from the southeastern pygmy rattlesnake
 - Rapidly bound and rapidly reversed

- Normalization of the bleeding time within 1 to 4 hours
- More effective in milder forms of acute coronary syndromes

Tirofiban

- A small nonpeptide compound derived from tyrosine
 - Interacts with arginine—glycine—aspartic acid fibrinogen receptor
 - Used in unstable angina with mixed results

Dipyridamole

- A phosphodiesterase inhibitor, reversibly inhibiting platelet aggregation
 - Increases cyclic adenosine monophosphate and cyclic guanosine monophosphate levels through inhibition of phosphodiesterases
 - Potentiates the effect of nitric oxide
 - Used adjunctively with ASA to reduce stroke events in patients younger than 70 years of age

ANTITHROMBOTIC THERAPY

Unfractionated Heparin (UH)

- UH a naturally occurring acidic glycosaminoglycan whose anticoagulant effect originates from its pentasaccharide sequence
 - Sequence binds to antithrombin
 - Causes conformational change at arginine reactive site
 - Potentiates effect of antithrombin, causing enhanced effect on inhibition of coagulation enzymes, in particular thrombin (factor IIa) and factor Xa
 - Heparin also inhibits activation of factors V and VIII by thrombin
- Increase in inhibition of enzymes in presence of UH up to 2,000 times faster than in its absence
 - Due to the variable size and structure of heparin about one-third of dose demonstrates therapeutic anticoagulant activity
 - Different-sized molecules cleared at different rates by kidney
 - Larger ones cleared more rapidly
 - Necessitates need for monitoring with activated partial thromboplastin time (aPTT)
- Obtained from bovine lung or porcine intestine, available as a sodium or calcium salt
 - Unit of heparin measured in animals in a biologic assay
 - Unit measurement variable by as much as 50% on a weight basis
 - UH prescribed for patients on a unit basis per kilogram
- UH clearance involves a combination of rapid, saturable, and slower first-order mechanisms
 - Saturable phase of UH clearance via binding to receptors on endothelial cells and macrophages, where it becomes depolymerized
 - Slower-phase first-order saturable mechanism is renal
 - At therapeutic doses cleared predominantly through the rapid, saturable dose-dependent mechanism
 - Anticoagulant effects are nonlinear
 - Intensity and duration of effect rising disproportionately to increasing dose

TABLE 119.1

WEIGHT-BASED HEPARIN DOSING NOMOGRAM

aPTT, s ^b	Dose change, U/kg/h	Additional action	Next aPTT, h
<35 (<1.2 × mean normal)	+4	Rebolus with 80 IU/kg	6
35–45 (1.2–1.5 × mean normal)	+2	Rebolus with 40 IU/kg	6
46–70 ^a (1.5–2.3 × mean normal)	0	0	6 ^c
71–90 (2.3–3.0 × mean normal)	–2	0	6
>90 (>3 × mean normal)	–3	Stop infusion 1 h	6

aPTT, activated prothrombin time; s, seconds.

Initial dosing: Loading 80 IU/kg; maintenance infusion: 18 IU/kg/hour (aPTT in 6 hours)

^aTherapeutic range in seconds should correspond to a plasma heparin level of 0.2–0.4 IU/mL by protamine sulfate or 0.3–0.6 IU/mL by amidolytic assay. When aPTT is checked at 6 hours or longer, steady-state kinetics can be assumed.

^bHeparin, 25,000 IU in 250 mL D₅W. Infuse at rate dictated by body weight.

^cDuring the first 24 hours, repeat aPTT every 6 hours. Thereafter, monitor aPTT once every morning unless it is outside the therapeutic range.

From Hyers TM, Agnelli G, Hull RD, et al. Antithrombotic therapy for venous thromboembolic disease. *Chest*. 2001;119(Suppl):179S, with permission.

Uses of Unfractionated Heparin

- UH indicated for prophylaxis of VTE, treatment of deep vein thrombosis (DVT) and pulmonary embolism (PE), and for early treatment of acute coronary syndromes
- **Prevention of Thromboembolism:** UH at fixed low dose of 5,000 units, subcutaneously every 8 to 12 hours, results in a 60% to 70% relative risk reduction for DVT and fatal PE
 - In high-risk surgical and acutely ill medical patients low-molecular-weight heparin (LMWH) becoming standard for prevention of thrombosis
 - In patient unable to tolerate any type of anticoagulation, compression stockings useful as mechanical means for preventing DVT
 - Intermittently squeezing patient's calves
 - Leads to increased blood flow through venous system
 - May also stimulate fibrinolysis by stimulating vascular endothelium

- **VTE and PE:** Therapy aimed at preventing extension of clot with further embolization and recurrence
- Most efficient and safe method for initiating intravenous (IV) UH therapy is using weight-adjusted nomograms
 - In first days of treatment, there is weak association between supratherapeutic aPTT and bleeding
 - This in **marked contrast** to significant relationship between subtherapeutic aPTT and VTE recurrence in first 24 hours
 - Must maintain therapeutic range when heparin anticoagulation therapy is initiated
 - Best achieved with monitoring of plasma aPTT
- The weight-based method results in a significant decrease in the time required to reach therapeutic levels
 - 97% of patients dosed using weight-based nomogram achieve therapeutic levels within 24 hours of initiation as opposed to 77% in standard dosing group (Tables 119.1 and 119.2)

TABLE 119.2

GUIDELINES FOR ANTICOAGULATION USING UNFRACTIONATED HEPARIN

Indication	Guidelines
VTE suspected	<ul style="list-style-type: none"> • Obtain baseline aPTT, PT, CBC • Check for contraindication to heparin therapy • Order imaging study, consider giving heparin 5,000 IU IV
VTE confirmed	<ul style="list-style-type: none"> • Rebolus with heparin 80 IU/kg IV and start maintenance infusion at 18 U/kg (see text and Table 119.1) • Check aPTT at 6 hours to keep aPTT in a range that corresponds to a therapeutic blood heparin level (see text and Table 119.1) • Check a platelet count between days 3 to 5 • Start warfarin therapy on day 1 at 5 mg and adjust subsequent daily dose according to INR • Stop heparin therapy after at least 4 to 5 d of combined therapy when INR is >2.0 • Anticoagulate with warfarin for at least 3 mo at an INR of 2.5; range: 2.0–3.0 (see Table 119.4)

aPTT, activated prothrombin time; PT, prothrombin time; CBC, complete blood count; IV, intravenously; INR, international normalized ratio.

For subcutaneous treatment with unfractionated heparin, give 250 IU/kg subcutaneously every 12 hours to obtain a therapeutic aPTT at 6–8 hours.

From Hyers TM, Agnelli G, Hull RD, et al. Antithrombotic therapy for venous thromboembolic disease. *Chest*. 2001;119(Suppl):180S, with permission.

- Therapy initiated with IV loading dose of 80 units/kg
 - Followed by 18 units/kg/hour
 - Doses adjusted using a standard nomogram to reach and maintain aPTT corresponding to therapeutic heparin levels of 1.5 to 2.5 times baseline
 - Alternatively, therapeutic heparin anticoagulation determined by achieving a plasma anti-factor Xa level of 0.35 to 0.7 units/mL
- UH anticoagulation continued for up to 5 days so adequate anticoagulation achieved
 - aPTT monitored every 6 hours until therapeutic range achieved
 - Once daily thereafter
- Preferably on day 1 patient transition begun to long-term oral warfarin (5 mg)
 - Anticoagulation effect of warfarin monitored by international normalized ratio (INR) to achieve a therapeutic range of two to three times normal level for a first thrombotic episode
 - Warfarin considered at therapeutic level if INR of 2 to 3 maintained for 2 consecutive days
- Warfarin interacts with many commonly used ICU drugs and metabolism may be affected by hepatic and renal impairment
 - May lead to erratic variation in anticoagulant effect of warfarin and exposes patient to increased risks of bleeding and thrombotic complications
- Minimum recommended duration of warfarin therapy is 3 months
 - Longer treatment beneficial
 - Now recommended warfarin therapy be continued for at least 6 to 12 months after an acute thromboembolic episode arising from an idiopathic DVT
 - With recurrent events or those who have permanent or long-term risk factors, indefinite therapy recommended
- **Acute Coronary Syndromes:** American College of Cardiology/American Heart Association updated guidelines for management of patients with acute myocardial infarction demonstrate clear benefit of LMWH over UH when it came to a lower event rate and relative risk reduction
- Guidelines recommend using LMWH due to:
 - Greater inhibition of factor Xa
 - Ability to administer the drug subcutaneously
 - High bioavailability
 - Other benefits include potential to prevent thrombin generation and inhibit thrombin, the lack of need to monitor coagulation, and the lower incidence of heparin-associated thrombocytopenia

Monitoring UH

- Most widely used test for evaluating the adequacy of UH anticoagulation is aPTT
- Global coagulation test not always a reliable indicator of plasma heparin levels and/or the antithrombotic activity of heparin
- aPTT can be impacted by various acute phase reactant plasma proteins, including factor VIII
- aPTT can be influenced by coagulation timer and reagents used to perform test
- If unable to measure plasma heparin levels directly:
 - Standardize therapeutic range of the aPTT to correspond to plasma levels of 0.3 to 0.7 IU/mL anti-factor Xa activity by an amidolytic assay

Complications of Anticoagulation Therapy

Heparin Resistance

- Patients considered heparin resistant if daily requirement exceeds 35,000 units per 24 hours
 - At least 25% of patients with VTE heparin resistant
 - May be associated with antithrombin deficiency, increased heparin clearance, increases in heparin-binding proteins, and increases in factor VIII, fibrinogen, and platelet factor 4
 - Aprotinin and nitroglycerin reported to cause drug-induced resistance
 - Association with nitroglycerin controversial
 - Factor VIII and fibrinogen elevated in response to acute illness or pregnancy
 - Elevation of factor VIII alters response of aPTT to heparin without decreasing the antithrombotic effect
 - Anticoagulant effect measured by plasma aPTT and antithrombotic effect measured by anti-factor Xa activity become dissociated
- For patients considered heparin resistant:
 - Dose of heparin adjusted to maintain the anti-factor Xa heparin levels between 0.35 and 0.7 mIU/mL
- In patients with VTE and manifesting heparin resistance:
 - Monitoring aPTT *versus* anti-factor Xa activity showed no difference in clinical outcomes, the anti-factor Xa heparin levels group required significantly less heparin with no differences in bleeding

Hemorrhagic Complications

- Incidence of major hemorrhagic complications, such as intracranial or retroperitoneal hemorrhage, hemorrhage requiring a transfusion, or hemorrhage directly related to death, from therapeutic anticoagulation is <5%
- Risk increases with age, total dose of heparin per 24 hours, premonitory condition of patient, concomitant use of ASA, GPIIb/IIIa antagonists, or thrombolytic therapy
- IV heparin infusion produces less marked bleeding complications than subcutaneously administered
 - May be due to lower total dose of heparin via IV route
- Anticoagulant effect of UH neutralized rapidly by IV protamine
 - A cationic protein derived from fish sperm
 - Strongly binds to anionic heparin compound in ratio of approximately 100 units of UH/mg of protamine
 - For example, 50 mg of protamine required to neutralize 5,000 units of IV heparin
 - When heparin infused, only drug given over prior 2 hours included in calculation
 - If heparin infusion discontinued for more than 30 minutes but less than 2 hours, use one-half of calculated protamine dose
 - If infusion discontinued for more than 2 hours use one-quarter of calculated protamine dose
 - Avoid giving 50 mg of protamine at one time
 - If given by infusion, it should not exceed 5 mg/minute to reduce incidence of adverse reactions
 - Heparin neutralization can be confirmed by a fall in the aPTT
- Risks of severe adverse reactions to protamine:
 - Such as hypotension and bradycardia
- Reduced with slow administration of drug over >3 minutes

- Some begin protamine infusion following a 3 to 5 mg test dose over 1 minute
- Allergic reactions including anaphylaxis associated with:
 - Previous exposure to protamine-containing insulin (NPH-insulin)
 - Fish hypersensitivity
 - Vasectomy
 - Patients at risk for antiprotamine antibodies pretreated with corticosteroid and antihistamine medications

Heparin-associated (Induced) Thrombocytopenia (HIT)

- HIT an antibody-mediated adverse reaction to the administration of UH and/or LMWH
 - May lead to both arterial and venous thrombosis
 - Diagnosis is made on clinical and serologic findings
 - HIT antibody formation, accompanied by otherwise unexplained fall in platelet count by >50% from baseline and/or skin lesions at injection sites are the manifestations of HIT
 - Incidence of HIT is <1% when heparin is given for <7 days
 - Thereafter, when given to patients with extended need for anticoagulation
 - Incidence may rise to as much as 10% to 20% for mild form (type 1) of HIT
 - To more than 5% for type 2, the more severe manifestation
 - Risk of developing HIT increased by use of heparin flush, prophylactic treatments, and increasing doses of heparin
 - HIT may occur more rapidly if patient has had recent exposure, within 100 days, to heparin
 - Can also develop after >9 to 30 days following cessation of therapy
 - Often goes undetected
 - Precipitous fall in platelet count from baseline platelet count usually seen with the type 1 syndrome
 - 50% to 75% of these patients go on to develop more ominous type 2 syndrome
 - Manifests with development of arterial or, more commonly, venous thrombotic complications
 - Patients who develop HIT generate large amounts of thrombin
 - *In vivo*, platelet activation results from binding of heparin platelet factor-4/immunoglobulin-G (PF4-IgG) immune complexes to platelet factor IIa receptors
 - Increased levels of thrombin demonstrated by elevated levels of thrombin-antithrombin complexes
 - Serve as an *in vivo* marker of thrombin generation
 - Much higher than what is seen in control patients with DVT
 - Diagnosis confirmed with platelet function testing or identification in blood of the antibody to heparin-platelet factor 4 complex
 - Using enzyme-linked immunosorbent assay
 - Once the determination of HIT is made patients at risk of thrombosis if no anticoagulation given
 - Alternative antithrombotic agents are detailed in Tables 119.3 and 119.4

- Molecular weight of LMWH ranges from 1,000 to 10,000
- About 20% of LMWH chains contain pentasaccharide sequences needed for antithrombin binding

Mechanism of Action

- LMWH chains too short to bridge thrombin to antithrombin
 - Binds to antithrombin
 - Brings about conformational changes, leading to inhibition of factor Xa
 - Ratio of inhibition of thrombin to factor Xa varies from 1:2 to 1:4 for different preparations of LMWH
- LMWH increasingly used for treatment of VTE disease in non-ICU patients
 - Administered as subcutaneous (SC) injection once or twice daily and IV when rapid effect needed
 - As safe and effective as IV/SC UH
 - Shorter LMWH chains bind less avidly to endothelial cells, macrophages, and heparin-binding proteins and have better bioavailability
 - Accumulate *in vivo*, leading to longer half-life
 - More predictable renal clearance
 - Greater ability to inactivate factor Xa
 - Compared to inactivation of thrombin
 - Consequently negligible effect on aPTT
 - Clearance of LMWH dose independent
 - Accomplished almost exclusively kidneys
 - Drug can accumulate in renal insufficiency
 - Cost effective because of reduced need for monitoring
 - Several advantages of LMWH over the UH (Table 119.5)
 - Disadvantages of LMWH, may be more pertinent to the ICU, include:
 - Absence of established dose for obese patients
 - Impaired clearance in patients with renal failure
 - Can be overcome by monitoring anti-factor-Xa levels
 - Adjusting subsequent doses
 - Based on anti-factor-Xa levels, LMWH has plasma half-life of 4 hours
 - Therapeutic levels range from 0.5 to 1.2 U/mL
 - When measured 3 to 4 hours after drug administration
 - No rapid/complete antagonist to anticoagulant effect of LMWH (Table 119.6)

Dosing

- Most commonly prescribed LMWHs are:
 - Enoxaparin
 - Dalteparin
 - Newer agents like tinzaparin
- *Enoxaparin* primarily metabolized in liver by desulfation and/or depolymerization
 - To lower-molecular-weight species with reduced biologic potency
 - Renal clearance of active fragments represents about 10% of administered dose
 - Total renal excretion of active/nonactive fragments about 40% of dose
- DVT Prophylaxis following Abdominal Surgery in Patients at Risk for Thromboembolic Complications: Patients at risk include those who are:
 - Older than 40 years of age
 - Obese
 - Undergoing surgery under general anesthesia lasting longer than 30 minutes

Low-molecular-weight Heparin

- Prepared from UH by controlled depolymerization of parent drug into short segments

TABLE 119.3

ALTERNATIVES TO HEPARIN FOR THE TREATMENT OF HEPARIN-INDUCED THROMBOCYTOPENIA (HIT)^a

Agent	Clearance	Therapeutic dose	Monitoring	Adverse effects
Direct thrombin inhibitors				
Lepirudin (Refludan, Berlex) ^b	Renal	IV, 0.4 mg/kg of body weight (up to 110 kg); IV bolus ^c followed by 0.15 mg/kg/hr (up to 110 kg) (maximal initial bolus, 44 mg; maximal initial infusion, 16.5 mg/hr)	Measure aPTT 2 hr after therapy started and after each dose adjustment; therapeutic range, 1.5 to 2.5 times the baseline value (optimal aPTT, <65 sec ^d); check baseline PT before switching therapy to warfarin ^e	Bleeding with therapeutic dose in 17.6% of patients; antilepirudin antibodies develop in 30% of patients
Argatroban (Novastan, GlaxoSmithKline) ^b	Hepatic	2 µg/kg/min continuous infusion (maximal infusion, 10 µg/kg/min)	Measure aPTT 2 hr after initiation of therapy and after each dose adjustment; therapeutic range, 1.5 to 3 times the baseline value (not to exceed 100 sec); switching to warfarin complicated by baseline prolongation of the PT ^f	Bleeding with therapeutic dose in 6 to 7% of patients
Bivalirudin (Angiomax, The Medicines Company) ^g	Enzymatic (80%) and renal (20%)	For PCI, 0.75 mg/kg IV bolus followed by 1.75 mg/kg/hr for remainder of procedure; infusion may be continued for 4 hr after the procedure or administered as low-dose infusion (0.2 mg/kg/hr) for an additional 20 hr	Measure ACT 5 min after completing IV bolus	Bleeding with dose used in PCI in 2.4% of patients
Anti-factor Xa therapy				
Danaparoid (Orgaran, Diosynth) ^b	Renal	IV, 2,250 U bolus followed by 400 U/hr for 4 hr, then 300 U/hr for 4 hr, then 150 to 200 U/hr	Not required, but if needed, maintain anti-factor Xa level, 0.5 to 0.8 U/mL	Bleeding with therapeutic dose in 8.1% of patients; cross-reactivity with PF4-heparin antibodies in 3.2% of patients

aPTT, activated partial thromboplastin time; PT, prothrombin time.

^aExcept where indicated, the guidelines for dosing and monitoring are from the manufacturers of the drugs. Guidelines for therapeutic dosing are for intravenous (IV) infusion, except for bivalirudin, which is used in patients undergoing percutaneous coronary intervention (PCI). The guidelines of the American College of Chest Physicians recommend overlap use of direct thrombin inhibitor therapy and warfarin therapy for more than 5 days, whereas the Hemostasis and Thrombosis Task Force of the British Committee for Standards in Haematology recommend overlap use of direct thrombin inhibitor therapy and warfarin therapy until the international normalized ratio (INR) is at a therapeutic level for at least 48 hours.

^bThese drugs have been approved in the United States for the treatment of heparin-induced thrombocytopenia.

^cBolus therapy is not advised in older patients or patients with renal insufficiency.

^dThis value is the maximal aPTT recommended by Lubenow et al.

^eTherapeutic lepirudin may prolong the baseline PT slightly, but it generally does not interfere with conversion from lepirudin to warfarin therapy. If the PT is prolonged by more than a few seconds, further evaluation should be undertaken before initiating warfarin.

^fCombined anticoagulant therapy with argatroban and warfarin produces an INR response that is significantly greater than that obtained with warfarin alone. To change therapy from argatroban to warfarin for outpatient anticoagulant therapy, the INR should be monitored daily, and when the INR is greater than 4, the argatroban infusion should be withheld and the INR rechecked to determine whether it is therapeutic. An alternative strategy would be to use a chromogenic factor X assay to monitor warfarin therapy while the patient is also receiving argatroban.

^gThis drug has been approved in the United States for the treatment of patients undergoing percutaneous coronary intervention (PCI) who have heparin-induced thrombocytopenia or a history of heparin-induced thrombocytopenia.

^hThis drug is not available in the United States.

From Arepally GM, Ortel TL. Heparin-induced thrombocytopenia. *N Engl J Med*. 2006;355:809, with permission.

- Have additional risk factors such as malignancy or history of DVT or PE
- Recommended dose of enoxaparin for this indication 40 mg SC daily
 - Beginning 2 hours preoperatively
- **Treatment of DVT with or without PE:** In patients with acute DVT with PE or acute DVT without PE who are not candidates for outpatient treatment
- Recommended dose of enoxaparin is 1 mg/kg every 12 hours SC
- **Unstable Angina and Non-Q Wave MI:** Recommended dose of enoxaparin is 1 mg/kg SC every 12 hours in conjunction with oral ASA (100–325 mg daily)
 - Based on currently available data on efficacy and safety of LMWHs
 - Enoxaparin the only LMWH consistently demonstrating short- and long-term improvements in major ischemic outcomes compared with UH
- **Hip or Knee Replacement Surgery:** Recommended dose of enoxaparin is 30 mg SC every 12 hours

TABLE 119.4

GUIDELINES FOR TRANSITION TO ORAL ANTICOAGULANT IN A PATIENT WITH HEPARIN-ASSOCIATED OR INDUCED THROMBOCYTOPENIA (HIT)

Step	Description
1	Stop heparin or LMWH therapy
2	Ensure adequate levels of anticoagulation with a DTI or alternative anticoagulant
3	Avoid interruptions during treatment with a DTI or alternative anticoagulant
4	Wait until the platelet count has “cooled” or is near normal before beginning therapy with an oral anticoagulant
5	Initiate modest doses of an oral anticoagulant (2.5–5 mg warfarin)
6	Avoid overshooting the target INR ^a
7	Avoid using warfarin (or equivalent) as monotherapy

LMWH, low-molecular-weight heparin; DTI, direct thrombin inhibitor; INR, international normalized ratio.

^aRecognize that cotherapy with a direct thrombin inhibitor prolongs the INR for a longer time than warfarin therapy alone.

From Bartholomew J. Transition to oral anticoagulants in patient with heparin-induced thrombocytopenia. *Chest*. 2005;127:32s, with permission.

- If hemostasis established initial dose given 12 to 24 hours after surgery
- Hip replacement surgery, 40 mg SC daily, given initially 12 (\pm 3) hours **prior** to surgery may be considered
 - Enoxaparin prophylaxis 40 mg SC daily recommended for 3 weeks
 - Usual duration of administration is 7 to 10 days
- **Restricted Mobility:** Medical patients at risk for thromboembolic complications
 - Recommended dose of enoxaparin 40 mg SC daily
- **Mechanical Prosthetic Heart Valves:** Use of enoxaparin not adequately studied for thromboprophylaxis or long-term use in patients with mechanical prosthetic valves
 - Isolated cases of prosthetic valve thrombosis reported in patients who have received enoxaparin for thromboprophylaxis
 - Some were pregnant women in whom thrombosis led to maternal and fetal deaths
- Pregnant women with mechanical prosthetic valves may be at higher risk for thromboembolism
- **Dalteparin** consists of small heparin molecules ranging from 2,000 to 9,000 Da
 - Administered SC, has better availability and longer half-life than UH
 - Similar mechanism as enoxaparin, selectively inhibiting factor Xa
 - Inhibitory activity is 2.7:1 compared to 1:1 for UH
 - Inhibition of factor Xa prevents formation of fibrin clots
 - Elimination of drug occurs via renal route and is dose independent
 - Plasma half-life of 3 to 5 hours
 - Does not significantly affect platelet activity, prothrombin time (PT), or aPTT
 - Superior to warfarin in preventing DVT following total hip replacement surgery

TABLE 119.5

ADVANTAGES OF LOW-MOLECULAR-WEIGHT HEPARIN OVER UNFRACTIONATED HEPARIN

Advantage	Consequence
Better bioavailability and longer half-life	Can be given subcutaneously once or twice after subcutaneous injection daily for both prophylaxis and treatment
Dose-independent clearance	Simplified dosing
Predictable anticoagulant response	Coagulation monitoring is unnecessary in most patients
Lower risk of heparin-induced thrombocytopenia	Safer than heparin for short- or long-term administration
Lower risk of osteoporosis	Safer than heparin for extended administration

From Weitz JI. Anticoagulants and fibrinolytic drugs. In: *Hematology: Basic Principles and Practice*. 4th ed. Orlando, FL: Churchill Livingstone; 2005:2254, with permission.

TABLE 119.6

DOSAGE REGIMENS FOR PATIENTS WITH SEVERE RENAL IMPAIRMENT

Indication	Dosage regimen
Prophylaxis in abdominal surgery	30 mg administered SC once daily
Prophylaxis in hip or knee replacement surgery	30 mg administered SC once daily
Prophylaxis in medical patients during acute illness	30 mg administered SC once daily
Prophylaxis of ischemic complications of unstable angina and non-Q wave myocardial infarction when concurrently administered with aspirin	1 mg/kg administered SC once daily
Inpatient treatment of acute deep vein thrombosis with or without pulmonary embolism when administered in conjunction with warfarin sodium	1 mg/kg administered SC once daily
Outpatient treatment of acute deep vein thrombosis without pulmonary embolism when administered in conjunction with warfarin sodium	1 mg/kg administered SC once daily

SC, subcutaneously.

- Dalteparin decreases risk of death or acute myocardial infarction (AMI) by 36% as compared to ASA alone
- Dalteparin found as effective as IV UH in preventing death or AMI in acute phase following unstable angina or non-Q wave MI
- *Tinzaparin* is a relatively new drug with a similar mechanism of action and pharmacokinetic profile as enoxaparin and dalteparin.
- Approved for treatment of symptomatic DVT

Complications

- **Bleeding:** Major complication of LMWHs is bleeding
 - Is as frequent as with UH
 - Of course, more common in patients receiving antiplatelet/antifibrinolytic therapy in addition to LMWH
 - Recent surgery, coagulopathy, or trauma increases risk of bleeding
 - Protamine sulfate can be used as antidote
 - Incompletely neutralizes anticoagulant activity by binding to longer chains of LMWH
 - These are responsible for antithrombin activity
 - Short chains, which inhibit factor Xa activity, don't bind to protamine
 - Only partially reverses effect of LMWH
- **Thrombocytopenia:** LMWH binds less avidly to platelets
 - Causes less release of PF4 and has reduced affinity for PF4
 - Less likely to trigger formation of antibodies
 - Incidence of HIT is lower compared to UH
 - Ab already formed in established HIT can cross-react with LMWH
 - Lead to thrombosis or other complications of disorder
 - LMWHs should not be used as substitute for UH in HIT patients

Warfarin (Coumadin)

- The most frequently prescribed oral anticoagulant
 - Fourth most prescribed cardiovascular agent
 - Overall, one of the most commonly prescribed drugs in United States
- Well absorbed in gut
 - Transported in plasma bound to albumin
- An antagonist of vitamin K

- Vitamin K required for posttranslational modification of:
 - Factors II, VII, IX, and X
 - As well as naturally occurring endogenous anticoagulant proteins C and S
- These factors biologically inactive without carboxylation of selected glutamic acid residues
 - Requires reduced vitamin K as cofactor
- Antagonism of vitamin K or vitamin deficiency reduces rate at which these factors are produced
 - Creating state of anticoagulation
- Therapeutic doses reduces production of functional vitamin K-dependent factors 30% to 50%
- Concomitant reduction in carboxylation of secreted clotting factors yields 10% to 40% decrease in biologic activity of clotting factors
 - Thus, coagulation system becomes functionally deficient
- PT the primary assay used in monitoring warfarin therapy
 - Changes noted in first few days of therapy primarily due to reduction in factors VII and IX
 - Have shortest half-lives, 6 and 24 hours, respectively
- PTs performed with different thromboplastins not always directly comparable
 - INR adopted using thromboplastins with international sensitivity index values near 1.0
- Warfarin used in lower extremity DVT patients to prevent extension and reduce risk of PE
 - Patients with PE treated with warfarin to prevent further thromboemboli
- Warfarin is used in patients with atrial fibrillation and artificial heart valves to reduce risk of embolic strokes
- Helpful in preventing blood clot formation in certain orthopedic surgeries:
 - Knee or hip replacements
- Helps prevent thrombotic stenosis of coronary artery stents (Table 119.7)
- Most common complication of warfarin therapy is bleeding
 - Occurs in 6% to 39% of patients annually
 - Incidence related to intensity of anticoagulation
 - Need for intense anticoagulation has evolved and been reduced over past 20 years
 - Incidence of bleeding decreased significantly
 - Moderate bleeding (elevated INR) treated by adjusting down dose
 - Severe bleeding can be treated with fresh frozen plasma

TABLE 119.7

THERAPEUTIC GOALS AND DURATION OF WARFARIN ANTICOAGULATION

Indication	INR	Duration
Prophylaxis of venous thrombosis for high-risk surgery	2–3	Clinical judgment
Treatment of venous thrombosis		
First episode	2–3	3–6 mo ^a
High risk of recurrent thrombosis	2–3	Lifelong
Thrombosis associated with antiphospholipid antibody	3–4	Lifelong
Treatment of pulmonary embolism		
First episode	2–3	3–6 mo
High risk of recurrent embolism	2–3	Lifelong
Prevention of systemic embolism		
Tissue heart valves	2–3	3 mo
Acute myocardial infarction (to prevent systemic embolism) ^b	2–3	Clinical judgment
Valvular heart disease (after thrombotic event or dilated left)	2–3	Lifelong
Atrial fibrillation		
Chronic or intermittent	2–3	Lifelong
Cardioversion	2–3	3 wk before and 4 wk after atrial fibrillation if normal sinus rhythm is maintained
Prosthetic heart valves		
Aortic position		
Mechanical	2.5–3.5 ^c	Lifelong
Bioprosthetic	2–3	Clinical judgment (3 mo optional)
Mitral position		
Mechanical	2.5–3.5 ^c	Lifelong
Bioprosthetic	2–3	3 mo

INR, international normalized ratio.

^aAll recommendations are subject to modification by individual characteristics. First event with reversible or time limited risk factors (surgery, trauma, immobilization, estrogen use). Hyers TM, Agnelli G, Hull RD, et al. Antithrombotic therapy for venous thromboembolic disease. *Chest*. 2001;119(Suppl):176s–193s.

^bIf oral anticoagulant therapy is elected to prevent recurrent myocardial infarction, an INR of 2.5–3.5 is recommended.

^cDepending on the type of prosthetic valve and valve position (mitral), some patients may benefit from INR in upper therapeutic range.

From Horton JD, Bushwick BM. Warfarin therapy: evolving strategies in anticoagulation. *Am Fam Physician*. 1999;59(4):636, with permission.

Alternative Therapies

Thrombin Inhibitors

- Heparin, LMWH, and warfarin used for treatment of venous and arterial thromboemboli
 - These drugs have drawbacks
 - Biophysical limitations of heparin include inability of heparin or antithrombin complex to inhibit factor Xa within the prothrombinase complex and thrombin bound to fibrin, clotting enzymes that are important triggers of thrombin growth
 - Direct thrombin inhibitors (DTIs) have advantageous properties over indirect thrombin inhibitors (ITIs) (heparins, including LMWH)
- Thrombin is a trypsin-like serine protease that converts fibrinogen to fibrin
 - Inhibited either directly or indirectly
 - ITIs act by catalyzing reaction of antithrombin and/or heparin cofactor II
 - Thrombin substrate specificity due to surface binding sites (i.e., exosite 1)
 - DTIs directly bind thrombin (at exosite 1 or other active site of thrombin)

- Block this procoagulant from reacting further
- More advantageous than ITIs, such as heparin
 - Don't bind plasma proteins
 - Produce more predictable response
 - DTIs do not bind PF4
 - Anticoagulant activity unaffected by large quantities of PF4 released in surrounding region of platelet-rich thrombi
 - DTIs inactivate fibrin-bound and fluid-phase thrombin
- Three parenteral DTIs approved for limited use in United States and Canada:
 - Hirudin and argatroban approved for treatment of patients diagnosed with heparin-associated thrombocytopenia
 - Bivalirudin approved as alternative therapy for heparin-sensitive patients undergoing percutaneous coronary interventions
- **Hirudin:** A 65 amino acid polypeptide originally isolated from salivary glands of medicinal leech
 - Now available via recombinant DNA technology
 - Recombinant form exhibits 10-fold reduced affinity for thrombin compared to native form
 - Directly inhibits thrombin in bivalent manner
 - Globular amino-terminal domain interacts with thrombin active site

- Anionic carboxy-terminal tail binds to exosite 1 on thrombin
 - The substrate recognition site
- Hirudin/thrombin complex essentially irreversible
- May create problem if significant bleeding occurs
 - No specific antidote
- Recombinant hirudins, for example, desirudin and lepirudin
 - Have leucine substituted for isoleucine at N-terminal end of molecule
 - Lepirudin (Refludan) approved in North America for treatment of heparin-induced thrombocytopenia subtypes 1 and 2
- Plasma half-life of hirudin approximately 60 minutes following IV injection
 - 120 minutes following SC administration
- Cleared via kidneys
 - Should be used with caution, if at all, in patients with renal insufficiency
- Anticoagulant activity measured using aPTT
 - Dose adjustment made to maintain aPTT within therapeutic range ratio of 1.5 to 2.0
 - Approximately 4 hours after drug initiation
 - Correlation between plasma hirudin levels and aPTT nonlinear
 - Ecarin clotting time more preferable monitor of anticoagulation
 - Dose adjustments needed in those with renal impairment
 - Rarely nonneutralizing hirudin antibodies prolonging anticoagulant effect due to delayed hirudin-antibody complex clearance may develop
- Successfully used and licensed for treatment of arterial or venous thrombosis complicating HIT
 - Also used in patients with HIT undergoing cardiopulmonary bypass
 - Shown superior to heparin or LMWHs for DVT prophylaxis in patients undergoing elective hip arthroplasty
 - Does not increase bleeding risk in this high-risk setting
- Used extensively in patients with acute coronary syndromes and for VTE prophylaxis
 - Narrow therapeutic index and high risk of bleeding
 - Must be used with extreme caution and not approved for this use
- **Bivalirudin:** A 20 amino acid synthetic polypeptide analogue of hirudin
 - The amino terminal D-Phe-Pro-Arg-Pro sequence, which binds to the active site of thrombin, is connected via four Gly residues to a carboxyl-terminal dodecapeptide that interacts with exosite 1 on thrombin
 - Differs from hirudin in that once bound to thrombin, Arg-Pro bond on amino terminal extension of bivalirudin is cleaved
 - Converting bivalirudin to lower-affinity thrombin inhibitor
 - Producing transient inhibition of active site of thrombin
 - Allowing recovery of thrombin activity
 - Shorter half-life of bivalirudin, 25 minutes after IV injection
 - Only about 20% renally excreted
 - Safer alternative to hirudin
 - Patients with a high risk of developing HIT
 - Bivalirudin typically administered as weight-adjusted (1 mg/kg) bolus dose given prior to percutaneous coronary interventions
- Followed by 4-hour infusion (0.2–0.5 mg/kg/hour)
 - Dose adjusted according to renal function
 - Plasma clearance of in patients with moderate or severe renal impairment reduced by approximately 20%
 - Suggests infusion reduction by 20% in patients with moderate to severe renal impairment
- Anticoagulant effect monitored by activated clotting time (ACT)
 - Additional bolus given if ACT <350 seconds
- **Argatroban:** A synthetic L-arginine derivative competitive inhibitor of thrombin
 - Binds noncovalently to active site of thrombin to form reversible complex
 - Plasma half-life is 45 minutes
 - Monitored using aPTT
 - Dose adjusted to maintain therapeutic aPTT ratio of 1.5 to 3.0
 - Therapy can prolong INR more than other DTIs
 - May complicate overlap therapy with vitamin K antagonists
 - Metabolized in liver and is used with caution in patients with hepatic dysfunction
 - Considered drug of choice for patients with severe renal impairment
 - Approved for use in patients with:
 - Documented HIT
 - For anticoagulation in HIT patients undergoing percutaneous coronary intervention
- **Melagatran/Ximelagatran:** Melagatran a dipeptide mimetic of region of fibrinopeptide A that interacts with active site of thrombin
 - Drug has poor oral bioavailability and must be given SC
 - **Ximelagatran** an uncharged lipophilic prodrug
 - Exhibits about 20% bioavailability after oral administration
 - Once absorbed, ximelagatran rapidly transformed to melagatran
 - Has half-life of approximately 4 to 5 hours
 - Primary route of excretion for melagatran is kidneys
 - Approximately 80% eliminated renally
 - Dose adjustments needed in elderly and those patients with renal impairment
 - No adverse food or drug interaction to influence absorption of ximelagatran
 - Produces predictable anticoagulant effect
 - Need for routine monitoring usually unnecessary
 - Ximelagatran under evaluation for thromboprophylaxis in orthopedic patients and for treatment of VTE and atrial fibrillation

Factor Xa Inhibitors

- Factor Xa the rate-limiting step in thrombin generation
 - Situated at beginning of common coagulation pathway
 - Where both intrinsic and extrinsic pathways converge
- Drugs blocking factor Xa considered either indirect or direct inhibitors
 - Indirect factor Xa inhibitors act by binding to and activating antithrombin
 - Which then inhibits free factor Xa
 - Direct factor Xa inhibitors bind to and inhibit factor Xa without antithrombin

TABLE 119.8

PROPERTIES OF LOW-MOLECULAR-WEIGHT HEPARIN, FONDAPARINUX, AND IDRAPARINUX

Property	LMWH	Fondaparinux	Idraparinux
Source	Porcine mucosal heparin	Chemical synthesis	Chemical synthesis
Molecular weight (daltons)	Mean 5,000	1,728	1,727
SC bioavailability	~90%	100%	100%
Target(s)	Multiple: FXa > FIIa > FIXa, FXIa, FXIIa	FXa only	FXa only
Binding to proteins other than target	Yes	No	No
Anti-Xa:anti-IIa	2–5:1	Anti-Xa only	Anti-Xa only
TFPI release from endothelium	Yes	No	No
Clearance	Renal primarily	Renal	Renal
Half-life (SC route)	3–4 h	17–21 h	80–130 h
Effects of protamine	Partial neutralization	No effect	No effect
Potential for HIT	Low	Very low	Very low

LMWH, low-molecular-weight heparin; SC, subcutaneous; FXa, factor Xa; FIIa, factor IIa; FIXa, factor IXa; FXIa, factor XIa; FXIIa, factor XIIa; TFPI, tissue factor pathway inhibitor; HIT, heparin-induced thrombocytopenia.

From Weitz JL, Middeldorp S, Geerts W, et al. Thrombophilia and new anticoagulant drugs. *Hematology*. 2004;1:429, with permission.

- **Indirect Factor Xa Inhibitors:** *Fondaparinux* and *idraparinux* two new parenteral indirect factor Xa inhibitors
 - Synthetic analogues of antithrombin-binding pentasaccharide sequence found in heparin and LMWH
 - Drugs are modified to increase affinity for antithrombin
 - As compared to heparin and LMWH
 - Chain length of molecules too short to bridge thrombin to antithrombin
 - Act by catalyzing factor Xa inhibition by antithrombin
 - Properties are different from those of LMWH (Table 119.8)
 - Potential benefits of fondaparinux over LMWH:
 - Synthetically produced
 - Has longer half-life
 - Does not bind to plasma proteins other than antithrombin
 - Does not bind to PF4 to form heparin/PF4 complexes
 - Serve as antigenic target for antibodies causing HIT
 - May be safer to use in these patients
 - Fondaparinux extensively studied and as effective as antithrombotic agent for prevention and treatment of both venous and arterial disorders
 - Currently approved as thromboprophylaxis:
 - Following orthopedic procedures
 - As initial treatment for VTE
 - Investigated as antithrombotic agent in cardiac disease
 - Idraparinux a chemically modified analogue of fondaparinux
 - Binds to antithrombin with such high affinity that half-life approximates that of antithrombin
 - Requires SC dosing weekly
 - Under evaluation for:
 - Treatment of VTE
 - Long-term prevention of stroke in chronic atrial fibrillation patients
 - May be useful in patients intolerant of vitamin K-antagonist medications
 - Possible drawback to use of drug is long half-life and lack of antidote
 - Healthy volunteers had anticoagulant effect reversed by hrfVIIa

- **Direct Factor Xa Inhibitors:** Several synthetic direct factor Xa inhibitors undergoing clinical trials
 - Inhibit both free and activated platelet-bound factor Xa trapped within thrombus as part of prothrombinase complex
 - Property may offer advantage over LMWH and indirect factor Xa inhibitor agents
 - Appear to inhibit thrombus formation while allowing time for sufficient thrombin to be generated to activate platelets
 - May be associated with a lower incidence of major bleeding

Thrombolytic Therapy

- Fibrinolytic system aids in dissolution of intravascular clots via fibrin digesting plasmin
 - Inactive plasminogen converted to plasmin by cleavage of single peptide bond
 - Plasmin a nonspecific protease
 - Acts by digesting fibrin clots as well as other proteins
- Thrombolytic drugs act as plasminogen-activating agents
 - Catalyze conversion of endogenous plasminogen to plasmin
 - Dissolve fibrin deposits and pathologic thrombi at sites of vascular injury
 - May be associated with significant hemorrhage
 - When thrombolytic therapy initiated, massive fibrinolysis may occur
 - Potentially overwhelming body's inhibitory controls
- Use of thrombolytic therapy in treatment of DVT and PE highly individual specific
 - Early use of thrombolytic therapy in setting of DVT may decrease subsequent pain, swelling, and loss of venous valves
 - Reportedly reduces incidence of postphlebitic syndrome
 - Guidelines do not recommend thrombolysis for treatment of DVT unless limb ischemia and limb loss imminent
- In treatment of PE
 - Thrombolytic therapy followed by heparin more efficacious in thromboembolus dissolution compared to heparin alone

- In acute (first 24 hours) setting
- Lead to more rapid resolution of lung scan abnormalities and hemodynamic improvements
- Benefit over longer term questionable
- Thrombolytic therapy standard treatment for patients presenting with:
 - Acute ST-segment elevation MI and new-onset left bundle branch block
 - Ischemic stroke, cerebral vein and sinus thrombosis, thrombosed mechanical valves, and thrombosed arteriovenous shunts and catheters
- Agents have evolved from non-fibrin-selective first generation agents to more fibrin-selective third generation agents
- There are still limitations with currently available agents
- *First-generation thrombolytic agents*
 - Not fibrin specific and convert circulating plasminogen to plasmin
 - Constant equilibrium between circulating plasminogen and plasminogen in thrombus
 - Eventual depletion of plasminogen, reducing clot lysis
 - Associated with increased risk of allergic reaction
 - Have comparatively short half-lives
 - *Streptokinase*
 - Single-chain polypeptide, molecular weight of 47 to 50.2 Kd, produced by group C β -hemolytic streptococci
 - Works by binding with circulating plasminogen to form activator complex, converting plasminogen to plasmin
 - 1:1 complex has increased catalytic activity compared to plasmin
 - Leads to stimulation of locally bound streptokinase–plasmin and streptokinase–plasminogen complexes
 - Results in acceleration in plasminogen activation and clot dissolution
 - Streptokinase increases levels of activated protein C
 - Half-life of streptokinase–plasminogen complex is 23 minutes
 - Lytic effect ranging from 82 to 184 minutes
 - No metabolites of streptokinase
 - Eliminated by the liver
 - Adverse reactions include allergic reactions, rarely anaphylaxis, and bleeding
 - Hypotension not related to bleeding or anaphylaxis seen during infusion in 1% to 10% of patients
 - Decreasing infusion and close monitoring recommended
 - For PE
 - Recommended dose 1 million IU infusion over 24 hours
 - For AMI
 - Adult dose is 1.5 million IU in 50 mL D₅W IV over 5 minutes
 - *Urokinase*
 - A two-chain serine protease containing 41 amino acid residues
 - Isolated from human urine and fetal kidney cell cultures
 - Single-chain precursor
 - Precursor converted to active two-chain urokinase plasminogen activator through limited hydrolysis by plasmin and kallikrein
 - Active form increases efficacy of plasmin activation
 - Enhances further conversion
 - Has a 15- to 20-minute half-life and metabolized in liver
 - Produces less sustained fibrinolysis
 - Potential disadvantages of significant bleeding
 - For PE regimen is administration of 4,400 IU/kg load
 - Followed by infusion of 4,400 IU/kg for 12 to 24 hours
 - For AMI less well studied than other agents
 - Most common regimen is 2 million U as IV load
 - Followed by 1 million U over the next 60 minutes
- *Second-generation thrombolytics* fibrin selective
 - Developed with intention to limit or avoid systemic thrombolysis
 - Present agents may cause mild to moderate depletion in levels of circulation fibrinogen and plasminogen
 - *Tissue-type plasminogen activator* (TPA, Alteplase)
 - Glycoprotein of 527 amino acids
 - First recombinant tissue-type plasminogen activator (rtPA)
 - Enzyme responsible for most of body's natural physiologic responses to clear and reduce excessive thrombus propagation
 - TPA binds fibrin with a greater affinity than streptokinase, converting plasminogen to plasmin once bound to fibrin clot surface
 - Hence term “clot selective”
 - TPA rapidly cleared from plasma, primarily by liver
 - Initial half-life of <5 minutes
 - Heparin usually administered with TPA due to short half-life to avoid reocclusion
 - Not antigenic and almost never associated with allergic reactions
 - For AMI, drug given as accelerated infusion (over 1.5 hours) or long infusion (>3 hours)
 - Must be given in 1 mg/mL concentration in sterile water
 - Accelerated infusion of rtPA 15 mg IV, followed by 0.75 mg/kg, up to 50 mg IV over 60 minutes
 - Maximum total dose of 100 mg
 - The >3-hour infusion begins as 10-mg IV load over 2 minutes, followed by a 50-mg infusion over first hour, and by a 20-mg/kg infusion over next 2 hours
 - For acute ischemic stroke with time of symptom onset of <3 hours
 - Dose of TPA 0.9 mg/kg, to maximum of 90 mg IV over 60 minutes
 - 10% of total dose administered as IV bolus over 1 minute
 - For thrombolysis of PE
 - 100 mg TPA as continuous infusion over 2 hours
 - Initial 15-mg IV load
 - Followed by 85 mg over 2 hours
 - Heparin improves clinical course in stable patients with acute submassive PE when receiving TPA
 - Beneficial to administer alteplase with heparin
- *Third-generation thrombolytics* based on modifications of TPA structure
 - May give agent longer half-lives, increased resistance to plasma protease inhibitors, and/or cause more selective binding to fibrin

TABLE 119.9

CHARACTERISTICS OF U.S. FOOD AND DRUG ADMINISTRATION-APPROVED THROMBOLYTIC AGENTS

	Streptokinase	Anistreplase	Alteplase	Reteplase	Tenecteplase
Molecular weight (Da)	47,000	131,000	70,000	39,000	70,000
Half-life (minutes)	23	100	<5	13–16	20–24
Dose/time	1.5 MU × 30–60 min	30 mg × 5 min	100 mg × 90 min	10 + 10 U × 30 min	0.5 mg/kg × 5–10 s
Bolus administration	No	Yes	No	Yes	Yes
Metabolism	Hepatic	Hepatic	Hepatic	—	—
Allergic reactions	1%–4%		<0.2%	No	<1%
Hypotension	Yes	Yes	No	No	No
Early heparin ^a	?Yes	?Yes	Yes	Yes	Yes
Fibrin selective	No	No	Yes	Yes	Yes
Systemic fibrinogen	Marked	Marked	Mild	Moderate	—
Fibrinogen breakdown	4+		1–2+	Unknown	4–15
Plasminogen binding	Indirect	Indirect	Direct	Direct	Direct
TIMI 3 flow (%)	32	43	54	60	66
≈90-minutes patency (%)	50	65	75	80	75
Intracerebral hemorrhage (%)	0.5	0.6	0.8	0.9	
Mortality rates (%)	7.3	10.5	7.2	7.5	

TIMI 3, thrombolysis in myocardial infarction flow 3 (normal)

^aThe need for concomitant heparin has been formally tested with only streptokinase and alteplase.

From Khan IJ, Gowda RM. Clinical perspectives and therapeutics of thrombolysis. *Int J Cardiol.* 2003;91:117, with permission.

- **Reteplase** (rtPA), a synthetic, nonglycosylated deletion-mutant form of TPA containing 355 of 527 amino acids of native TPA
 - Produced in *Escherichia coli* via recombinant technology
 - Binds fibrin five times less avidly than native TPA
 - Allowing drug to diffuse through clot rather than binding to it
 - In high concentrations allows plasminogen at clot to be converted into plasmin
 - Results in faster clot resolution compared to alteplase
 - More rapidly cleared from plasma
 - Somewhat extended half-life, 11 to 19 minutes, than alteplase
 - Primarily renal and some hepatic clearance
 - Not antigenic and is rarely associated with allergic reactions
 - NOT given with heparin due to physical incompatibility
 - For AMI adult dose of reteplase two IV loads of 10 U
 - Each given over 2 minutes
 - Second load given 30 minutes following first
 - Approved only for use in AMI
 - Reteplase has wide off-label use in acute DVT and PE
 - Dosing schedule same as for AMI
- **Tenecteplase** a genetically engineered mutation of TPA with similar mechanism of action to alteplase
 - Produced recombinantly with Chinese hamster ovary cells
 - A 527 amino acid glycoprotein
 - Has decreased plasma clearance
 - 15- to 19-minute half-life
 - Reduced sensitivity to plasminogen activator inhibitor
 - Greater fibrin specificity
 - May lead to decreased hemorrhagic complications
 - Administered a 30- to 50-mg IV bolus over 5 seconds
 - Dose calculated based on patient's weight as follows:
 - 0.5 mg/kg
 - Currently under investigation for ischemic stroke
- Thrombolytic agents differ in:
 - Ability to lyse clots
 - Fibrin selectivity
 - Ability to activate thrombolysis and platelet aggregation
 - Clinical effectiveness of same agent can be altered by:
 - Dose
 - Route of administration
 - Concomitant use of adjunctive agents
 - All thrombolytic agents administered via IV route in dosing regimens designed to achieve >90% activation of the fibrinolytic system (Table 119.9)

CHAPTER 120 ■ TRANSFUSION THERAPY: WHEN TO USE IT AND HOW TO MINIMIZE IT

- Routine, safe administration of blood products required several important scientific advances
 - Discovery of A, B, and O blood types by Landsteiner in 1900
 - The AB blood type by Decastello and Sturli in 1902
 - The first blood bank established in 1932 in a Leningrad hospital
 - The first blood bank in the United States established by Fantus in 1937 at Cook County Hospital in Chicago
 - 1940s techniques of cross-matching, anticoagulation, and storage of blood, and establishment of blood banks made routine blood transfusion a reality
 - Introduction of plastic storage containers in 1950 and the introduction of refrigerated centrifugation instruments in 1953 made component therapy possible

BLOOD PRODUCT COLLECTION AND ADMINISTRATION

- Approximately 14 million units of RBCs (packed RBCs [PRBCs] and whole blood), 9,875,000 units of platelets, and 4 million units of plasma are transfused annually in United States
 - Represents 11.8% increase since 1999 and 56% increase since 1980
 - Use of other components, especially platelets, has also increased
 - Only about 5% of eligible donors ever donate blood
 - Transfusion rates in the United States for 2001 estimated at 48.75 units of RBC transfusion per 1,000 population
 - Compared to 44.93 units of RBC transfusion per 1,000 population in England
 - 28 units of RBC transfusion per 1,000 population in Australia
 - 54.8 units of RBC transfusion per 1,000 population in Denmark
- Anemia in critical illness is common
 - 25% to 37% of patients receive at least one blood transfusion during intensive care unit (ICU) stay
 - 85% of patients with ICU length of stay over 1 week received at least one transfusion
 - Blood transfusion not associated with acute blood loss in >66% of cases
 - Phlebotomy and decreased production of blood cells implicated as significant contributors to ICU anemia
 - Many studies estimated daily blood loss from phlebotomy at least 40 mL/day

- Practitioners should carefully consider need for frequent blood draws in ICU

Collection and Preparation of Blood Products

- Blood is collected from donors and separated into individual components
 - PRBCs, plasma, platelets, and proteins
 - Collected into plastic bags containing a citrate solution that binds calcium, preventing coagulation
 - Citrate phosphate dextrose (CPD)
 - Citrate phosphate double dextrose (CP2D)
 - Citrate phosphate dextrose adenine (CPDA-1)
 - Solutions now available that extend the shelf life of PRBCs, and contain dextrose, adenine, sodium chloride, and phosphate (AS-3) or mannitol (AS-1 and AS-5)
 - After collection, each unit gently centrifuged to pack RBCs
 - Leaving approximately 70% of platelets suspended in plasma
 - Platelet-rich plasma removed and centrifuged to sediment the platelets
 - All but a small amount of the resulting supernatant plasma is removed and rapidly frozen
 - Platelets are then resuspended, yielding a platelet concentrate
 - When frozen plasma is stored at <18°C, referred to as fresh frozen plasma (FFP)
 - If frozen plasma allowed to thaw at 4°C, precipitate that remains can be collected to yield cryoprecipitate
 - Albumin and other proteins extracted from remaining plasma
 - Another option for collection of blood leukocytes, platelets, or plasma is automated cell separators (apheresis)
 - Blood is withdrawn from donor and separated by centrifuge
 - Desired component removed
 - Remaining blood returned to donor
 - Allows blood banks to offer products such as single-donor platelet packs
 - Administration of a single-donor unit of platelets exposes recipient to only one person's antigens
 - Equivalent dose of pooled platelet transfusion ("six pack" or "ten pack") exposes patient to six or ten sets of antigens, respectively
 - Making subsequent platelet transfusion less effective
 - Additionally bacterial contamination less likely with single-donor apheresis platelets

Storage Lesion

- Storage or refrigeration creates progressive changes in PRBCs, *storage lesion*, and include:
 - Increase in concentration of potassium, phosphate, and ammonia
 - Decrease in pH
 - Altered affinity of hemoglobin for oxygen
 - Changes in RBC deformability
 - Hemolysis
 - Development of microaggregates
 - Release of vasoactive substances
 - Denaturation of proteins
 - Lifespan of RBCs becomes shorter the longer cells are stored
 - Associated with decreased intracellular 2,3-diphosphoglycerate (2,3-DPG) and adenosine triphosphate (ATP)
 - Large volumes of cold blood contributes to development of hypothermia
 - A clinically significant effects of storage on subsequent transfusion
 - Except for hypothermia, many of these changes reversed shortly after transfusion
 - In some cases, cause metabolic effects different from predicted based on *ex vivo* observations
 - Critical not to empirically treat theoretically anticipated effects of blood transfusions using “cookbook” approaches (such as giving one ampule of bicarbonate and one ampule of calcium with every “x” units of blood)

Administration of Blood Products

- Progressive abandonment of “10/30” transfusion “trigger” for red cell transfusion in favor of lower triggers
 - Even more appropriately, transfusion practice based on patient physiology
 - 10/30 transfusion trigger likely resulted from recommendation in 1942 that it was “wise” to maintain hemoglobin levels “between 8 and 10 grams per cubic centimeter” for patients who were poor surgical risks by giving a preoperative transfusion
 - No data were available to support this recommendation
 - Stood relatively unchallenged for about 50 years
 - Expanding body of literature suggests arbitrary transfusion for a set transfusion trigger (e.g., the “10/30 rule”) ill-advised
 - Purported cardiac risks with anemia overemphasized

Whole Blood

- Few widely accepted indications for whole blood in modern transfusion practice
 - Storage of whole blood precludes extraction of components
 - From systems perspective, is highly inefficient
 - Experience with use of whole blood by the U.S. military has rejuvenated use
 - Experience, especially with fresh whole blood having potentially beneficial effects on coagulopathy and hypothermia, may result in modification of civilian practices in future

Red Blood Cells

- PRBCs the most commonly utilized blood product
 - Providing oxygen-carrying capacity in cases of acute or chronic blood loss
 - Longest storage life currently allowed by U.S. Food and Drug Administration (FDA) is 42 days
 - Longer storage times result in fewer than 75% of RBCs remaining viable in circulation 24 hours after transfusion
 - Platelets degenerate at refrigerator temperatures
 - Refrigerated PRBCs contain essentially no functioning platelets
 - Levels of factors V and VIII decrease significantly at 1°C to 6°C
 - Levels of other factors remain essentially unchanged
- PRBCs provide oxygen-carrying capacity and maintain oxygen delivery provided:
 - Intravascular volume and cardiac function are adequate
 - Decision to transfuse, and amount of PRBCs transfused, depend on clinical situation
 - Hematocrit (Hct) 30% (or hemoglobin [Hgb] of 10 g/dL) as transfusion trigger no longer acceptable
 - One or more units of PRBC transfused with no predetermined number of units applicable
 - Each PRBC unit typically raises Hct 2% to 3% in 70-kg adult
 - Varies depending on the donor, the recipient’s fluid status, the method of storage, and its duration
 - With blood loss, O₂ delivery maintained through a series of complex interactions and compensatory mechanisms, including:
 - Increased cardiac output
 - Increased extraction ratio
 - Rightward shift of oxyhemoglobin curve
 - Expansion of volume
- Many anemic patients tolerate Hgb of 7 to 8 g/dL or less
 - Demonstrated in chronic renal failure and Jehovah’s Witnesses
 - Cardiac output does not increase significantly until Hgb below about 7 g/dL
 - Young healthy patients tolerate acute anemia to Hgb 7 g/dL or less through increases in CO, provided they have a normal intravascular volume and high arterial oxygen saturation
- Multicenter, randomized controlled study of transfusion in 838 patients in ICU
 - Liberal transfusion strategy (transfusion for Hgb <10 g/dL) compared with a restrictive strategy (transfusion for Hgb <7 g/dL)
 - Restrictive strategy at least as effective as liberal strategy
 - Possible exception of patients with acute myocardial infarction (MI) and unstable angina
- Suggested guidelines for RBC transfusion are listed in Table 120.1

Leukocyte-reduced Red Blood Cells

- Transfusion of PRBCs has been associated with immunosuppression
 - Effect thought to be related to exposure to leukocytes
 - Use of leukocyte-reduced components proposed to minimize immunosuppression

TABLE 120.1**GUIDELINES FOR TRANSFUSION OF PACKED RED BLOOD CELLS**

- Ongoing bleeding with hemodynamic instability unresponsive (or incompletely responsive) to infusion of 2,000 to 3,000 mL crystalloid
- Hemoglobin <7 g/dL
- Majority of PRBC and platelet transfusions in United States are leukocyte reduced
- Efficacy of these preparations remains controversial, and data are lacking
- Recommendations for transfusion of leukocyte-reduced blood components are listed in Table 120.2

Platelets

- Platelet transfusions indicated for patients at significant risk of bleeding
 - Because of quantitative or qualitative platelet deficits
 - A unit of platelets prepared from individual (or “random”) donors or by apheresis
 - A single donor provides equivalent of 6 to 10 single “random” donor units
 - In selected cases human leukocyte antigen (HLA)-matched platelets can be obtained by apheresis from HLA-matched donors
 - Platelet count 1 hour posttransfusion of 1 unit of platelets increases by 5,000 to 10,000 platelets/ μ L
 - Less pronounced responses expected with:
 - Repeated transfusion and development of alloimmunization
 - In presence of fever, sepsis, or splenomegaly
 - If alloimmunization thought to be cause of a poor response, platelets from an HLA-matched donor may be needed
- Prophylactic transfusion of platelets should be considered inappropriate:
 - Absent microvascular bleeding
 - With a low platelet count in a patient undergoing a surgical procedure

TABLE 120.2**INDICATIONS FOR TRANSFUSION OF LEUKOCYTE-REDUCED BLOOD COMPONENTS**

- To decrease the incidence of subsequent refractoriness to platelet transfusion caused by human leukocyte antigen (HLA) alloimmunization in patients requiring long-term platelet support
- To provide blood components with reduced risk for cytomegalovirus transmission
- To prevent future febrile nonhemolytic transfusion reactions (FNHTRs) in patients who have had a documented FNHTR
- To decrease the incidence of HLA alloimmunization in nonhepatic solid-organ transplant candidates

Data from Ratko TA, Cummings JP, Oberman HA, et al. Evidence-based recommendations for the use of WBC-reduced cellular blood components. *Transfusion*. 2001;41:1310–1319.

TABLE 120.3**INDICATIONS FOR TRANSFUSION OF PLATELETS**

- Disseminated intravascular coagulation: 20,000–50,000 platelets/ μ L
- Major surgery in leukemia: 50,000 platelets/ μ L
- Thrombocytopenia with massive transfusion: 50,000 platelets/ μ L
- Invasive procedures in cirrhosis: 50,000 platelets/ μ L
- Cardiopulmonary bypass: 50,000–60,000 platelets/ μ L
- Liver biopsy: 50,000–100,000 platelets/ μ L
- Neurosurgical procedures: 100,000 platelets/ μ L

Data from Rebutta P. Platelet transfusion trigger in difficult patients. *Transfus Clin Biol*. 2002;9:249–254.

- A platelet count that has fallen below 10,000 platelets/ μ L, in most medical patients
- Disease state-specific triggers for platelet transfusion are noted in Table 120.3
- Hypothermia depresses platelet function
 - Platelet transfusion generally ineffective with depressed temperatures
 - Restoration of normal temperature returns platelet function to normal
 - Ameliorates microvascular bleeding

Plasma

- A source of clotting factors in patients with coagulopathy and documented factor deficiency
 - May occur with liver dysfunction, congenital absence of factors, and transfusion of factor-deficient blood products, or after the use of warfarin
- One unit of plasma contains near-normal levels of all factors including:
 - About 400 mg of fibrinogen
 - Generally increases factor levels by about 3%
- Adequate clotting usually achieved with factor levels >30%
 - Higher levels advisable in patients undergoing operative or invasive procedures
 - Prothrombin time (PT) and activated partial thromboplastin time (aPTT) used to assess patients for plasma transfusion
 - Also to follow the efficacy of administered plasma
 - Recent experience suggests that use of thromboelastography (TEG) may provide advantages over the PT as a guide for the treatment of coagulopathy
- Plasma can be frozen and stored for up to 1 year
- Should not be given routinely or prophylactically by “cook-book” formula after RBC transfusion or “prophylactically” after cardiac bypass or other procedures
- Plasma should not be used as a volume expander
 - Crystalloids are cheaper, safer, and at least as effective
 - Broadly accepted guidelines plasma transfusion are noted in Table 120.4

Cryoprecipitate

- Indications for use of cryoprecipitate include (Table 120.5):
 - Factor deficiency (hemophilia A)
 - von Willebrand disease
 - Hypofibrinogenemia

TABLE 120.4**INDICATIONS FOR TRANSFUSION OF PLASMA**

- International normalized ratio (INR) >1.5 with an anticipated invasive procedure or surgery
- Massive hemorrhage (over one blood volume) with an INR >1.5
- Treatment of thrombotic thrombocytopenia purpura
- Inherited coagulopathies where a specific factor concentrate is not available
- Emergent reversal of anticoagulant therapy

Data from Toy P, Popovsky MA, Abraham E, et al., and the National Heart, Lung and Blood Institute Working Group on TRALI. Transfusion-related acute lung injury: definition and review. *Crit Care Med.* 2005;33:721–726.

- Some patients with uremic bleeding may benefit from cryoprecipitate transfusion
- Usually administered as a transfusion of 10 single units. Each 5 to 15 mL unit contains over 80 units of factor VIII and about 200 mg of fibrinogen
- Relatively high concentrations allow use of smaller volume of cryoprecipitate than would be required if plasma were used

Risks of Blood Transfusion

- Blood transfusion is potentially life-saving, but significant risks still involved
- Risks range from (Table 120.6):
 - Minor febrile transfusion reactions
 - To transmission of viral infection
 - To potentially fatal transfusion of incompatible blood
- Blood banks in United States conduct over 10 tests or checks on donated units of blood in addition to screening interview
 - 9 are for infectious diseases
 - Donor screening and introduction of effective tests for hepatitis and human immunodeficiency virus (HIV) have dramatically reduced the risks of transmission
- Recent data reveal leading causes of fatalities after blood transfusion are:
 - Administrative error leading to transfusion of ABO-incompatible blood
 - Bacterial contamination
 - Transfusion-related acute lung injury (TRALI)
 - Infectious risks of transfusion far outweighed by noninfectious risks
- TRALI the leading cause of transfusion-related mortality in 2003

TABLE 120.5**INDICATIONS FOR TRANSFUSION OF CRYOPRECIPITATE**

- Hemophilia A
- von Willebrand disease
- Hypofibrinogenemia
- Uremic bleeding
- As substitute for plasma if lower volume is desired

TABLE 120.6**RISKS OF BLOOD TRANSFUSION**

- Transfusion-related acute lung injury
 - Bacterial contamination of blood products
 - Administrative error leading to transfusion of ABO-incompatible blood
 - Viral infection transmission
 - Hepatitis B
 - Hepatitis C
 - Human immunodeficiency virus 1 and 2
 - Human T-cell leukemia virus 1 and 2
 - Epstein-Barr virus
 - Cytomegalovirus
 - Parvovirus B19
 - Human herpesvirus 8
 - Transfusion-transmitted virus
 - Mad cow disease (bovine spongiform encephalopathy)
 - West Nile virus
 - Bacterial/protozoal infection transmission
 - Syphilis
 - Malaria
 - Babesia microti*
 - Trypanosoma cruzi*
 - Yersinia enterocolitica*
 - Serratia marcescens*
 - Staphylococcus aureus*
 - Staphylococcus epidermidis*
 - Klebsiella pneumoniae*
 - Trypanosoma cruzi*
 - Transfusion reactions
 - Acute
 - Delayed
 - Immunosuppression
-
- Average of 11.7 deaths from bacterial sepsis per year in United States reported to FDA from 2001 to 2003
 - Decreased to 7.5 deaths per year in 2004 and 2005
 - Partly due to 2004 mandating of bacterial screening of platelets
 - Transfusion of blood to the wrong person a serious threat
 - Review of a 10-year experience in New York State risk of an ABO-incompatible transfusion estimated at 1 in 38,000 units of PRBC
 - Risk of a fatal reaction 1 in 1.8 million transfusions
 - Rate of ABO-incompatible transfusion of 1 in 12,000 units of PRBC transfused reported from hemovigilance program in Quebec
 - Given risks and benefits of blood transfusion
 - Informed consent for transfusion of components crucial in nonemergent situations
 - Summary of rates of more common or more concerning risks is in Table 120.7
 - Data useful for discussions with patients and families

Transfusion Reactions

- Given Classification of American Association of Blood Banks for transfusion reactions shown in Table 120.8

Transfusion-related Acute Lung Injury

- Acute onset of pulmonary edema associated with transfusion and leading to death first described in 1951 by Barnard

TABLE 120.7**INFORMATION FOR PATIENTS: COMMONLY ASKED QUESTIONS ABOUT BLOOD TRANSFUSION**

Complication	Risk from blood product transfusion	Comments
Febrile nonhemolytic transfusion reactions	Occurs in 0.5%–38% of all transfusions	Usually mild fever only More common with platelet transfusions
Severe acute hemolytic reaction	Fatal in 1 of 600,000 transfusions	Stop transfusion immediately and initiate supportive measures
Delayed hemolytic reaction	1 in 260,000 transfusions	Suspect when unexplained fever, fall in hematocrit, or jaundice occur
Bacterial contamination	1 in 15,000 platelet transfusions	Among leading causes of transfusion-related fatalities
Cytomegalovirus	Of concern in low-birth-weight infants and immunocompromised patients (e.g., transplant)	Between 50% and 85% of adults in the United States are carriers
Hepatitis B virus	<1 in 137,000	25% of carriers have active hepatitis and may progress to cirrhosis
Hepatitis C virus	<1 in 1 million	Most infected persons asymptomatic, but 80% become chronic
Human immunodeficiency virus	<1 in 1.9 million	Potentially fatal
Human T-cell leukemia virus 1 and 2	Very small	Rarely found in U.S. blood donors
West Nile virus	Very small when donors are properly screened	80% of those infected remain asymptomatic, 20% develop mild symptoms, and 1 in 150–200 infected people develop severe disease that may be fatal
Transfusion-related lung injury	1 in 5,000 units (estimated)	5%–10% fatal

Source: American Association of Blood Banks. www.aabb.org/content/About_Blood/Facts_About_Blood_and_Blood_Banking/fabloodtrans.htm.

- TRALI currently leading cause of death after transfusion
- Estimated rate of 1 in 5,000 units transfused, although higher rates have been reported
- TRALI likely underappreciated and underdiagnosed
- Other more commonly recognized conditions (acute lung injury and acute respiratory distress syndrome [ARDS] often associated with blood transfusion
- Makes diagnosis of TRALI more difficult

TABLE 120.8**TRANSFUSION REACTIONS: AMERICAN ASSOCIATION OF BLOOD BANKS CLASSIFICATION**

Type	Clinical features	Comments
Immunologic		
Hemolytic	Chills, fever, hypotension, renal failure, back pain, hemoglobinuria	Caused by red blood cell mismatch
Fever and/or chills, nonhemolytic	Temperature elevation >1°C, chills and/or rigors, headache, vomiting	
Urticarial	Pruritus, urticaria, flushing	
Anaphylactic	Hypotension, urticaria, bronchospasm, respiratory distress, wheezing, local edema, anxiety	Varies from isolated urticaria to fatal anaphylaxis
Transfusion-associated acute lung injury	Hypoxemia, respiratory failure, hypotension, fever	Leading cause of transfusion-associated mortality
Nonimmunologic		
Hypotension (associated with angiotensin-converting enzyme inhibition)	Flushing, hypotension	
Circulatory overload	Dyspnea, orthopnea, cough, tachycardia, hypertension, headache	
Nonimmune hemolysis	Hemoglobinuria	Caused by physical destruction of blood (heating, freezing, etc.)
Air embolus	Sudden dyspnea, cyanosis, chest pain, cough, hypotension, cardiac arrhythmia	
Hypocalcemia	Paresthesia, tetany, arrhythmia	
Hypothermia	Cardiac arrhythmia	
Transfusion-associated sepsis	Bacterial contamination of transfused blood	Consider in patients with fever >40°C and/or cardiovascular collapse

- Mortality rate associated with TRALI ranges 5% to 10%
 - All patients receiving blood products should be monitored, including SpO₂
- TRALI occurs with transfusion of all blood components
 - Especially with platelets and plasma
- Clinical syndrome characterized by:
 - Acute onset of dyspnea, hypotension, hypoxemia, fever, and noncardiogenic pulmonary edema
 - Symptoms appear within 6 hours of transfusion
 - Most often within 30 minutes
 - Diagnosis of TRALI made by exclusion
 - TRALI causes increased pulmonary microvascular permeability with increased protein levels in edema fluid
 - Two theories:
 - First hypothesis suggests leukocyte antibodies from donor unit activate recipient leukocytes in pulmonary circulation, leading to increased microvascular permeability and noncardiogenic pulmonary edema
 - Blood donations from multiparous women have been implicated
 - Second hypothesis assumes an initial predisposing event that primes the patient's neutrophils and sequesters them in lung
 - Biologically active lipids and cytokines in donor unit then further prime and activate recipient's neutrophils
 - Resultant microvascular permeability and noncardiogenic pulmonary edema
- Treatment of TRALI supportive and consists of appropriate hemodynamic and ventilatory support
 - Once TRALI suspected transfusion terminated immediately and blood bank notified
 - Donor unit can be tested for anti-HLA and/or antigranulocyte antibodies

Bacterial Contamination

- Most frequent cause of transfusion-transmitted infectious disease
 - After hemolytic reactions and TRALI bacterial contamination the most frequently reported cause of transfusion-related fatalities to the FDA
 - Agents most often implicated in PRBC bacteremia were:
 - *Serratia* and *Yersinia*
 - For platelets:
 - *S. aureus*, *Escherichia coli*, *Enterobacter*, and *Serratia* species more frequently identified
- Fever, chills, hypotension, tachycardia, and shock after transfusion should raise suspicion of bacterial contamination
 - Blood cultures of patient AND unit should be obtained
 - Platelets are stored at 20°C to 24°C and are good bacterial growth medium
 - Platelets are now screened for bacterial contamination in the United States

Hepatitis

- Transmission of hepatitis agents among most serious risks of blood transfusion
 - Past estimates of posttransfusion hepatitis were approximately 10%
 - Current data suggest infectious risk of hepatitis is <0.01% per unit transfused
 - Pooled nucleic acid amplification testing (NAT) used to test for HIV and hepatitis C virus (HCV)

- Involves pooling of 16 to 24 individual blood samples and using polymerase chain reaction (PCR) or other amplification techniques to test for HIV and HCV nucleic sequences
- All blood screened for hepatitis B virus (HBV), with tests for HBsAg and anti-HBc
 - Also screened for HCV with anti-HCV testing
 - Risk of transfusion-associated HBV infection approximately 1 in 30,000 to 1 in 250,000 per unit
 - With pooled NAT tests for HCV the window period has decreased
 - The risk of HCV transmission now as low as 1 in 1 million
 - No new case of transfusion-associated HCV detected by Centers for Disease Control and Prevention Sentinel Counties Viral Hepatitis Surveillance System since 1994 in United States
 - Approximately half of blood recipients who contract HBV infection develop symptoms
 - Much smaller percentage requires hospitalization
 - Approximately half of patients contracting posttransfusion HCV infection develop chronic form of disease
 - Many patients eventually develop significant liver dysfunction, including cirrhosis

Human Immunodeficiency Virus

- Risk of HIV transmission from blood transfusion decreased dramatically since early 1980s
- Despite increasing incidence of HIV infection in general population
- Window period from initial infection to development of antibody to the virus poses problem with ability to detect all seropositive donors
- With pooled NAT window period for detection of HIV reduced by 30% to 50%
- Risk of HIV transmission estimated to be as low as 1 in 2 million units

Human T-cell Leukemia Virus

- Blood carries risk of transmission of human T-cell leukemia virus (HTLV) 1 and 2 infection
 - Transmission of virus especially to immunocompromised patients may cause illnesses such as T-cell leukemia, spastic paraparesis, and myelopathy
 - Prompted routine screening of donors in United States since 1989
 - Risk of HTLV 1 and 2 transmission is estimated to be 1 in 641,000 units

Herpesviruses

- Cytomegalovirus (CMV) infection is endemic, so routine screening is not performed in the United States
 - 20% of blood donors infected with CMV by 20 years of age
 - Approximately 70% infected by 70 years of age
 - Infection carried in white blood cells
 - Most patients who encounter problems with CMV are immunocompromised
 - Especially transplant recipients on immunosuppressive drugs
 - Such patients require transfusion with CMV-reduced-risk–leukocyte-reduced or seronegative blood products to avoid transmission of viral infection

- Human herpesvirus 8 causes Kaposi sarcoma and lymphoma in patients with acquired immunodeficiency syndrome (AIDS) and other immunosuppressed states

Graft versus Host Reaction

- Blood transfusion exposes recipient to many cells and proteins from donor
- When immunologically competent lymphocytes introduced into immunocompromised patient
 - Graft versus host reaction can occur
 - Functional donor lymphocytes attack recipient tissues
 - Notably bone marrow, causing aplasia
 - Patients present with fever, rash, nausea, vomiting, diarrhea, liver function test abnormalities, and depressed cell counts
 - Complication fatal in as many as 90% of cases
 - Prevalence of complication in United States not known but thought to be rare
 - Rare cases also reported from familial directed donations and with HLA-matched platelets
 - γ -Irradiation of blood products eliminates this risk

Immunomodulation

- Allogeneic blood transfusion may alter immune response and susceptibility to infection, tumor recurrence, and reactivation of latent viruses
- Known since 1974 that transfusion of PRBCs depresses immune response in patients undergoing renal transplantation
- Unclear to what extent immunosuppressive effects exist in other recipients
- Contradictory evidence exists concerning increased infections in patients given allogeneic blood transfusions
 - Controversy exists regarding exact relationship of blood transfusions to increased recurrence of tumor and poor prognosis
 - Early studies on colorectal cancer showed decreased survival and increased tumor recurrence in heavily transfused patients
 - Blood transfusion may represent a covariable
 - Very ill patients and those undergoing more difficult procedures for more extensive disease more likely to receive blood transfusion

- In light of immunomodulating effects of allogeneic blood transfusion:
 - Leukocyte-depleted transfusions suggested as alternative
 - Reasonable to adopt a policy of blood conservation in perioperative period in absence of clear indications and acute symptoms
 - Leukocyte reduction of blood products thought to decrease risk of immunomodulation

Decision Making in Blood Transfusion

Blood Transfusion in Hemorrhagic Shock

- Goal of resuscitation from shock is prompt restoration of adequate tissue and end-organ perfusion and oxygen transport
- American College of Surgeons Committee on Trauma developed a classification of hemorrhagic shock that permits useful guidelines for resuscitation (Table 120.9)
 - Crystalloid infused at 3:1 ratio for every unit of RBCs administered, and therapy is monitored primarily by hemodynamic response
 - Resuscitation proceeds with use of blood products, depending on patient's response
 - Colloid solutions offer no advantages over crystalloids for resuscitation in critically ill patients
 - Crystalloid solutions considered solutions of choice because:
 - They are less expensive
 - Need not be cross-matched
 - Do not transmit disease
 - Probably result in less fluid accumulation in lung
 - No data indicate using colloid rather than crystalloid solutions prevents pulmonary edema
 - Updated review of randomized controlled trials of albumin resuscitation yielded no suggestion of reduction in mortality when the colloid was used in hypovolemia or in critically ill patients with burns and hypoalbuminemia
- Several crystalloid solutions available for resuscitation
 - Isotonic solutions used to avoid free water overload
 - Lactated Ringer (LR) solution recommended as initial therapy
 - Metabolic alkalosis common after successful resuscitation with this solution and blood products

TABLE 120.9

CLASSES OF HEMORRHAGIC SHOCK

Class of hemorrhage	Blood volume loss	Characteristics	Treatment
I	15% (750 mL)	Vital signs essentially normal	No resuscitation generally needed
II	15%–30% (750–1,500 mL)	Tachycardia, decreased pulse pressure, anxiety, pallor, diaphoresis, acidosis	Crystalloid resuscitation needed; blood transfusion given if no response to fluids (or if response is transient)
III	30%–40% (1,500–2,000 mL)	Hypotension, tachycardia, decreased mental status, oliguria	Blood transfusion generally needed, with crystalloids in 3:1 ratio
IV	>40% (>2,000 mL)	Severe tachycardia and hypotension, lethargy	Massive resuscitation with fluids and blood products needed

Adapted from the American College of Surgeons, Advanced Trauma Life Support.

- Due to lactate in LR solution and citrate in banked blood
- Both converted to bicarbonate in liver
- LR solution contains calcium and if mixed with blood product blood may clot in bag
- Normal (0.9%) saline solution (SS) an acceptable alternative to LR solution
 - Large volumes can produce hyperchloremic metabolic acidosis
 - May complicate use of base deficit in resuscitation
 - 0.9% SS compatible with all blood products
 - Use is sometimes preferred if transfusion a possibility
- Decision to transfuse blood highly dependent on acuity of blood loss
- Patients with acute, massive hemorrhage, trauma or gastrointestinal bleeding, show signs of hemodynamic instability early in presentation
- Diagnosis of hemorrhagic shock and decision to administer blood transfusion not based solely on hypotension, tachycardia, or anemia
- Hypotension does not occur until >30% of blood volume lost
 - Particularly so in children who maintain blood pressure despite severe blood loss
 - Elderly patients on β -blocking agents may not manifest significant tachycardia
 - Hgb levels obtained early in course of hemorrhagic shock do not reflect severity of blood loss
 - Not been enough time for fluid shifts to occur
 - Blood transfusion based on comprehensive assessment of patient, including vital signs and estimation of amount of blood loss
 - As well as clinical and laboratory evaluation of end-organ perfusion
- Acute, massive hemorrhage managed initially with aggressive crystalloid replacement
 - After 2,000 to 3,000 mL of crystalloid solution
 - Blood transfusion initiated in patients who continue to manifest unstable vital signs
 - Should occur concomitantly with expeditious surgical control of bleeding sites
 - Cross-matched blood given as soon as available
 - If needed:
 - Type O negative blood given to women of childbearing age
 - Type O positive blood given to men of all ages and women older than 50 years until cross-matched blood available
 - Correction of coagulopathy and hypothermia paramount
 - “Damage control” surgical approach
 - Aimed at rapid control of bleeding while delaying less urgent procedures utilized
 - Helps reduce transfusion requirements
 - Allows patient to recover more quickly from shock

Blood Transfusion in the Normovolemic Patient

- Anemic patients with normal blood volume are generally hemodynamically intact
- Concerns regarding diminished oxygen-carrying capacity of blood may persist in some patients
- For years standard of care dictated that Hct level of 30% should be maintained

- Rationale included faster recovery and prevention of myocardial ischemia
 - Especially in patients with coronary artery disease
- Recent data indicate lower Hct levels well tolerated
 - Even in patients at risk for myocardial ischemia
 - Has resulted in lowering the trigger level for transfusion
- Many reports demonstrating blood transfusion an independent risk factor for:
 - Worse outcome, including increased mortality, especially in trauma patients
 - Maintaining Hgb at or above 10 g/dL in euvolemic critically ill patients compared to 7 g/dL was not associated with improvement in overall mortality
 - Mortality was significantly lower with conservative strategy (Hgb 7 g/dL) among patients less acutely ill and those younger than 55 years of age
 - In patients with unstable angina and acute MI, maintaining Hgb at or above 10 g/dL remains standard of care
 - Although there are conflicting data on that subject
 - Medicare discharge records showed elderly patients with acute MI had lower mortality if Hct was 30% or higher
 - Another review suggested a higher hematocrit on admission to ICU after coronary artery bypass grafting was associated with higher rate of MI
 - Reports advocating Hct level of 30% in septic patients
 - Reports do not establish blood transfusion to Hct of 30% an independent factor contributing to improved outcome
 - General trend is that of increasingly restrictive strategy of blood transfusion

MINIMIZING TRANSFUSIONS IN THE INTENSIVE CARE UNIT

Immediate Concerns

- Comprehensive strategy of blood conservation should be followed
 - Need to correct anemia should be assessed
 - Sources of ongoing blood loss controlled
 - Measures to enhance erythropoiesis should be entertained

Minimizing Unnecessary Blood Loss

- Significant blood can be lost with repeated phlebotomy in the ICU
 - Particularly significant in children
 - Routine serial “blood draws” should be avoided
 - Obtaining laboratory results only when clinically indicated should be followed
 - Microsampling techniques, including bedside point-of-care testing, limit amount of blood lost with each draw
 - Estimated daily blood loss from phlebotomy at least 40 mL/day
 - Practitioners should carefully consider need for frequent phlebotomy in ICU

Optimization of Red Cell Production

Iron

- Essential for properly functioning Hgb
 - Site of attachment of oxygen molecule
 - Other oxygen-carrying proteins, myoglobin and cytochrome *a-a3*, depend on iron
 - Many enzymes in Krebs cycle contain iron in functional groups
 - In critically ill patient, iron deficiency anemia multifactorial:
 - Poor gastrointestinal absorption
 - Nutrient antagonism
 - Concomitant copper and vitamin A deficiencies
 - Patients with systemic inflammatory response syndrome (SIRS) have circulating cytokines, impairing release of iron stored in reticuloendothelial system
 - Creates situation where total body iron levels are normal
 - But iron not available for incorporation into RBC precursors (functional iron deficiency anemia)
 - Not known whether iron supplementation in critically ill anemic patients beneficial
 - Iron deficiency could be functional, not an absolute reduction in total body iron
 - Iron supplementation implicated with increased risk and severity of infection, since free iron acts as a chelator of free radicals
 - Currently no clear indication to administer supplemental iron to critically ill patients who are anemic

Erythropoietin

- A circulating glycoprotein secreted primarily by kidneys in response to hypoxia
 - Principal action to stimulate production and release of RBCs from bone marrow
 - Commercially available using recombinant DNA technology
 - Approved for use in anemic patients with end-stage renal disease
 - Indications extended to include anemic patients with chronic renal insufficiency, cancer, and AIDS
 - Indications still being expanded
 - Patients undergoing elective surgical procedures typically associated with severe blood loss may benefit from preoperative erythropoietin therapy.
 - Combined with autologous blood transfusion
 - Potential therapeutic value of erythropoietin in anemia of critical illness an area of intense research
 - Erythropoiesis in critically ill patients suppressed for variety of reasons
 - Including renal and hepatic failure
 - Circulating cytokines in SIRS suppress erythropoiesis both by blunting response to and inhibiting production of erythropoietin
 - Erythropoietin formation in patients with multiple organ dysfunction was inadequate to stimulate reticulocytosis in relative erythropoietin deficit
 - High doses of recombinant human erythropoietin therapy stimulated erythropoietic system
 - Evidenced by higher rate of reticulocytosis
 - No increase in Hct or reduction in PRBC transfusion

- Corwin in two randomized controlled trials demonstrated a reduction of up to 19% in PRBC units transfused and a greater increase in Hct in group treated with erythropoietin
 - No differences in morbidity or mortality between two groups
- Georgopoulos showed similar results
 - Additional finding that effects of erythropoietin therapy are dose dependent
- More recently less favorable results
 - Use of erythropoietin alfa did not reduce incidence of PRBC transfusion among critically ill patients
 - Treatment with agent associated with increase in incidence of thrombotic events
 - Second study concluded use of target hemoglobin level of 13.5 g/dL in chronic kidney disease was associated with:
 - Increased risk of complications
 - No improvement in quality of life
- Several reports demonstrated adverse outcomes in cancer patients
 - Adverse effects potentially attributable to erythropoietin therapy include:
 - Hypertension
 - Thrombotic complications
 - Cardiovascular events
 - Tumor progression
 - Increased risk of death
 - FDA issued alert to provide new safety information for erythropoiesis-stimulating agents (ESAs)
 - Alert based on analyses of studies on cancer and orthopedic surgery patients
 - Found to have a higher chance of serious and life-threatening effects and/or death with the use of ESAs
 - FDA recommends using lowest dose possible to achieve a Hgb that
 - Avoids need for transfusion
 - And withholding dose of ESA if Hgb level exceeds 12 g/dL
 - Or rises by 1 g/dL in any 2-week period

Autotransfusion

- Blood lost during surgical procedures can be:
 - Retrieved, spun, washed, and filtered
 - Recovered RBCs then reinfused back into patient
 - Blood from drains such as thoracostomy tubes can be retrieved
 - Collected in containers with citrate solutions to prevent clotting and reinfused
 - Relative contraindications include:
 - Contamination of blood with bacteria, malignant cells, or amniotic or ascitic fluids
- Other strategies of blood conservation include:
 - Preoperative autologous donation and acute normovolemic hemodilution

Hemoglobin-based Oxygen Carriers

- Current investigation focused on hemoglobin-based oxygen carriers (HBOCs)

- Hemoglobin obtained from three sources:
 - Human blood from discarded units of PRBCs
 - Animal blood
 - Recombinant DNA technology

Structure and Function of Normal Human Hemoglobin

- Hgb a large molecule made up of four polypeptide chains:
 - Two α - and two β -chains
 - Molecular weight of 64,450
 - Each chain is conjugated with heme moiety
 - Iron-containing porphyrin derivative to which O_2 attaches, forming oxyhemoglobin
 - When fully saturated each Hgb molecule has four O_2 molecules attached
 - Iron has to be in ferrous state (Fe^{2+}) for oxygen to attach
 - When blood is exposed to various drugs and other oxidizing agents
 - Ferrous iron converted to ferric iron (Fe^{3+})
 - Forming methemoglobin (met-Hgb)
 - Cannot bind oxygen
 - Enzyme within red cells, met-Hgb reductase, converts met-Hb back to Hgb
 - Affinity of Hgb for O_2 increases exponentially as more oxygen molecules attach
 - Hence sigmoid nature of oxygen–Hgb dissociation curve
 - Factors that decrease the affinity of Hgb to oxygen (i.e., making off-loading of oxygen easier) include:
 - Acidosis and 2,3-DPG
- **Vasoactivity:** Most HBOCs have systemic pressor effect, some have same effect on pulmonary circulation
 - Two other pressor mechanisms described:
 - Binding of nitric oxide
 - Stimulation of catecholamine release
 - Effects associated with decreased cardiac output
- **Affinity for Oxygen:** Once released from RBC, Hgb loses its 2,3-DPG
 - Affinity for oxygen increases
 - Causes leftward shift of the oxygen–Hgb dissociation curve
 - Impairing off-loading of oxygen
 - Strategies to decrease the affinity of Hgb for oxygen include:
 - Pyridoxalation
 - Use of bovine Hgb
 - Not clear whether decreasing affinity of Hgb for oxygen is beneficial
 - Higher levels of oxygen at tissue level may trigger autoregulatory response by blood vessel wall
 - With decreased secretion of relaxing factors, resulting in vasoconstriction and decreased flow
- **Oxidation:** Deprived of met-Hgb reductase in red cells, free Hgb at higher risk of being oxidized into met-Hgb
 - Antioxidants such as glutathione available in plasma to serve this function
 - Levels of met-Hgb in patients receiving HBOCs not physiologically significant
- **Effects on the Inflammatory Response:** HBOCs lack ability to stimulate neutrophils and incite inflammatory response with attendant systemic manifestations of multiple organ dysfunction

Characteristics of Cell-free Hemoglobin

- **Dissociation:** When free in plasma, the Hgb tetramer dissociates into two $\alpha\beta$ -dimers
 - Filtered through renal glomeruli and can precipitate in renal tubules
 - Causing obstruction
 - Further compounded by decreased renal blood flow that results from the vasoconstrictive effect of Hgb
 - Technologies developed to produce large stable Hgb polymers by cross-linking Hgb molecules
 - Most commonly used cross-linking reagent is glutaraldehyde
 - Results in formation of polymers of varying sizes that do not filter through glomeruli
 - Another strategy to stabilize Hgb was intramolecular cross-linking
 - Cross-link was between α -chains of same molecule so that neither polymerization nor subunit dissociation occurred
 - Product was abandoned due to intense vasoconstrictive features
- **Viscosity:** Lower viscosity of Hgb solutions initially thought advantageous
 - Provided less systemic vascular resistance
 - Deeper insight into physiology of vascular endothelium revealed that reduced shear stresses on blood vessel wall were associated with decreased secretion of relaxing factors such as prostacyclin and endothelin
 - With net vasoconstrictive effect
 - Resulting decrease in blood flow antagonizes oxygen delivery function of Hgb

Clinical Trials of Hemoglobin-Based Oxygen Carriers

- Most widely studied HBOC in clinical practice is human polymerized Hgb product (PolyHeme, Northfield Laboratories, Evanston, IL)
 - First randomized trial in acute trauma and emergency surgery published in 1998 showing that PolyHeme maintained total hemoglobin *in lieu* of RBCs despite marked fall in RBC Hgb
 - Reduced use of blood transfusion
 - Study concluded that PolyHeme appears to be a clinically useful blood substitute
 - Phase III trial involving 720 patients from 32 level I trauma centers recently completed
 - Trial randomized trauma patients with evidence of hemorrhagic shock at scene to either normal saline or PolyHeme
 - Treatment started in field and continued for up to 12 hours after injury
 - Primary end point was survival at 30 days
 - Preliminary results showed no statistically significant difference in survival
 - PolyHeme may be useful when blood is needed but not available

REFUSAL OF BLOOD TRANSFUSION

- Critically ill patients with transfusion preferences present a challenging management problem

- Jehovah's Witnesses' refusal of blood and blood products part of religious beliefs
 - Genesis 9:4–5, Leviticus 17:10–12
- Honoring these beliefs requires modification of medical management strategies
- Care of these patients requires early identification of transfusion preferences
- All patients admitted to critical care setting should have treatment preferences (including blood transfusion) discussed with them or legal representative as soon as possible
- Transfusion may be emergent in some situations but in most circumstances should be able to discuss the risks, benefits, and potential complications of transfusion of various blood products with patient or representative
- Discussion with patient and family members includes detailed explanation of each product
 - Origin and technical aspects of products may affect acceptance
 - In case of Jehovah's Witnesses, or other groups with religious preferences, assistance from church representative or elder may be helpful to family and physician
- Survival at lower levels of Hgb (>3 g/dL) reported
 - Mortality exceeds 50% when Hgb below 3 g/dL
 - Implementation of blood conservation strategies, hormonal stimulation, and use of RBC substitutes as available are options in the management of these patients
 - Use of high-dose erythropoietin (40,000 units subcutaneously every other day) and supplemental iron provide accelerated erythropoiesis under extreme circumstances

TABLE 120.10**MANAGEMENT STRATEGIES FOR JEHOVAH'S WITNESSES WITH SEVERE ANEMIA**

- **Blood conservation**
 - No routine blood draws
 - Consequential blood tests only
 - Use of capillary tubes for arterial blood gas analysis
 - Pediatric-size tubes for other tests
 - Decisive surgical interventions in cases of bleeding
 - Intraoperative and peri-procedure blood conservation
- **Hemostasis**
- **Autologous transfusion (cell salvage device)**
- **Normovolemic hemodilution**
- **Maximization of oxygen delivery**
 - Maintain high oxygen saturation
 - Minimize oxygen demand
- **Sedation**
- **Mechanical ventilation**
- **Neuromuscular blockade**
- **Allow permissive hypercapnia/metabolic acidosis**
- **Hormonal stimulation**
 - High-dose recombinant erythropoietin
 - Iron supplementation
- **Red cell substitutes (as they become available)**

- Table 120.10 lists potential strategies useful in management of Jehovah's Witnesses and others requesting blood transfusion not be administered
- Some of these strategies are considered for all patients in critical care setting to minimize the need for transfusion

CHAPTER 121 ■ HEMATOLOGIC CONDITIONS IN THE ICU

HEMATOPOIESIS

Cellular Components

- Hematopoiesis a polyclonal process responsible for production and maintenance of blood and immune cells
 - Large numbers of blood and immune cells traced to pool of hematopoietic stem cells (HSCs) from which these clones originated
 - Two hallmarks of an HSC:
 - It can renew itself
 - It can produce cells that give rise to all the different types of blood cells
 - These cells also can mobilize out of bone marrow into circulating blood and can undergo programmed cell death

- Called *apoptosis*—process by which detrimental or unneeded cells undergo programmed self-destruction to maintain homeostasis
- Most primitive stem cell in bone marrow responsible for:
 - Production of all lymphoid (T, B, and natural killer lymphocytes), myeloid (granulocytes, monocytes), erythroid, and megakaryocytic (platelets) cell lineages
 - While maintaining sufficient numbers of pluripotent stem cells to sustain hematopoiesis throughout adult life
 - These cells found in small population of cells characterized by the surface expression of CD34 molecule and by lack of markers of differentiation
- In course of producing mature, circulating blood cell
- Original single hematopoietic stem cell undergoes between 17 and 19.5 divisions

- Providing net output between approximately 170,000 and 720,000 blood cells
- Wide array of environmental factors regulate quantity and behavior of stem cells including:
 - Cytokines and chemokines
 - Extracellular matrix components
 - Hematopoietic and nonhematopoietic cells such as natural killer (NK) cells, T cells, macrophages, fibroblasts, osteoblasts, adipocytes, and perhaps even neurons

Humoral Mediators

- Production of specific type of differentiated blood cell from stem cell thought to occur randomly
- Cytokines promote proliferation and survival of certain types of cells
 - But do not affect which cell type is produced from stem cell
- As progenitors differentiate phenotype-specific receptors evolve so that only certain cytokines affect these new and more mature cells
- Others maintain stem cell self-renewal and expansion
- Cytokines made and secreted mainly by helper T lymphocytes and macrophages and other stroma cells such as fibroblasts and endothelial cells
- Some cytokines have been synthesized and are U.S. Food and Drug Administration–approved for clinical use:
 - Erythropoietin (epoetin alfa, or long-acting darbepoetin alfa) for erythrocyte production
 - Granulocyte colony-stimulating factor (G-CSF, filgrastim or long-acting pegfilgrastim), and granulocyte–macrophage colony-stimulating factor (GM-CSF, sargramostim) for neutrophil production
 - Stem cell harvest for transplantation and interleukin-11 (IL-11; oprelvekin) for stimulation of megakaryocytes and production of platelets
- *Cytokine*, a general term, more specific terms include:
 - *Lymphokine*, for cytokines made by lymphocytes
 - *Monokine*, for cytokines made by monocytes
 - *Chemokine*, for cytokines with chemotactic activities
 - *Interleukin*, cytokine made by one leukocyte and acting on other leukocytes
- Cytokines act on target cells by binding specific membrane receptors through which they mediate their effect on inflammation, immunity, and hematopoiesis
- Responses to cytokines include:
 - Increasing or decreasing expression of membrane proteins—including cytokine receptors, proliferation, and secretion of effector molecules
 - Cytokines in clinical use today mainly interferon- α and interferon- γ
- Cytokines important in critical care medicine, especially those proinflammatory cytokines released by monocytes or macrophages in response to infectious and noninfectious inflammation
 - Release results in whole body inflammation such as that seen in SIRS
 - These patients also undergo an anti-inflammatory phase
 - Includes release of cytokines with opposing—anti-inflammatory—biologic effects or naturally occurring cytokine antagonists, such as interleukin-1 receptor

antagonist and tumor necrosis factor- α soluble receptors p55 and p75

DECREASED BLOOD COUNTS

Anemias

- Hemoglobin concentration <12 g/dL
 - Present in 95% of patients in the intensive care unit (ICU)
 - About one-third of those having upon admission concentration of <10 g/dL
 - In the assessment attention paid to:
 - Time of onset
 - Patient's ethnic origin
 - Concurrent illness
 - Procedures patient has undergone
 - Drugs patient is receiving
 - History of transfusions
- One approach to classify anemia into two major categories:
 - Anemia resulting from underproduction
 - Anemia due to increased destruction of red blood cells (RBCs) (Table 121.1)
- Obtain diagnostic tests prior to transfusions, including:
 - Complete blood count

TABLE 121.1

ANEMIA CLASSIFICATION

Anemias Secondary to Marrow Underproduction

- **Decreased erythropoietin production**
 - Renal disease
 - Endocrine deficiency
 - Starvation
- **Inadequate response to erythropoietin**
 - Iron deficiency
 - B₁₂ deficiency
 - Folic acid deficiency
 - Anemia of chronic disease
 - Marrow infiltration
 - Sideroblastic anemia
 - Myelodysplastic syndrome
- **Marrow failure**
 - Congenital dyserythropoietic anemia
 - Aplastic anemia
 - Pure red cell aplasia
 - Toxic marrow damage

Anemias Secondary to Increased Destruction

- **Acquired**
 - Immune-mediated hemolytic anemia
 - Paroxysmal nocturnal hemoglobinuria
 - Hemolytic anemia due to red cell fragmentation (TTP, DIC)
 - Hemolytic anemia due to chemical or physical agents
 - Infections
 - Acquired hemoglobinopathies (methemoglobinemia)
- **Hereditary**
 - Congenital hemoglobinopathies (sickle cell disease)
 - Enzyme deficiency (G6PD, pyruvate kinase)
 - Red cell membrane defects (spherocytosis, elliptocytosis)

TTP, thrombotic thrombocytopenic purpura; DIC, disseminated intravascular coagulation.

- Including hematocrit, hemoglobin, mean corpuscular volume (MCV) and hemoglobin (MCH)
- Reticulocyte count
- Stained blood smear
- Additionally serum bilirubin and lactic acid dehydrogenase useful to determine presence of hemolysis
- If immune hemolysis is suspected:
 - Direct Coombs test should be ordered
 - Indirect Coombs test done routinely with cross-match request to blood bank
- If hemoglobinopathy suspected:
 - Hemoglobin electrophoresis obtained before transfusion
- Does patient require transfusion with packed RBC (PRBCs)?
 - Hemoglobin (Hgb) of 10 g/dL/hematocrit (Hct) of 30% thought desirable
 - Especially those undergoing surgery and/or with critical illness
 - The main reason for high transfusion rates in ICU patients
 - Replaced by a more physiologic approach
 - Patient's intravascular volume and tissue oxygen needs considered
 - Restrictive transfusion policy:
 - Hgb maintained between 7 and 9 g/dL effective
 - Yields decreased death rates compared to liberal strategy
 - Young traumatized patients Hgb allowed to drift to 5 g/dL
 - As long as no signs of DO₂ deficit such as elevated lactate levels, an unacceptable heart rate, or other symptoms
 - These patients most often started on recombinant erythropoietin and have iron stores repleted to keep from undergoing transfusion
 - Patients with acute myocardial infarction or unstable angina and some cancer patients may benefit from higher Hgb level
 - Patients with Hgb ≥ 10 g/dL unlikely to benefit from blood transfusion

Anemia in Critical Illness

- Anemia with Hgb ≤ 8.5 g/dL the most frequent type in the ICU
 - More than 50% of these patients receive RBC transfusions during ICU stay
 - As do more than 85% of patients with ICU length of stay >7 days
 - Studies showed that number of RBC transfusions independently associated with longer ICU stay and increase in mortality
 - Vast majority of critically ill patients have anemia on admission to ICU
 - Most common indication for RBC transfusion in ICU was treatment of anemia
 - Transfusion trigger in all studies Hgb about 8.5 g/dL
 - RBC transfusions increased in patients with prolonged ICU length of stay and increased age
- Possible mechanisms involved in anemia of acute critically ill patients include:
 - Blunted erythropoietin (EPO) response to anemia

- Blood concentrations of EPO inappropriately low in these patients
- Suppression of erythropoiesis by proinflammatory cytokines
- Possible blood loss from frequent phlebotomies
- Blood loss from gastrointestinal bleeding as a result of gastric tubes, stress-induced mucosal ulcerations, acute renal failure, and frequent coagulation problems in ICU patients
- Shares characteristics with anemia of chronic inflammation such as high ferritin concentrations and low-to-normal transferrin saturation with functional iron deficiency
- Appears inflammatory cytokine IL-6 induces production of hepcidin
 - Iron-regulatory hormone may be responsible for hypoferremia and suppressed erythropoiesis
- Approach to treatment of this type of anemia includes:
 - Measures to reduce blood loss
 - Restrictive blood transfusion policy
 - Possibly the use of recombinant human EPO (rh-EPO)
 - Subcutaneous administration of rh-EPO at 40,000 units weekly
 - Starting between days 3 and 7 of ICU stay
 - Resulted in significant reduction in RBC transfusions and a higher hemoglobin level
- Iron is locked up in the phagocytic system and unavailable
 - Administration of intravenous (IV) iron, together with rh-EPO, may result in an enhanced rh-EPO effect
 - Only about 10% of oral iron bioavailable, so not appropriate in ICU patients
 - Have been anaphylactoid reactions reported with iron dextran
 - Iron gluconate the preferred formulation
 - Dose is 125 mg diluted in 100 mL saline over 1-hour infusion
 - To a total cumulative dose of 1,000 mg

Autoimmune Hemolytic Anemia (AIHA)

- A patient critically ill from AIHA presents with:
 - Signs and symptoms of normovolemic anemia
 - Unless massive hemolysis associated with hypotension, significant hemoglobinuria, and acute renal failure
 - Variable levels of jaundice may be present in nonmassive AIHA
- Initial laboratory data may show:
 - Elevated reticulocyte index (>2) identifying mechanism of anemia as hemolytic
 - Elevated indirect bilirubinemia and lactate dehydrogenase
 - Blood smear shows increased numbers of diffusely basophilic red cells
 - Reflecting increased reticulocytes
 - Variable numbers of microspherocytes and fragmented cells, indicative of hemolysis
 - Urine may be discolored red, brown, or black if sufficient intravascular hemolysis to produce hemoglobinuria
 - Positive result on direct antiglobulin (Coombs) test
 - Indicates immunoglobulin or complement is on surface of circulating RBCs
 - Identifies immune etiology of hemolysis
 - Absent recent transfusion, the diagnosis of AIHA is confirmed

- Information may become available when blood bank attempts to cross-match patient's blood for transfusion
- Important to determine, by history and appropriate laboratory studies:
 - Whether hemolysis related to drug patient is taking
 - Whether caused by warm-reacting (usually immunoglobulin [Ig] G) or cold-reacting (usually IgM) antibodies (Ab)
 - Mechanisms whereby drugs produce immune hemolysis not absolutely clear
 - Evidence suggests alteration of RBC surface antigens by drug and production of antibodies that lead to hemolysis
 - Underlying diseases associated with AIHA include:
 - Infections, such as infectious mononucleosis and pneumonia caused by *Mycoplasma pneumonia*
 - Collagen vascular diseases, especially systemic lupus erythematosus
 - Lymphoproliferative disorders such as chronic lymphocytic leukemia
- Mainstay of treatment of AIHA caused by warm-reacting antibodies is corticosteroids:
 - Usually given in dosages equivalent to 60 to 80 mg/day of prednisone
 - In nonresponders splenectomy, high-dose intravenous gamma globulin, rituximab chimeric anti-CD20 antibody, alemtuzumab humanized anti-CD52 antibody, or treatment with other immunosuppressive drugs may be useful
- Steroids usually ineffective in AIHA caused by cold-reactive antibodies (cold agglutinin disease), but responses observed using larger doses
 - Patients with cold agglutinins may have symptoms related to impaired blood flow in acral parts where blood temperature low enough to permit agglutination of RBCs by antibodies
 - Warming usually prevents or alleviates such symptoms
 - Rarely, plasmapheresis needed to reduce concentration of offending IgM Ab
 - If drug-induced immune hemolysis, discontinuation usually the only treatment needed
- When transfusion considered
 - May be impossible to find compatible RBCs by usual cross-matching procedures
 - Transfused cells may be subject to rapid antibody-mediated destruction
 - Patient must not be allowed to die because of undue caution regarding transfusion of incompatible RBCs
 - Key to optimal care is close communication between the intensivist and blood bank physician
 - When transfused, patient must be observed closely for signs of accelerated hemolysis, such as visible hemoglobin in the plasma or urine
- Certain special considerations for transfusion of patients with cold-reacting Ab:
 - Administered blood should be warmed to body temperature
 - Transfusion of plasma, which contains complement, should be avoided because hemolysis is complement mediated and may be limited by depletion of complement *in vivo*
 - In massive hemolysis, therapeutic efforts directed at maintenance of blood pressure, renal blood flow, and urinary output
 - IV fluids and diuretics such as furosemide used to maintain a urine flow of 100 mL/hour

Hemolytic Anemia from G6PD Deficiency

- RBC glucose-6-phosphate dehydrogenase (G6PD) deficiency an X-linked recessive disorder
 - Affects various population groups around the world
 - In United States African Americans most often affected
 - Gene frequency of about 11%
 - Have G6PD A-variant of the enzyme and a mild to moderate deficiency
 - Study by U.S. Army found 2.5% of males and 1.6% of females were deficient
 - Highest rates of G6PD deficiency in:
 - African American males (12.2%) and females (4.1%)
 - Asian males (4.3%)
 - RBC G6PD levels in affected men are 8% to 20% of normal
 - Clinically significant hemolysis occurs when RBCs subjected to oxidative metabolic challenge
 - May occur with exposure to certain drugs or with certain illnesses
 - Drugs include some sulfonamides, nitrofurantoin, and antimalarials such as primaquine
 - Illnesses most likely to trigger hemolysis are acute infections
 - Infectious hepatitis, in particular, associated with severe hemolytic episodes in G6PD-deficient patients
 - Hemolysis, sudden and massive, usually apparent 1 to 3 days after inciting stress
 - Hemoglobinemia and hemoglobinuria may occur
 - Blood smear shows polychromatophilia within a few days, reflecting developing reticulocytosis
 - Early in course of hemolytic episode Heinz bodies may be identified
 - Precipitates of oxidatively denatured hemoglobin
 - Useful diagnostic clue should be sought if G6PD deficiency is suspected
 - Absence of Heinz bodies does not exclude diagnosis
 - RBC enzyme deficiency readily detected by laboratory assay when patient is in stable state, more difficult during hemolytic episode
 - Because the enzyme deficiency greatest in oldest red cells
 - These are the first destroyed in hemolytic episode
 - As replaced by newly produced young cells, overall RBC enzyme level may rise to the normal range
 - Tends to ameliorate the hemolysis with time
 - If diagnosis suspected, potentially offending drugs should be stopped
 - Supportive care usually all that is necessary
 - Deficiency an X-linked trait, female heterozygotes may have hemolytic episodes

Hemolytic Anemia from Red Cell Injury in the Circulation

- Fragmentation and destruction of RBC in circulation may result from increased shear stresses caused by turbulent blood flow
- Two major categories of disease in which this hemolysis occurs are:
 - Malfunctioning intravascular prosthetic devices: heart valves, vascular grafts, and shunts
 - Disorders affecting blood vessels that result in microangiopathic hemolytic disease, such as disseminated intravascular coagulation or thrombotic microangiopathy (TMA)

- Encompasses spectrum of thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome
- Hemolysis is intravascular, hemoglobinemia and hemoglobinuria may be present
 - Characteristically blood smear shows RBC fragmentation producing micropoikilocytes (schistocytes)
 - TMA patients also have thrombocytopenia, fever, and possibly neurologic and renal involvement
- Specific treatment directed at underlying disorder
- Supportive measures include:
 - Blood transfusion and hydration to ensure good urine flow
 - Badly malfunctioning prosthesis, such as an artificial heart valve, may require replacement
 - Treatment of TMA with plasma administration, either infusion or plasmapheresis, the only effective therapy

Sickle Cell Anemia

- Sickle cell Hgb (Hgb S) the result of a single nucleotide mutation in the sixth codon of the β globin gene (β^s)
- Heterozygous inheritance does not usually cause disease or symptoms—sickle trait
- Homozygous inheritance or compound heterozygous inheritance with another β globin gene results in disease (Table 121.2)
- Clinical symptoms of sickle cell disease (SCD) affect multiple organs and may vary widely among patients
- Chief among clinical features are episodes of severe pain (crises)
 - In chest, back, abdomen, or extremities
 - Acute chest syndrome, frequent and sometimes fatal complication
 - Affects more than 40% of all patients with SCD
 - Can lead to:
 - Acute and chronic respiratory insufficiency,
 - Including pulmonary hypertension
 - Cardinal features are fever, pleuritic chest pain, referred abdominal pain, cough, lung infiltrates, and hypoxia
 - Other complications of SCD include:
 - Recurrent strokes in young adults
 - Parvovirus B19-induced aplastic crisis
 - Hyperbilirubinemia from cholestatic syndrome or cholecystitis
 - Liver disease
 - Splenic infarctions
 - Autospplenectomy with increased risk of fulminant septicemia caused by encapsulated organisms such as *Streptococcus pneumoniae* and *Haemophilus influenzae*
 - Hematuria
 - Priapism
 - Bone infarctions with the risk of avascular necrosis, osteomyelitis, and other musculoskeletal manifestations
 - Leg ulcers
 - Spontaneous abortions
 - Many patients survive into fifth and sixth decades in industrialized countries
- Goals of SCD treatment are:
 - To relieve symptoms of complications

TABLE 121.2

CLINICAL AND HEMATOLOGIC FINDINGS IN THE COMMON VARIANTS OF SICKLE CELL DISEASE AFTER THE AGE OF 5 YEARS

Disease group	Hemoglobin electrophoresis				Hematologic values				
	Clinical severity	S (%)	F (%)	A ₂ (%)	A (%)	Hb g/dL	Retic (%)	MCV (fl)	RBC morphology
SS	Usually marked	>90	<10	<3.5	0	6–11	5–20	>80	Sickle cells, NRBC, normochromia, anisocytosis, poikilocytosis, target cells, Howell-Jolly bodies
S β^o Thal	Marked to moderate	>80	<20	>3.5	0	6–10	5–20	<80	Sickle cells, NRBC, hypochromia, microcytosis, anisocytosis, poikilocytosis, target cells
S β^+ Thal	Mild to moderate	>60	<20	>3.5	10–30	9–12	5–10	<75	No sickle cells, hypochromia, microcytosis, anisocytosis, poikilocytosis, target cells
SC	Mild to moderate	50	<5	^a	0	10–15	5–10	75–95	“Fat” sickle cells, anisocytosis, poikilocytosis, target cells
S HPFH	Asymptomatic	<70	>30	<2.5	0	12–14	1–2	<80	No sickle cells, anisocytosis, poikilocytosis, rare target cells

MCV, mean corpuscular volume; RBC, red blood cell; NRBC, nucleated red blood cells; Hb, hemoglobin; S, Hb S; F, Hb F; A₂, Hb A₂; A, Hb A.

^a 50 percent Hb C.

Hematologic values are approximate. There is tremendous variability between disease groups and between individual patients of the same group, particularly regarding clinical severity.

For findings in younger children, see Brown AK, Sleeper LA, Miller ST, et al. Reference values and hematological changes from birth to five years in patients with sickle cell disease. *Arch Pediatr Adolesc.* 1994;48:796–804.

Adapted from NIH Publication No. 96–2117.

- To prevent complications using new treatments targeting disease mechanisms
- Treatment of painful crisis is supportive
 - Dehydration, acidosis, infection, and hypoxemia promote red cell sickling and should be prevented or corrected
 - Adequate relief of pain usually requires parenteral administration of opioid analgesics at frequent fixed intervals
 - Analgesics should be used without worrying about addiction or side effects of opiates
 - Patients can be given oral analgesics to take at home
 - Oxygen is often administered in sickle cell crisis; benefits uncertain
 - Antibiotics covering major pulmonary pathogens should be administered in acute chest syndrome
 - Transfusions of blood:
 - No clear evidence transfusion therapy shortens simple painful crisis; thus not a treatment for uncomplicated painful crisis
 - Urgent transfusions are needed when:
 - There is severe sudden drop in hemoglobin, especially in children in whom splenic sequestration or aplastic crises present in this manner
 - Severe acute chest syndrome with hypoxia
 - Chronic RBC transfusions shown to prevent strokes in patients with SCD
 - Optimal duration of transfusion is unknown
 - Risks of transfusions must be weighed against the benefits
 - Alloimmunization
 - Infections
 - Iron overload
 - For patients undergoing general anesthesia, preoperative transfusion to hematocrit above 30% reduced postoperative complications
 - Leukocyte-depleted RBC phenotypically matched for antigens most frequently associated with immune response are preferred
 - Exchange transfusion most rapid method to reduce Hgb S concentration to <30% in urgent situations
 - Such as stroke and severe acute chest syndrome, and in patients with striking cholestatic syndrome and signs of liver failure
 - Preventive treatments should include:
 - Early vaccinations against *S. pneumoniae* and *H. influenzae*
 - Prophylactic penicillin in children until age of 5 years
 - Folic acid (1 mg daily) to prevent megaloblastic erythropoiesis
 - Hydroxyurea treatment to prevent complications
 - Shown to reduce pain episodes, acute chest syndrome, blood transfusions, and hospitalizations
 - Improvements noted correlate to increases in Hgb F levels and a decrease in granulocytes, monocytes, and reticulocytes
 - Reserved for SCD patients with severe complications

Specific Clinical Problems of SCD

- If abdominal symptoms present possibilities of cholecystitis and complications of cholelithiasis must be considered
- Rarely, bone marrow infarction may be extensive, producing syndrome of fat embolism
- Manifested by severe bone pain, fever, neurologic abnormalities, and respiratory distress
- May be fatal
- Treatment by exchange transfusion can be life saving
- May be a cause of some cases of acute chest syndrome
- Hematuria occurs as complication SCD, including sickle cell trait, and may be severe
 - Usually results from sickling and vaso-occlusion in the renal medulla, but other causes unrelated to SCD must be excluded
 - Treatment with hydration and, perhaps, urinary alkalinization often sufficient for this self-limited complication
 - Priapism, a frequent and painful complication of SCD
 - Arises from vaso-occlusion that produces congestion and sickling in corpora cavernosa
 - May resolve spontaneously, and initial conservative treatment with analgesics, hydration, and alkalinization is appropriate
 - Exchange transfusion and various surgical procedures successful in terminating priapism

Aplastic Crisis in Hemolytic Anemia

- Sudden intensification of anemia in hemolytic disease resulting from a precipitous reduction in rate of RBC production
- May occur in course of any hemolytic disease but most commonly reported in congenital hemolytic disorders:
 - Hereditary spherocytosis
 - Sickle cell anemia
- Most common in children but also occurs in adults
- Patients characteristically have:
 - Fever
 - Anorexia
 - Nausea and vomiting
 - Abdominal pain and headache common
- Anemia usually severe and may be life-threatening
 - Mild leukopenia and thrombocytopenia often present
 - Aplastic nature of anemia demonstrated by extremely low reticulocyte count and marked reduction in erythroid precursors in bone marrow
 - Episode self-limited, and recovery usually begins by 2 weeks
 - In recovery phase a return of vigorous erythropoiesis
 - Often outpouring of nucleated RBC and reticulocytes
 - Frequently accompanied by leukocytosis and immature white blood cells (WBCs)
 - Convincing evidence that parvovirus B19 the cause of most aplastic crises
- Prompt recognition of syndrome important because of suddenness and severity of anemia
 - Low reticulocyte count in patient with hemolytic disease usually main clue to diagnosis
 - Treatment is via RBC transfusion
 - Volume given sufficient to alleviate signs and symptoms of inadequate tissue DO₂

LEUKOPENIAS

- Refers to total WBC count of <4,000 cells/ μ L
- Granulocytopenia/neutropenia refers to circulating granulocyte count below 1,500 cells/ μ L

- Clinical importance of granulocytopenia relates to increased risk of bacterial infection
- If the absolute neutrophil count ≤ 500 cells/ μ L bacterial infection the rule
- Agranulocytosis implies severe neutropenia or a complete absence of granulocytes
- Three patient groups most pertinent to critical care situations:
 - Patients with neutropenia from primary bone marrow diseases or cytotoxic treatment
 - Patients in whom neutropenia exists alone or in combination with other cytopenias as an aplastic process
 - Patients with neutropenia or agranulocytosis caused by immunologic mechanisms

Primary Bone Marrow (BM) Diseases and Cytotoxic Treatment

- Largest and most frequent entity that causes neutropenia
 - BM diseases such as leukemias, myelodysplastic syndrome, and marrow fibrosis frequently present with neutropenia
 - Chemotherapy-induced neutropenia common complication of treatment of cancer
 - Risk of life-threatening infections increases with:
 - Increased severity of neutropenia and its duration
 - Increasing patient age
 - Coexistence of other severe illnesses
 - These patients end up in the ICU due to a rapid onset of septic shock
 - Neutropenic fever an indication for hospitalization and institution of IV wide-spectrum antibiotics
 - Before antibiotics, cultures of blood, sputum, and urine obtained
 - Other sites cultured as indicated in individual patients
 - Patients should have chest radiographs taken
 - Common effects of bacterial infections
 - Purulent sputum in pneumonia
 - Pyuria in urinary tract infection
 - Abscess formation
 - Usually absent because of lack of granulocytes
 - Choice of antibiotic regimen should take into account findings in individual patient that suggest specific site of infection and any knowledge of patterns of infection in a given institution
 - If cultures are positive antibiotic treatment should be adjusted accordingly
 - If cultures are negative empirical therapy continued if patient remains neutropenic and until counts recover
 - If fever continues and patient's condition deteriorates with persistent neutropenia:
 - Appropriate to prescribe empirical antifungal agent, such as amphotericin B
 - Patients screened by obtaining a computed tomography (CT) scan of sinuses, chest, abdomen, and pelvis for possible foci of invasive fungal infections
 - Galactomannan antigen test for aspergillus should be done routinely on blood and sputum (usually bronchoalveolar lavage) of immunosuppressed patients with neutropenia
 - If patients have a central venous line (CVL), fungal and bacterial blood cultures obtained
- Removal of CVL considered if blood cultures are positive
- Routine therapeutic use of colony-stimulating factors (G-CSF, GM-CSF) not recommended by American Society of Clinical Oncology (ASCO)
 - Should be considered in patients at high risk for infection-related complications or who have prognostic factors that are predictive of poor clinical outcomes, including:
 - Expected prolonged (>10 days) and profound ($<0.1 \times 10^3$ cells/ μ L) neutropenia
 - Age older than 65 years
 - Uncontrolled primary disease, pneumonia, hypotension, multiorgan dysfunction, invasive fungal infection, or being hospitalized at the time of development of the fever
 - CSFs recommended for primary and secondary prophylaxis used to prevent chemotherapy-induced neutropenia
 - Respiratory status deterioration or acute respiratory distress syndrome can develop during neutropenia recovery with or without the use of G-CSF
 - Could be related to release of inflammatory cytokines by resident alveolar neutrophils and macrophages
 - Mortality as high as 62% in these patients
 - Immediate evaluation by bronchoscopy to rule out infection and early use of high-dose steroids could be critical for their survival

Bone Marrow Aplasia

- Neutropenia part of pancytopenia commonly present in aplastic anemia
- Etiologies:
 - Autoimmune basis
 - Drug or chemical exposure may be suspected
 - No tests are available to prove an association in individual cases
 - Benzene and derivatives potentially toxic to bone marrow
 - Other chemicals, dichlorodiphenyltrichloroethane (DDT), other insecticides, suspect
 - Toluene exposure in glue sniffers may be associated
 - Many medications linked with aplastic anemia
 - Occurs as idiosyncratic reaction in small percentage of patients exposed to drug:
 - Chloramphenicol
 - Phenylbutazone
 - Indomethacin
 - Diphenylhydantoin
 - Sulfonamides
 - Gold preparations
 - In 50% of cases of aplastic anemia, no cause found or suspected
- Principles of treating infectious complications resulting from neutropenia in aplastic states the same as those outlined earlier for neutropenia in malignant diseases
- Allogeneic bone marrow transplantation in suitable patients
- Immunosuppressive therapy including antithymocyte globulin
- Other supportive care measures
 - Antibiotic prophylaxis
 - Colony-stimulating factors

Immune and Drug-Related Granulocytopenia

- Neutropenia in adults often occurs as:
 - Isolated finding
 - In association with autoimmune disease:
 - Rheumatoid arthritis
 - Systemic lupus erythematosus
 - Other similar conditions
 - Evaluation includes:
 - Peripheral blood smear to seek out large granular lymphocytes (LGL)
 - Measurement of antinuclear antibodies, rheumatoid factor, and other autoantibodies
 - Possibly bone marrow examination
 - Chronic neutropenia, idiopathic or autoimmune, usually does not require treatment
 - Patients with absolute neutrophil count <500 cells/ μ L prone to develop recurrent fevers and infections
 - Antibiotics and G-CSF may improve neutrophil count during infection
 - Patients with LGL syndrome may not respond well to G-CSF
 - May require immunosuppressive therapy, such as methotrexate or cyclosporine, alone or with G-CSF
 - Chronic neutropenia in association with rheumatoid arthritis, or Felty syndrome
 - Usually seen in severe cases with elevated rheumatoid factor
 - Patients who have recurrent fevers and infection require treatment similar to patients with LGL syndrome
 - Splenectomy should be considered in refractory cases
 - Drug-induced agranulocytosis a serious medical problem
 - Occurs in 1% to 3% of patients treated with certain medications
 - Characteristic clinical syndrome includes:
 - High fever
 - Chills
 - Severe sore throat (agranulocytic angina) caused by bacterial infection
 - Oral and pharyngeal ulcers, necrotizing tonsillitis, pharyngeal abscesses, and bacteremia may occur
 - Blood demonstrates virtual absence of granulocytes
 - Bone marrow may show absence of all granulocyte precursors or only the mature cells
 - May superficially resemble acute leukemia, or state of maturation arrest
 - Serial blood counts recommended for patients on some drugs:
 - Phenothiazines
 - Clozapine
 - Sulfasalazine
 - Antithyroid drugs
 - Management includes prompt withdrawal of all potentially offending drugs and use of broad-spectrum antibiotics
 - Bone marrow examination not usually indicated
 - Time to recovery may be proportional to severity but usually within about a week after withdrawal of the offending drug

THROMBOCYTOPENIAS

- Thrombocytopenia a common laboratory abnormality in ICU patients associated with adverse outcomes
 - Defined as platelet count $<150 \times 10^3$ cells/ μ L
 - Incidence reported to be 23% to 41.3%, with mortality rates up to 54%
 - Incidence of more severe thrombocytopenia lower, about 10% to 17%
 - Associated with greater mortality
 - Defined as fewer than 50×10^3 cells/ μ L
- Systematic evaluation of thrombocytopenia essential to identification and management of causes (Table 121.3)
 - Sepsis the most common cause
 - Accounts for $>48\%$ of thrombocytopenia cases in ICU
 - More than 25% of ICU patients have more than one cause
 - Drug-induced thrombocytopenia a diagnostic challenge
 - Many medications can cause thrombocytopenia
 - Critically ill patients often receive multiple drugs
 - Heparin is the most common cause of drug-induced thrombocytopenia due to immune mechanisms
 - Steps in diagnosis of true thrombocytopenia:
 - Mechanism
 - Increased destruction
 - Decreased production
 - Sequestration
 - Presence of large platelets on blood smear or by mean platelet volume (MPV) suggests active thrombopoiesis
 - Examination of bone marrow for megakaryocytes often necessary to distinguish between increased destruction (presence of megakaryocytes) and decreased production (absence of megakaryocytes)
 - Splenomegaly raises possibility of sequestration
 - Other laboratory tests not necessary to evaluate thrombocytopenia itself
 - Also the possibility of platelet clumping induced by:
 - Commonly used anticoagulant EDTA (ethylenediaminetetraacetic acid)
 - Platelet cold agglutinins
 - Partial clotting of blood sample
 - Platelet satellitosis, a disorder in which platelets cluster around white blood cells
 - When pseudothrombocytopenia is suspected, examining the peripheral blood smear and close communication with the laboratory necessary
 - Treatment of thrombocytopenia depends on cause

TABLE 121.3

POTENTIAL CAUSES OF THROMBOCYTOPENIA

Sepsis, infections
 Disseminated intravascular coagulation
 Perioperative and postresuscitation hemodilution
 Immune thrombocytopenias
 Drug-induced thrombocytopenias
 Liver disease/hypersplenism
 Massive transfusion
 Primary marrow disorder
 Antiphospholipid antibody syndrome/lupus anticoagulant
 Intravascular devices

- General principles of platelet transfusion are outlined:
 - Thrombocytopenia caused by destruction or sequestration of patient's own platelets means transfused platelets subject to same fate
 - Platelet transfusions most often are of little benefit
 - Reserved for treatment of severe bleeding
 - Thrombocytopenia caused by decreased platelet production
 - Hematologic malignancies
 - Recovery from stem cell transplantation
 - Serious hemorrhage prevented by regular transfusion of platelets
 - Generally acceptable to use prophylactic transfusion to keep platelet count $>10,000$ to $20,000$ cells/ μL
 - Transfusion of one random donor platelet unit per 10 kg of recipient weight, or single-donor unit from apheresis usually used to achieve that goal
 - Effectiveness of platelet transfusions diminished in febrile, infected patients who may require larger and more frequent transfusions
 - Actively bleeding patients require more frequent transfusion and a higher target of platelet count, usually above $50,000$ cells/ μL
 - Chronically transfused patients become refractory to transfusions from random donors because of alloimmunization
 - Single-donor platelets limit exposure to foreign antigens and may delay immunization
 - Platelets obtained from family members by platelet apheresis used in patients at risk for bleeding and refractory to random-donor platelets

Thrombocytopenia with Infection

- Mild and transient thrombocytopenia occurs with many systemic infections
 - Mechanism may be a combination of suppressed bone marrow production, increased destruction, and increased splenic sequestration
 - In bacteremia, platelets consumed because of disseminated intravascular coagulation (DIC)
 - In viral infection, platelet production may be suppressed
 - Thrombocytopenia common with human immunodeficiency virus (HIV) infection, mainly due to decreased production, although sometimes autoimmune mechanism involved
 - Thrombotic thrombocytopenic purpura (TTP) or thrombotic microangiopathy (TMA) associated with HIV as well with streptococcal and *Escherichia coli*
 - Treating underlying infection usually adequate to correct thrombocytopenia

Drug-Induced Thrombocytopenia

- Presents diagnostic challenge because many medications cause thrombocytopenia, and patients in ICU often on multiple medications
 - Most common reported drugs with probable or definite relation to thrombocytopenia were:

- Quinidine, quinine, rifampin, and trimethoprim-sulfamethoxazole
- Many other drugs can cause thrombocytopenia:
 - Heparin (see below)
 - Intravenous antibiotics
 - Anticonvulsants
 - Diuretics
 - Platelet glycoprotein (GP) IIb/IIIa antagonists used in acute coronary syndrome
- Underlying mechanism of drug-induced thrombocytopenia usually immune
 - At least three different types of antibodies appear to play a role:
 - Hapten-dependent antibodies
 - Drug-induced platelet-reactive autoantibodies
 - Drug-dependent antibodies
 - Targets for drug-dependent antibodies GP on cell membrane of platelets, such as GP Ib/IX and GP IIb/IIIa
 - Diagnosis of drug-induced thrombocytopenia supported by recovery to a normal platelet count within 5 to 7 days
- Treatment may require only withdrawal of the offending drug
 - Prednisone given if diagnosis of ITP cannot be ruled out
 - Patients with severe thrombocytopenia caused by GP IIb/IIIa antagonists may require platelet transfusions because they are typically also receiving heparin and aspirin for acute coronary syndrome
 - Platelet serology tests available but may not be available in time frame that allows information to be used in decision-making process

Heparin-Induced Thrombocytopenia (HIT)

- HIT an anticoagulant-induced prothrombotic disorder caused by platelet activation of heparin-dependent antibodies of IgG class
 - Diagnosis of HIT considered when platelet count, between days 5 and 14 from start of heparin therapy falls:
 - To $<150 \times 10^3$ cells/ μL
 - More than 50% decrease from baseline platelet count
 - High index of suspicion key in making diagnosis
 - Thrombocytopenia usually moderate and resolves within a few days of discontinuing heparin
 - HIT without thrombosis:
 - Called isolated HIT
 - HIT thrombotic syndrome (HITTS) denotes HIT complicated with thrombosis
 - Mortality rate associated with HIT ranges between 10% and 20%
- HIT an immune-mediated hypersensitivity reaction to platelet factor 4 (PF4)/heparin complex
 - PF4 a heparin-binding protein found naturally in platelet α granules
 - Undergoes conformational changes once bound to heparin
 - Anti-PF4/heparin antibodies produced by many patients taking heparin
 - Only a few develop thrombocytopenia
 - Anti-PF4/heparin antibodies transient and usually undetectable within median of 50 to 85 days
 - If heparin is readministered to patient with high levels of HIT antibodies, abrupt thrombocytopenia can occur.
 - Likely will be more than 100 days after the last exposure to heparin

- Seroconversion found by enzyme-linked immunosorbent assay (ELISA) in up to 15% of patients on heparin
 - Does not constitute a diagnosis of HIT
- Patients more likely to develop HIT are:
 - Surgical patients
 - Individuals exposed to higher doses of heparin for longer time
 - Patients receiving unfractionated heparin (UFH), as opposed to low-molecular-weight heparin (LMWH)
- Small minority of ICU patients with thrombocytopenia receiving UFH have HIT
 - PF4/heparin-reactive antibodies more likely to be detected by ELISA assay than serotonin release assay (SRA)
 - Suggests *over* diagnosis, due to a high false-positive rate by ELISA, of HIT
- Thrombotic sequelae of HIT carry significant morbidity and may be lethal:
 - Deep venous thrombosis (DVT) most common
 - Lower extremity predominates
 - Pulmonary embolism
 - Skin necrosis
 - Limb ischemia
 - Thrombotic stroke
 - Myocardial infarction
- All strategies should be used to prevent HIT in ICU patients
 - Elimination of heparin locks for CVLs and hemodialysis catheters
 - Hemodialysis without heparin is safe and effective
- To reduce risk of life-threatening thromboembolic events, once diagnosis of HIT recognized heparin promptly substituted with:
 - Direct thrombin inhibitor, such as argatroban or lepirudin
 - Heparinoid danaparoid (not available in United States)
 - Warfarin temporarily reduces synthesis of protein C and S, causing a hypercoagulable state, so is never be used alone in initial treatment of HIT
 - Use should be postponed until substantial platelet recovery has occurred
 - Consultation with a hematologist should be considered
- Argatroban dose is 2 $\mu\text{g/kg/minute}$ IV infusion and dilution of 1 mg/mL
 - Dose adjustment needed for hepatic impairment (25% of the dose)
 - Aim of a 1.5 to 3 times prolongation of activated partial thromboplastin time (aPTT) compared to baseline
- Lepirudin treatment consists of a bolus 0.4 mg/kg (maximum of 44 mg)
 - Given over 10 to 15 seconds
 - Followed by continuous infusion at 0.15 mg/kg/hour
 - Goal of a 1.5 to 3 times prolongation of aPTT over baseline
 - Dose should be modified if creatinine is >1.5 mg/dL or clearance is <60 mL/minute
 - If given with warfarin, discontinue lepirudin when international normalized ratio (INR) of 2.0 obtained
- Approach to patients with suspected or confirmed HIT includes the following:
 - Discontinuation of all heparin
 - Administration of nonheparin anticoagulation, such as argatroban or lepirudin
 - Testing for anti-PF4/heparin antibodies, followed, if positive, by SRA

- Avoiding prophylactic platelet transfusions
- Allowing platelet recovery before starting warfarin
- Assessing for lower extremity DVT
- Patients with previous HIT who are antibody negative and require cardiac surgery should receive UFH in preference to other anticoagulants
 - Preoperative and postoperative anticoagulation handled with anticoagulant other than UFH or LMWH
- Patients with recent or active HIT should have surgery delayed until antibody is negative
 - Otherwise, alternative anticoagulant should be used

Idiopathic Thrombocytopenic Purpura

- Idiopathic thrombocytopenic purpura (ITP):
 - Also known as immune thrombocytopenic purpura
 - Categorized as acute, chronic, or refractory
 - Common cause of thrombocytopenia in both adults and children
 - Usually in differential diagnosis of thrombocytopenia diagnosis of ITP made only after exclusion of other causes of thrombocytopenia
 - When history, physical examination, and blood count with peripheral smear consistent with ITP, and other causes not suggested, few diagnostic tests necessary
 - Bone marrow examination important to rule out other primary marrow diseases
 - Myelodysplastic syndrome or lymphoproliferative disorders
 - In ITP, marrow shows increased number of megakaryocytes with immature forms and normal erythroid and myeloid lineages
 - Test for HIV important in patients with risk factors
 - Tests for platelet Abs not helpful because of limited specificity and sensitivity
 - TTP may occur as one of autoimmune complications of collagen vascular diseases such as systemic lupus erythematosus, or lymphoproliferative diseases such as chronic lymphocytic leukemia
 - May even be the presenting manifestation of these disorders
- Many forms of treatment have demonstrated effectiveness in ITP
 - Platelet transfusions used only in case of severe, life-threatening hemorrhage
 - Initial therapy usually with corticosteroids
 - Dosage equivalent to 1 mg/kg/day of prednisone
 - If platelet count does not rise substantially within 2 to 3 weeks
 - Splenectomy usually the next step
 - Produces prolonged remissions in two-thirds of cases
 - Partial remission in 15% of patients
 - May be necessary in patients who responded to steroids but cannot be weaned from drug without recurrence
 - The 10% to 20% of patients who don't respond to splenectomy may benefit from:
 - Vincristine or immunosuppressive agents such as cyclophosphamide
 - Anabolic steroid, danazol, given for several months, effective in some cases of ITP
 - Large doses of IVIG may increase platelet count in ITP

- Perhaps through blockage of reticuloendothelial sites of platelet destruction
- Therapy costly and short duration
 - Usually 2 to 3 weeks
- Anti-D therapy effective only in Rh(D)+ patients
 - Not effective in splenectomized patients
- Rituximab, a chimeric anti-CD20 monoclonal antibody shown to be effective in chronic ITP
 - Goal in treating chronic or refractory ITP to maintain a safe platelet count
 - Defined as $>10,000$ to $20,000$ cells/ μL
 - And minimize morbidity and mortality associated with treatment
- When ITP occurs during pregnancy additional concern that IgG autoantibody may cross placenta and produce thrombocytopenia in fetus and newborn
 - Lowest platelet count usually seen several days after birth
 - Current practice is to use standard obstetric management of pregnancy and delivery
 - ITP should be differentiated from gestational thrombocytopenia
 - Occurs in about 5% of normal women with uncomplicated pregnancies
 - Most important clue to differentiating is a history of previous thrombocytopenia when woman was not pregnant
 - More severe thrombocytopenia occurring before third trimester more likely to be ITP

Thrombotic Thrombocytopenic Purpura

- TTP and its closely related disorders may be catastrophic and rapidly fatal:
 - Hemolytic-uremic syndrome (HUS)
 - Thrombotic microangiopathy (TMA)
 - Peripartum HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome
- TTP a pentad of abnormalities:
 - Thrombocytopenia from increased platelet destruction
 - Microangiopathic hemolytic anemia (MHA)
 - Caused by mechanical damage to RBCs as a result of the vascular lesions
 - Neurologic abnormalities
 - Renal abnormalities
 - Fever
- Thrombocytopenia and MHA sufficient to begin plasma-pheresis
- Clinical presentation variable, but thrombocytopenia and hemolytic anemia often severe
 - Wide variety of fluctuating neurologic abnormalities may be present, including:
 - Seizures
 - Altered consciousness
 - Delirium
 - Paresis
 - Renal abnormalities may include:
 - Uremia
 - Hematuria
 - Proteinuria
 - Reasons for fever are unclear
 - Typical presentation for young children:

- Prodrome of bloody diarrhea caused by the Shiga toxin-producing enterohemorrhagic strain of *E. coli*
- Laboratory findings in TTP those related to the above features:
 - Thrombocytopenia
 - Hemolytic anemia with red cell fragmentation
 - Renal dysfunction
 - Elevation of serum lactic acid dehydrogenase from intravascular hemolysis, and perhaps also damage to other tissues, is an index of activity of the disease
 - Coagulation tests usually normal
- Basic pathogenic mechanism behind these syndromes most likely vascular endothelial cells
 - Role for ultralarge von Willebrand factor (vWf) multimers identified
 - Linked to endothelial damage and occurrence of disseminated platelet thrombi
 - Specific metalloprotease (ADAMTS13) that rapidly cleaves multimers identified
 - Deficiency of metalloprotease activity associated with many TTP cases
- Plasma exchange has dramatically changed TTP-HUS prognosis and outcome
 - Plasma infusion less effective in adults
 - Could be adequate in congenital TTP caused by ADAMTS13 deficiency
 - Duration of plasma exchange is unpredictable
 - Up to several months, may be required in patients with repeated relapses
 - Efficacy of additional treatments such as prednisone, platelet aggregation inhibitors, and splenectomy unknown

Alcoholism-Associated Thrombocytopenia

- Platelet counts $<100,000$ cells/ μL present in $>25\%$ of critically ill alcoholic patients
 - Many possible causes for thrombocytopenia in such patients
 - Hypersplenism
 - Folic acid deficiency
 - Reversible severe thrombocytopenia may be direct effect of alcohol ingestion in some patients
 - Studies of mechanism have demonstrated:
 - Decreased effective platelet production
 - Shortened platelet survival
 - Abnormalities of platelet function have been noted
 - Recovery begins 2 to 3 days after cessation of alcohol ingestion
 - Maximum platelet counts reached in 1 to 3 weeks
 - Often an overshoot to abnormally high platelet counts
 - Then return to baseline levels
 - Therapy consists of having patient discontinue alcohol ingestion and providing appropriate supportive measures

Thrombocytopenia Associated with Bone Marrow Disorders

- Severe thrombocytopenia from impaired platelet production a frequent concomitant of bone marrow disorders
 - Aplastic anemia
 - Leukemia

- Other malignancies metastatic to the bone marrow
- Cytotoxic chemotherapy
- Treatment is directed at the underlying disease

INCREASED BLOOD COUNTS

Erythrocytosis

- An abnormally increased red cell mass
 - May require critical care due to:
 - Complications of blood hyperviscosity
 - Hemorrhagic or thromboembolic complications
- Initial clue to presence of erythrocytosis usually high value for Hgb/Hct
 - May be present without true erythrocytosis if plasma volume contracted
 - Red cell mass (RCM) usually increased when hematocrit above 60% in a man or 57% in a woman
- True erythrocytosis results from one of two general mechanisms:
 - Polycythemia vera (PV), a clonal abnormality of bone marrow stem cells resulting in autonomous overproduction of RBCs and often of granulocytes and platelets
 - Secondary erythrocytosis, resulting from excess erythropoietin production in response to:
 - Hypoxemia
 - Abnormalities of oxygen release from hemoglobin
 - Autonomous hormone production (e.g., by renal or other tumors)
- When RCM expanded and hematocrit increased
 - Blood viscosity is increased
 - Diminished blood flow, stasis, thrombosis, and tissue hypoxia may ensue
 - Hemorrhagic tendency also increased, particularly in PV
 - Elevated platelet counts and abnormalities of function may be present

Polycythemia Vera

- Diagnosis of PV shown in Table 121.4
- Detection by polymerase chain reaction (PCR) of Janus kinase 2 (JAK2) tyrosine kinase in up to 97% of patients with PV increases sensitivity/specificity of early diagnosis
 - JAK2 V617F point mutation makes hematopoietic progenitors hypersensitive to the different growth factors, resulting in proliferation of all lineages
- Uncontrolled PV risks primarily hyperviscosity and thromboembolic or hemorrhagic events
- Patients at highest risk those:
 - Whose disease has shown particularly active cell proliferation, requiring extensive therapy
 - With a prior history of complications
 - The elderly
 - Level of Hct or platelet count not a reliable predictor
- Symptoms resulting from decreased cerebral flow:
 - Headache
 - Dizziness
 - Changes in vision the most common manifestations of hyperviscosity

TABLE 121.4

PROPOSED MODIFIED CRITERIA FOR THE DIAGNOSIS OF POLYCYTHEMIA VERA (PV)

- A1: Raised red cell mass
25% above mean normal predicted value, or a hematocrit value >60% in males or 56% in females
- A2: Absence of causes of secondary erythrocytosis
- A3: Palpable splenomegaly
- A4: Clonality marker (i.e., acquired abnormal marrow karyotype)
- B1: Thrombocytosis
Platelet count $>400 \times 10^3$ cells/ μ L
- B2: Neutrophil leukocytosis
Neutrophil count $>10 \times 10^3$ cells/ μ L, or $>12.5 \times 10^3$ cells/ μ L in smokers
- B3: Splenomegaly demonstrated on isotope or ultrasound scanning
- B4: Characteristic BFU-E growth or reduced serum erythropoietin
- A1 + A2 + A3 or A4 establishes PV
- A1 + A2 + two of B establishes PV

BFU-E, erythroid burst-forming units.

Adapted from Pearson TC, Messinezy M, Westwood N, et al. A polycythemia vera updated: diagnosis, pathobiology, and treatment. *Hematol Am Soc Hematol Educ Program*. 2000;51.

- Hemorrhage or thrombosis can affect almost any body part
 - Peptic ulcer disease with bleeding common
 - Thromboses may be arterial or venous
- Fatigue, plethora, pruritus particularly with hot bath, excessive sweating, paresthesias (erythromelalgia), fullness in the left upper abdomen (splenomegaly), and shortness of breath PV manifestations
- Surgery poses enormous risk in patient with uncontrolled PV
- High incidence of thrombotic or hemorrhagic complications
- Uncontrolled PV patients may present as medical emergencies requiring ICU care and urgent therapy
 - Mainstay of such therapy is phlebotomy to reduce Hct to <45%
 - May be done as rapidly as 1 unit RBC every other day in young adults
 - Electrolyte solutions administered with phlebotomy to avoid circulatory instability
 - Elderly patients may tolerate phlebotomy less well
 - Removal of volumes of 200 to 300 mL at less frequent intervals may be necessary
 - Clinical observations of increased thrombosis with aggressive phlebotomy
 - Simultaneous use of cytotoxic chemotherapy is recommended as part of the initial therapy of patients older than 60 years and in younger patients with thrombotic risk factors or a history of thrombosis
 - Hydroxyurea used for this purpose
 - Initial dose of 15 to 30 mg/kg/day
 - Long-term treatment with hydroxyurea may be linked with increased risk of transformation to acute leukemia
 - Emergency plateletpheresis may also be considered in such emergencies to lower an elevated platelet count

- Other treatment options include:
 - Low-dose aspirin (81 mg/day)
 - Interferon- α
 - Anagrelide
- Patients with PV should avoid practices and habits that augment hypercoagulability:
 - Smoking
 - Use of oral contraceptives
 - Hormone replacement therapy
 - Aggressive antithrombotic prophylaxis given postoperatively in addition to maintaining normal hematocrit and platelet counts

Secondary Erythrocytosis or Polycythemia

- Diagnosis of secondary erythrocytosis is made in patient with:
 - Increased RCM in whom the criteria for PV not met
 - These patients either have:
 - Physiologically appropriate increased RCM (i.e., secondary to tissue hypoxemia)
 - Inappropriately increased RCM (i.e., secondary to increased erythropoietin production)
 - Additional studies needed to differentiate diverse causes of polycythemia
 - Indications for phlebotomy in secondary erythrocytosis less clear than in PV
 - Best current advice to individualize therapy to maximize patient's exercise tolerance and overall sense of well-being

Thrombocytosis

- Literature dealing with thrombocytosis in ICU patients very scant
- Presence of thrombocytosis predicts a favorable outcome in ICU patients
- Blunted rise in platelet count may be associated with worse outcome
- Classified according to origin into primary (clonal) and secondary (reactive) forms
 - Primary, a persistent elevation of platelet count due to clonal thrombopoiesis
 - Occurs in myeloproliferative disorders including essential thrombocythemia (ET), PV, myelodysplastic syndrome, chronic myelogenous leukemia, and myelofibrosis
 - Secondary, due to various conditions, some of them short-lived, such as acute bleeding, infection, trauma or other tissue injury, and surgery
 - Other causes, such as malignancy, postsplenectomy, chronic infection, iron deficiency, or chronic inflammatory disease may persist for a longer time
- Multiple studies conducted on adult and pediatric hospitalized patients with an elevated platelet count ($>500 \times 10^3$ cells/ μ L)
 - Most patients have secondary thrombocytosis
 - Higher platelet count and increased thromboembolic complications are significantly associated with primary thrombocytosis
 - Even when using $\geq 1,000 \times 10^3$ cells/ μ L as the basis for defining extreme thrombocytosis

- 82% of 231 patients analyzed were found to have an elevated platelet count due to reactive (secondary) thrombocytosis
- Risk of bleeding and/or thrombosis:
 - 56% in primary thrombocytosis
 - 4% in secondary type
 - Unless additional risk factors present, secondary thrombocytosis not associated with increased risk of thromboembolic events

- Treatment for primary thrombocytosis, such as ET, based on risks for thrombosis or bleeding in presence of vasomotor symptoms
- Patients at increased risk should receive platelet-lowering agents such as hydroxyurea, anagrelide, or interferon- α (IFN- α)
 - Age older than 60 years
 - History of thromboembolism
 - Platelet count $>1,500,000$ cells/ μ L
- Low-dose aspirin can be used for relief of vasomotor symptoms
 - If no relief, platelet-lowering agents should be added
 - Hydroxyurea the recommended drug in patients ≥ 60 years of age
 - IFN- α is the cytoreductive agent of choice for childbearing women
- Aim to lower the platelet count to $<400,000$ cells/ μ L
- Arterial or venous thrombosis treated with heparin, possibly, thrombolysis
- Plateletpheresis may be indicated in both types of events
- Low-dose aspirin may be useful in arterial thrombosis
- In hemorrhage, it is appropriate to stop antiplatelet agents and transfuse platelets if bleeding persists
- Some patients with uncontrolled thrombocytosis ($>1,500,000$ cells/ μ L) have an acquired defect of vWf
 - Contributes to risk of bleeding
 - DDAVP, cryoprecipitate, or factor VIII concentrate may be indicated

Leukocytosis

- Can be due to primary bone marrow disorders or secondary disorders in response to acute infection or inflammation
- Secondary leukocytosis is physiologic and transient, resolving after treating the underlying cause
 - *Leukemoid reaction* refers to a persistent leukocytosis of more than 50,000 cells/ μ L with shift to left
 - Major causes for such a reaction include severe infections, severe hemorrhage, acute hemolysis, hypersensitivity, and malignancies (paraneoplastic syndrome)
- Due to a primary bone marrow disorder with uncontrolled clonal growth of immature cells can result in an emergency situation known as hyperleukocytosis syndrome
 - Occurs in leukemic states when the WBC count is high
 - Signs and symptoms are most commonly related to the central nervous system, eyes, and lungs and include:
 - Stupor
 - Altered mentation
 - Dizziness
 - Visual blurring
 - Retinal abnormalities

- Dyspnea
- Tachypnea
- Hypoxia
- Intracranial and pulmonary infarction or hemorrhage and sudden death may occur
- Priapism and peripheral vascular insufficiency linked with syndrome
- Pathogenesis incompletely understood, but autopsies have shown WBC aggregates, microthrombi, and microvascular invasion (leukostatic tumors)
- Syndrome occurs more commonly in acute (AML) and chronic myelogenous leukemia (CML) than in acute lymphoblastic leukemia
 - Rarely in chronic lymphocytic leukemia
- Level of WBC count syndrome appears is variable
 - Depending on maturity and size of WBCs present and degree of coexisting anemia
 - WBC count $>100,000$ cells/ μL in AML or accelerated phase of CML usually an alarming sign and indication for prompt treatment
 - Signs or symptoms attributable to the hyperleukocytosis syndrome:
 - Leukophoresis indicated, rapidly/safely decrease WBC count
 - Chemotherapy initiated
 - Treatment with allopurinol and IV hydration with urine alkalization started in anticipation of hyperuricemia
 - Hydroxyurea (6 g by mouth) frequently used initially to produce rapid leukemic cell kill

OTHER HEMATOLOGIC DISORDERS

Plasma Cell Dyscrasias

- Presenting symptoms for these malignant disorders may include:
 - Severe infection
 - Spinal cord compression
 - Hyperviscosity syndrome
 - Total serum protein abnormally high on routine chemistry blood test
 - Subsequent evaluation will reveal monoclonal gammopathy:
 - IgM in Waldenstrom macroglobulinemia
 - IgG/IgA in multiple myeloma
- Hyperviscosity syndrome rare and less frequent when IgG or IgA, respectively, are abnormal proteins
- Most common manifestations of the hyperviscosity syndrome are:
 - Neurologic, including headache, visual disturbances, hearing loss, vertigo, altered consciousness (ranging from stupor to coma), paresis, seizures, and peripheral neuropathy
 - Bleeding tendency may exist because of associated thrombocytopenia or interference by abnormal protein with function of platelets or plasma coagulation factors
- Most rapidly effective form of therapy for hyperviscosity from serum protein abnormalities is plasmapheresis
 - Hydration and specific therapy for underlying disease should start

STEM CELL TRANSPLANTATION (SCT)

- After allogeneic SCT a large proportion admitted to ICU
 - Usually admitted with respiratory distress requiring mechanical ventilation, multiorgan failure, or septic shock
 - Have the highest mortality among cancer patients admitted to ICU
 - Because of generally poor outcome, especially for patients requiring mechanical ventilation, utility of such support questioned
- Generally accepted that patients admitted to ICU during engraftment period be fully supported because of better outcome
 - Patients may have *engraftment syndrome*, can result in cytokine-induced capillary leak syndrome with multiorgan failure or alveolar hemorrhage
 - Early high-dose steroids dramatically reverse downhill course
 - Patients should also undergo bronchoscopy to rule out infection while receiving steroid therapy
 - Early intervention and transfer to ICU in septic shock results in improved outcome
- After autologous SCT patients usually have better survival in ICU than after allogeneic SCT
 - Even those requiring mechanical ventilation
- Admission to surgical ICU less frequent for patients after SCT, most frequent reasons include:
 - Intestinal perforation
 - Intracranial bleeding

CHAPTER 122 ■ ONCOLOGIC EMERGENCIES

- Cancer the second leading cause of death in United States, surpassed only by heart disease
- Approximately 1 million new cases of squamous and basal skin cancers, and 1,445,000 new cases of all other cancers (excluding carcinoma *in situ*, with the exception of *in situ* bladder carcinoma) diagnosed yearly
- 5-year relative survival rate of 66% calculated for all cancers diagnosed between period of 1996 and 2002
 - Compared to 51% between 1975 and 1977

HYPERCALCEMIA

- The most common of paraneoplastic syndromes
- Develops in 10% to 30% of all patients with malignancy at some time during disease
 - Breast cancer, lung cancer, and multiple myeloma most common associated malignancies
- Presence in patient with cancer portends an extremely poor prognosis
 - Particularly when elevated parathyroid hormone-related protein (PTHrP) levels detected
 - About 50% of cancer patients with hypercalcemia die within 30 days

Pathophysiology

- Results from increased bone resorption
- Subsequent release of calcium from bone into extracellular fluid
- Classification based on mechanism by which elevated calcium generated; four recognized types:
 - Humoral hypercalcemia of malignancy (HHM)
 - Local osteolytic hypercalcemia
 - Tumor production of the active form of vitamin D
 - Ectopic parathyroid hormone (PTH) secretion

Humoral Hypercalcemia of Malignancy

- Most common cause of cancer-induced hypercalcemia (CIH)
- Seen in 80% of cases
- Mechanism mediated by PTHrP
 - Secreted into systemic circulation by malignant tumors
 - Most frequently squamous cell carcinoma, renal cell carcinoma, ovarian and endometrial carcinomas, human T-cell lymphoma/leukemia virus (HTLV)-associated lymphomas, and breast carcinoma
 - Normally PTHrP expressed in nonneoplastic adult and fetal tissues
 - Involved in cell growth and differentiation
 - Not systemically secreted in significantly detectable levels

- Due to structural homology with parathyroid hormone at amino terminal end, humoral PTHrP binds to PTH receptors in bone and kidney
 - With increased bone resorption, distal tubular calcium resorption

Local Osteolytic Hypercalcemia

- Seen in about 20% of cases of malignant hypercalcemia
- Occurs when tumor cells in bone metastases induce osteoclastic bone resorption
 - By secreting cytokines such as tumor necrosis factor (TNF), interleukin-1 (IL-1), IL-6, macrophage inflammatory protein, and lymphotoxin
 - Stimulate local macrophages within tumor to differentiate into osteoclasts
- Seen frequently in breast cancer, non-small cell lung cancer, and multiple myeloma

Tumor Production of the Active Form of 1,25-dehydroxyvitamin D

- Occurs in <1% of cases
- Seen in some lymphomas
- Hypercalcemia mediated by:
 - Enhancement of osteoclastic bone resorption
 - Intestinal resorption of calcium

Ectopic Parathyroid Hormone Secretion

- Final mechanism of hypercalcemia of malignancy is ectopic PTH secretion
- Adequately described in only eight patients

Differential Diagnosis

- Malignancies and primary hyperparathyroidism account for about 90% of hypercalcemia cases
- May coexist in critically ill cancer patient
- In hospitalized patients, neoplastic disease most common cause in >65% of cases
- Renal failure, thyrotoxicosis, granulomatous diseases (sarcoid, tuberculosis), adrenal insufficiency, immobilization, vitamin A or D intoxication, milk alkali syndrome, familial hypocalciuric hypercalcemia, and medications (thiazide diuretics, lithium, estrogens, and tamoxifen) included in the differential diagnosis of hypercalcemia

Clinical Presentation

- Multiple symptoms of hypercalcemia (Table 122.1)
- Nonspecific and often attributed to coexisting chronic or terminal illness

TABLE 122.1**CLINICAL MANIFESTATIONS IN HYPERCALCEMIA****NEUROLOGIC**

Drowsiness, weakness, lethargy
Stupor, coma
Psychosis
Visual and speech impairment
Focal neurologic deficits

GASTROINTESTINAL

Anorexia
Nausea, vomiting
Constipation
Abdominal pain
Peptic ulcer disease
Pancreatitis

RENAL

Nephrogenic diabetes insipidus
Acute renal failure

CARDIAC

PR interval prolongation
QRS complex widening
QT interval shortening
T wave changes
Bradyarrhythmias
Bundle branch block
Atrioventricular nodal block
Cardiac arrest

BONE

Pain
Pathologic fractures

Data from Stewart AF. Hypercalcemia associated with cancer. *N Engl J Med.* 2005;352:373; Halfdanarson TR, Hogan WJ, Moynihan TJ. Oncological emergencies: diagnosis and treatment. *Mayo Clin Proc.* 2006;81(6):835; Hypercalcemia. *CancerMail from the National Cancer Institute.* <http://cancerweb.ncl.ac.uk>; Germano T. The parathyroid gland and calcium-related emergencies. *Top Emerg Med.* 2001;23(4):51; Bushinsky DA, Monk RD. Calcium. *Lancet.* 1998;352:306; Cogan MG, Covey GM, Arief AL, et al. Central nervous system manifestations of hyperparathyroidism. *Am J Med.* 1978;65:963; 2005 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation.* 2005;112(24 Suppl):IV1–121; and Berensen JR. Treatment of hypercalcemia with bisphosphonates. *Semin Oncol.* 2002;29(6 Suppl 21):12.

- Symptoms generally correlate with absolute concentration and rapidity in rise of serum calcium
- Neurologic symptoms mild at lower levels or when hypercalcemia developed slowly
 - Mild drowsiness or fatigue may progress to weakness, lethargy, stupor, and eventually coma in hypercalcemic crisis or in acutely rising hypercalcemia
 - Psychotic behavior, visual and speech abnormalities, hypotonia, and occasionally localizing signs on examination, often attributed to metastatic disease, may be exhibited
 - May resolve with therapy that lowers serum calcium
 - In older patients, neurologic dysfunction more pronounced at lower concentrations of serum calcium
- Gastrointestinal symptoms related to smooth muscle hypotonicity and include anorexia, nausea, vomiting, constipation, and abdominal pain

- Infrequently may present as peptic ulcer disease and pancreatitis
- Renal manifestations due to impairment of renal water-concentrating ability
 - Antidiuretic hormone (ADH) secretion inhibited by hypercalcemia
 - Dehydration decreases glomerular filtration rate (GFR) and renal excretion of excess calcium
 - With expansion of extracellular volume (ECV), compensatory proximal tubular resorption of sodium and calcium occurs
 - Leads to paradoxical increase in serum calcium
 - Frank renal failure may ensue
 - Particularly in patient with multiple myeloma
 - Hypercalcemia of malignancy rarely associated with nephrolithiasis and nephrocalcinosis
 - Hypercalciuria must be chronic for these to occur
- Cardiovascular symptoms of hypercalcemia marked by:
 - Increased myocardial contractility and irritability
 - Electrocardiogram (ECG) changes include:
 - PR-interval prolongation
 - QRS-complex widening
 - QT-interval shortening
 - T-wave changes
 - At increasing serum calcium levels patients may experience bradyarrhythmias and bundle branch block
 - With progression to atrioventricular (AV) nodal block and cardiac arrest at serum concentrations of 18 mg/dL
- Bone symptoms of hypercalcemia include:
 - Pathologic fractures and pain
 - Due to osteolytic metastases or humorally mediated bone resorption

Diagnosis

- Calcium present in ECF in three fractions:
 - 50% is ionized free fraction
 - 40% is protein bound (primarily to albumin) and is not renally filtered
 - 10% complexed to anions
- Hypercalcemia diagnosed by measuring ionized calcium level
 - Biologically active level correlating with signs and symptoms of hypercalcemia
 - Except in presence of hypoalbuminemia ionized calcium inferred from total plasma calcium
 - In cancer patients, hypoalbuminemia common
 - Total plasma calcium must be corrected to reflect the calcium level measured as if albumin were in normal range
 - For each 1 g/dL decrease in serum albumin, there is a 0.8 mg/dL decrease in serum calcium
 - Calculation inaccurate with calcium-binding immunoglobulins (multiple myeloma)
 - Warrants measurement of ionized calcium level
 - Total serum calcium significantly overestimates ionized fraction
 - Ionized calcium concentrations increase with acidosis and decrease with alkalosis
 - Changes small and not clinically significant
 - Once diagnosis of hypercalcemia confirmed by obtaining corrected calcium levels

- Measurement of intact PTH level necessary:
 - Suppressed in hypercalcemia of malignancy
 - Elevated in primary hyperparathyroidism
 - PTH lowers serum phosphate and increases serum Cl^- concentrations
 - Low serum Cl^- (<100 mEq/L) suggests hypercalcemia of malignancy
 - Elevation of serum Cl^- caused by hyperchloremic acidosis resulting from PTH-induced renal bicarbonate loss
 - Ectopic hyperparathyroidism rare cause of malignant hypercalcemia
 - Elevations in PTH levels more likely indicate concomitant primary hyperparathyroidism
- Determination of serum PTHrP concentration not routine
 - Useful in identifying mechanism of hypercalcemia
 - Low in patients with primary hyperparathyroidism
 - High in patients with either HHM alone or concomitant primary hyperparathyroidism and malignant hypercalcemia
 - Used in evaluating response to bisphosphonate therapy
 - Patients with PTHrP levels >12 pmol/L less responsive to pamidronate
 - More likely to develop recurrent hypercalcemia within 14 days

Treatment

- Only effective long-term therapy of malignancy-associated hypercalcemia reduction in tumor burden (Table 122.2)
- Antihypercalcemic therapy a temporizing measure
 - Does not affect survival
- Hypercalcemia classified based on serum calcium levels into:
 - Mild hypercalcemia (10.5–11.9 mg/dL)
 - Moderate hypercalcemia (12.0–13.9 mg/dL)
 - Severe hypercalcemia (14.0 mg/dL or greater)
 - Treatment strategy dependent on:
 - Magnitude of hypercalcemia
 - Severity of symptoms
 - Cause of hypercalcemia
- Severe hypercalcemia requires emergent, aggressive treatment regardless of symptoms
- Interventions in mild to moderate hypercalcemia contingent on severity of symptoms
 - Prior to initiating therapy assess for correctable factors contributing to hypercalcemia
 - Exogenous sources of calcium
 - Thiazide diuretics, vitamins A and D, calcitriol, lithium, and estrogens or antiestrogens used as therapy for breast carcinoma

TABLE 122.2

TREATMENT OF HYPERCALCEMIA OF MALIGNANCY

Definitive Treatment

Antitumor therapy to reduce tumor burden

Initial Treatment

Removal of exogenous calcium sources:

Intravenous fluids, parenteral nutrition, oral calcium supplements, thiazide diuretics, vitamins A and D, calcitriol, lithium, estrogens, antiestrogens

Weight-bearing ambulation

Phosphate repletion

Fluids and diuresis

Saline hydration

Loop diuretics Judicious use in euvolemic or hypervolemic patients; now less favorable because of hypokalemia, hypomagnesemia, volume depletion

Pharmacologic Treatment

Bisphosphonate therapy

Principal agents in hypercalcemic treatment

Zoledronate 15-min infusion

Pamidronate 2-h infusion

Bisphosphonate adverse effects: acute and chronic renal failure, fever arthralgias, ocular inflammation, electrolyte imbalance, osteonecrosis of the jaw

Other agents

Calcitonin Useful in congestive heart failure or renal failure

Glucocorticoids Used in lymphomas with elevated levels of 1,25-vitamin D

Mithramycin Use limited by adverse effects: thrombocytopenia, anemia, leukopenia, renal failure

Gallium nitrate Use limited by 5-day continuous infusion, nephrotoxicity

Dialysis

For patients with renal failure or congestive heart failure

Data from Stewart AF. Hypercalcemia associated with cancer. *N Engl J Med*. 2005;352:373; Halfdanarson TR, Hogan WJ, Moynihan TJ. Oncological emergencies: diagnosis and treatment. *Mayo Clin Proc*. 2006;81(6):835; Hypercalcemia. *CancerMail from the National Cancer Institute*. <http://cancerweb.nci.ac.uk>; Germano T. An unrecognized cause of recurrent hypercalcemia: immobilization. *South Med J*. 2006;99(4):371; Body JJ. Hypercalcemia of malignancy. *Semin Nephrol*. 2004;24:48; Berenson JR, Lipton A. Bisphosphonates in the treatment of malignant bone disease. *Annu Rev Med*. 1999;50:237; and Tanveyanon T, Stiff PJ. Management of the adverse effects associated with intravenous bisphosphonates. *Ann Oncol*. 2006;(17):897.

- Immobilization well-established cause of hypercalcemia
 - Weight-bearing ambulation recommended whenever possible
- In the presence of hypophosphatemia, hypercalcemia more difficult to treat
 - Observed in cancer patients for multiple reasons including:
 - Poor nutrition
 - Saline diuresis
 - PTHrP effects
 - Use of antacids and loop diuretics
 - Hypercalcemia itself
 - Oral/nasogastric tube phosphate supplementation administered to keep the calcium-phosphate product between 30 and 40
 - Intravenous (IV) phosphorous may precipitate hypocalcemia, seizures, and acute renal failure
 - Reserved for patient in whom oral/nasogastric tube administration cannot be performed

Fluids and Diuretics

- Initial intervention administration of isotonic saline at a rate of 200 to 500 mL/hour
 - Based on degree of hypovolemia and renal and cardiovascular dysfunction
 - Once fluid deficit replaced
 - Rate decreased to 100 to 200 mL/hour
 - In patients without cardiac or renal impairment
 - Reduces serum calcium level by:
 - Increasing glomerular filtration rate
 - Increasing calcium delivery to proximal tubule
 - Urinary calcium excretion augmented by calciuric effects of saline
 - Loop diuretics inhibit calcium reabsorption at loop of Henle, increasing calciuresis
 - Judiciously used after euolemia achieved in hypovolemic patients or in patients presenting with volume overload
 - Complications include hypokalemia, hypomagnesemia, and volume depletion

Bisphosphonate Therapy

- Inhibit osteoclastic bone resorption
 - The principal agents in management of hypercalcemia of malignancy
- Compared to saline and diuretics alone, and other antiresorptive agents including calcitonin
 - Bisphosphonates superior treating hypercalcemia of malignancy
 - Only 1% to 2% of oral bisphosphonates absorbed
 - Drugs administered IV
 - Pamidronate and zoledronate most commonly used bisphosphonates for treatment of hypercalcemia of malignancy
 - Clodronate and ibandronate available in Europe and elsewhere
 - Patients respond to bisphosphonate therapy within 2 to 4 days
 - Nadir in serum calcium occurring within 4 to 7 days
 - Normocalcemia may persist for 2 to 4 weeks
 - Zoledronate 850 times more potent than pamidronate and is more efficacious

- Pooled analysis of two randomized controlled trials
 - Single 4-mg dose of zoledronic acid to 90-mg dose of pamidronate
 - Serum calcium concentrations normalized within 10 days
 - In 88% versus 70% of patients, respectively
 - Duration of response was 32 days versus 18 days, respectively
- Zoledronate administered over shorter interval of 15 minutes
 - Advantageous in outpatient setting
 - Pamidronate requires a 2-hour infusion
- Both zoledronate and pamidronate associated with acute and chronic renal failure
 - More adverse events reported with zoledronate
 - Dose reduction of zoledronate recommended in patients with creatinine clearance between 30 and 60 mL/minute
 - No change in dose or infusion rate of pamidronate in patients with serum creatinine of <3 mg/dL
- Other complications of bisphosphonates include:
 - Acute systemic inflammatory reactions such as fever and arthralgias
 - Ocular inflammation
 - Electrolyte imbalance
 - Osteonecrosis of the jaw

Other Agents

- Calcitonin a well-tolerated synthetic polypeptide analogue of salmon calcitonin
 - Reduces serum calcium levels by inhibiting bone resorption
 - Administered subcutaneously or intramuscularly, produces rapid, transient decrease in serum calcium in 12 to 24 hours
 - Useful in patients with congestive heart failure (CHF) or renal failure where saline, diuresis, and bisphosphonates contraindicated
 - Tachyphylaxis may occur with continued use
- Glucocorticoids effective in decreasing serum calcium in hypercalcemia of malignancy associated with some lymphomas, particularly Hodgkin lymphoma
 - Elevated 1,25-vitamin D present in Hodgkin lymphoma
 - Glucocorticoids
 - Increase renal calcium excretion
 - Block vitamin D–mediated calcium absorption in gastrointestinal (GI) tract
 - Have limited utility in acute setting because reduction in serum calcium may not be observed for 1 to 2 weeks
- Mithramycin, an inhibitor of osteoclast RNA synthesis
 - Formerly first-line hypocalcemic agent
 - Has serious adverse effects including:
 - Thrombocytopenia
 - Anemia
 - Leukopenia
 - Renal failure
- Gallium nitrate
 - Disadvantage of requiring continuous IV infusion over 5 days
 - Potential nephrotoxicity
- Dialysis may be used to treat patients with hypercalcemia complicated by renal failure or CHF

ACUTE TUMOR LYSIS SYNDROME (ATLS)

Definition

- ATLS occurs as a consequence of rapid and massive destruction of tumor cells, resulting in
 - Release of intracellular metabolites into circulation
 - In quantities sufficient to exceed renal excretory capacity
 - The four biochemical disturbances generated by this process that characterize the syndrome are life threatening:
 - Hyperkalemia
 - Hyperphosphatemia
 - Hypocalcemia
 - Hyperuricemia
- ATLS is most frequently observed after administration of cytotoxic chemotherapy in patients with high-grade hematologic malignancies:
 - Burkitt's lymphoma
 - Acute lymphocytic leukemia (ALL)
 - Incidence of clinically significant ATLS in non-Hodgkin lymphoma and ALL:
 - Reported as 6% and 5.2%, respectively
 - Metabolic derangements in patients may develop within hours to days after chemotherapy
- Other malignancies in which ATLS has been described include:
 - Chronic leukemia
 - Low-grade lymphoma
 - Rarely, multiple solid tumors such as:
 - Metastatic breast carcinoma
 - Lung carcinoma
 - Seminoma
 - Thymoma
 - Medulloblastoma
 - Ovarian carcinoma
 - Rhabdomyosarcoma
 - Melanoma
 - Vulvar carcinoma
 - Merkel cell carcinoma
 - Syndrome can also occur after:
 - Radiation therapy
 - Immunotherapy (rituximab and interferon)
 - Endocrine therapy (corticosteroids and tamoxifen)
- Spontaneous tumor lysis syndrome (STLS) a rare entity that develops primarily in Burkitt lymphoma and leukemia absent any treatment
 - Increased purine metabolism from high tumor cell turnover rates leads to hyperuricemia and consequent uric acid nephropathy
 - Prompt recognition of STLS essential because it is associated with poor outcomes and high mortality rates
- Predisposing factors for developing ATLS include:
 - Large tumor burdens
 - Bulky lymphadenopathy
 - Extensive bone marrow involvement
 - Rapid tumor cell proliferation
 - Leukocytosis ($>50 \times 10^3$ cells/ μL)
 - Elevated lactate dehydrogenase (LDH) ($>1,500$ IU)
 - High tumor chemosensitivity

- Pretreatment hyperuricemia, renal dysfunction, and hypovolemia, and treatment with nephrotoxic agents confer increased risk of ATLS

Pathophysiology

- Rapid dissolution of cells with aggressive cytotoxic therapy results in:
 - Increase in plasma uric acid, potassium, and phosphorus levels
 - Hyperphosphatemia results in precipitation secondary hypocalcemia
 - Hyperkalemia occurs 6 to 72 hours after administration of chemotherapy
 - Associated manifestations include:
 - Lethargy
 - Nausea and vomiting
 - Diarrhea
 - Muscle weakness
 - Paresthesias
 - ECG abnormalities such as peaked T waves, PR-interval prolongation, and QRS-complex widening
 - Ventricular arrhythmias may lead to sudden death
 - Hyperphosphatemia is seen 24 to 48 hours following chemotherapy
 - Malignant cells have up to four times more phosphorous than nonneoplastic cells
 - As plasma phosphorous increases with cell lysis:
 - The normal renal mechanism that excretes excess phosphate and prevents distal tubular reabsorption becomes overwhelmed
 - Leading to hyperphosphatemia
 - Signs and symptoms of acute hyperphosphatemia are manifestations of secondary hypocalcemia, and range from:
 - No symptoms to anorexia, vomiting, confusion, neuromuscular irritability, tetany, carpopedal spasm, seizures, dysrhythmias, and cardiac arrest
 - Secondary hypocalcemia seen with hyperphosphatemia because:
 - Calcium phosphate precipitates when product exceeds 60, into:
 - Renal interstitium and tubules, resulting in nephrocalcinosis
 - Hypocalcemia persists after correction of hyperphosphatemia
 - Inappropriately low plasma calcitriol level present
 - Causes rise in serum PTH
 - Increases phosphate resorption in proximal tubule
 - Leads to nephrocalcinosis, acute renal failure
 - Hyperuricemia occurs 48 to 72 hours after chemotherapy
 - Patients may exhibit nonspecific symptoms such as:
 - Nausea, vomiting, anorexia, and lethargy
 - Acute renal failure with associated oliguria, edema, hypertension, and altered sensorium seen in untreated patients
 - Uric acid generated from hepatic purine metabolism
 - Adenosine and guanosine nucleotides degraded to hypoxanthine and xanthine, respectively
 - Xanthine oxidase converts these to uric acid

- Rapidly proliferating neoplastic cells have high turnover rates:
 - With accelerated purine catabolism from DNA and RNA degradation
 - Cells contain large amounts of purine nucleotides
 - With cytotoxic therapy, there is rapid rise in plasma uric acid
 - Uric acid excreted by kidneys through processes of:
 - GFR
 - Partial proximal tubular reabsorption
 - Distal tubular secretion
 - Clearance of uric acid independently proportional to:
 - Intravascular volume status
 - Urinary flow rate
 - May be significantly reduced in presence of dehydration or tubular obstruction from acute nephrocalcinosis or uric acid nephropathy
- Uric acid nephropathy develops when:
 - Urate deposit in renal tubules and collecting ducts because of acidic conditions
 - Urinary pKa of uric acid is 5.4
 - Luminal pH of distal tubules and collecting ducts is 5.0
 - Resulting in poor solubility of uric acid in acidic urine
 - Poor solubility, coupled with the marked hyperuricosuria present in ATLS, leads to:
 - Uric acid precipitation
 - Intraluminal obstruction
 - Oliguria
 - Acute renal failure
- Acute renal failure (ARF) in ATLS may also be mediated by:
 - Renal calculi from phosphate and uric acid precipitation
 - Ischemic acute tubular necrosis caused by renal hypoperfusion
 - Drug toxicity, sepsis, and tumor-associated obstructive uropathy or renal parenchymal infiltration may exacerbate ATLS-induced ARF

Classification

- No widely accepted definition of ATLS currently exists
- First classification of ATLS into laboratory TLS and clinical TLS
- Modified/further developed classification system into the Cairo-Bishop definition:
 - Uses laboratory and clinical data and grading scale to assess severity of ATLS
 - Laboratory TLS (LTLS) defined as two or more of following metabolic abnormalities occurring 3 days before or 7 days after chemotherapy:
 - Uric acid 8 mg/dL or greater
 - Potassium 6 mEq/L or greater
 - Phosphorous 6.5 mg/dL or greater
 - A 25% increase in baseline levels of these metabolites
 - Calcium 7 mg/dL or less
 - Or 25% decrease from baseline level
 - Clinical tumor lysis syndrome is defined as LTLS in addition to one or more of the following findings:

- Increased serum creatinine (1.5 times the upper limit of normal)
- Cardiac arrhythmia/sudden death
- Seizure
- The grading of ATLS from 0 through 5 is determined by:
 - Presence or absence of LTLS
 - Degree of serum creatinine elevation
 - Presence and severity of the cardiac arrhythmia and seizure

Prevention and Treatment

- Early recognition of patients at high risk for ATLS an essential component of management strategy so appropriate prophylactic interventions can be instituted

Fluids and Alkalinization

- Except in patients at risk for CHF
 - Aggressive IV hydration with isotonic or hypotonic saline the single most important intervention for both prevention and treatment of ATLS
 - Cytotoxic therapy should be delayed if possible to administer appropriate hydration
 - IV hydration should commence 2 days before and for 2 to 3 days after chemotherapy
 - At rate of 3,000 mL/m²/day or two to four times daily fluid maintenance
 - To achieve urine output of ≥ 100 mL/m²/hour
 - IV fluid increases intravascular volume, renal blood flow, GFR, and urine output (UOP):
 - Results in correction of electrolyte derangements by ECF dilution
 - Prevents phosphate and uric acid precipitation by increasing urinary excretion
- Volume expansion alone may be insufficient to maintain adequate UOP
 - Necessitating administration of diuretics
 - Once euvoemia achieved, and no signs of acute obstructive uropathy present
 - Furosemide, 0.5 to 1 mg/kg
 - 2 to 4 mg/kg for severe oliguria or anuria
 - May induce or improve UOP
 - Effectiveness of furosemide diminished with uric acid precipitation in renal tubules
 - Here, mannitol 0.5 mg/kg may be administered
- Alkalinization of urine to pH 7.0 or greater remains controversial
 - Practice based on biochemical properties of uric acid
 - 13 times more soluble at pH 7.0 than at pH 5.0
 - Maximal solubility attained at pH 7.5
 - Urine alkalinization (pH ≥ 6.5) enhances renal excretion of uric acid
 - Calcium phosphate precipitation increases with systemic alkalinization
 - Exacerbating nephrocalcinosis
 - Hypoxanthine and xanthine solubility substantially reduced
 - Leading to xanthine nephropathy with concurrent allopurinol therapy

Management of Hyperuricemia

- Allopurinol reduces risk of ATLS when administered 2 to 3 days prior to chemotherapy
 - Inhibits production of uric acid
 - Allopurinol a synthetic structural analogue of hypoxanthine and competitive inhibitor of xanthine oxidase
 - In presence of allopurinol, xanthine oxidase cannot catalyze conversion of hypoxanthine to xanthine and xanthine to uric acid
- Allopurinol
 - Administered orally at 300 to 800 mg daily
 - 10 mg/kg/day, or up to 400 mg/m²/day
 - In one to three divided doses
 - Titrated to uric acid level
 - IV allopurinol approved 1999; administered in doses of 200 to 400 mg/m²/day
 - To a maximum 600 mg/day in patients unable to tolerate orally
 - Dose adjustment of allopurinol required for reduced creatinine clearance
 - Several limitations with allopurinol therapy:
 - Reduction in serum uric acid level not seen before 48 to 72 hours after initiating drug
 - Agent inhibits uric acid synthesis but does not affect pre-treatment concentration
 - Inhibition of xanthine oxidase by allopurinol leads to increased plasma levels of xanthine and hypoxanthine, which may precipitate in renal tubules
 - 3% of patients develop hypersensitivity reactions
 - Including Stevens-Johnson syndrome
 - Interacts with drugs, including cyclosporine and azathioprine
 - Another agent that lowers uric acid concentration is urate oxidase
 - Converts uric acid to allantoin
 - Five to 10 times more soluble in urine than uric acid
 - Urate oxidase not expressed in human beings resultant from nonsense mutation in coding region during hominoid evolution
 - Recombinant urate oxidase, rasburicase, developed due to 4.5% of hypersensitivity reactions in nonrecombinant form
 - Rasburicase approved in 2002 for use in pediatric patients at risk for ATLS
 - Injectable dose of 0.15 to 0.20 mg/kg normalizes uric acid levels within 4 hours of administration in children and adults
 - May be repeated daily for a total of 5 days
 - Chemotherapy should be initiated 4 to 24 hours after first dose
 - Rasburicase does not generate increased xanthine and hypoxanthine levels
 - Thereby minimizing risk of uric acid nephropathy
 - Rasburicase contraindicated in patients with G6PD deficiency
 - Bronchospasm and anaphylaxis rarely occur with rasburicase therapy
 - Insufficient evidence that rasburicase reduces incidence of dialysis in ATLS
 - 5-day course of therapy is approximately 2,000 to 3,000 times more expensive than a 5-day course of oral allopurinol

– Cost-effectiveness must be considered in treatment plan

Correction of Electrolyte Abnormalities

- Because of potential for life-threatening dysrhythmias, prompt recognition imperative
 - Laboratory monitoring every 4 to 6 hours in first 24 hours of chemotherapy in patients at high risk for ATLS
 - Every 6 to 8 hours thereafter
 - Baseline ECG obtained to assess for cardiac effects
- Hyperkalemia
 - Treated with calcium gluconate to stabilize the cardiac membrane
 - IV insulin/dextrose and inhaled β_2 agonists to facilitate intracellular shift of K⁺
 - Sodium bicarbonate shifts K⁺ intracellularly by improving the metabolic acidosis
 - May result in inappropriate volume expansion
 - K⁺ binding resins
 - Sodium polystyrene sulfate, increase K⁺ elimination in GI tract
 - Have delayed hypokalemic effect
 - Diuretics administered to reduce serum K⁺ in patients without renal failure
 - When acute renal failure occurs, dialysis may be required emergently
- Asymptomatic hypocalcemia should be left untreated
 - To preclude calcium phosphate precipitation
 - Symptomatic hypocalcemia managed with IV calcium gluconate
 - Hyperphosphatemia treated with oral phosphate binders
 - Aluminum hydroxide or aluminum carbonate
 - Usually concurrently correct the hypocalcemia

Dialysis

- Indicated in patients with marked elevations in serum uric acid, phosphate, and potassium
 - That do not respond to aggressive treatment
 - In patients with ARF with volume overload, severe uremia, or acidosis
 - Hemodialysis used in ATLS
 - Superior to peritoneal dialysis in clearance of both uric acid and phosphorous

OBSTRUCTIVE SYNDROMES

Superior Vena Cava Syndrome (SVCS)

Definition

- SVCS describes set of signs and symptoms associated with obstruction of SVC
 - May be caused by extrinsic compression, vascular invasion, or intraluminal thrombosis of vein
 - SVC a thin-walled, compliant, low-pressure middle mediastinal vessel
 - Easily vulnerable to disease processes in adjacent right lung, paratracheal and perihilar lymph nodes, main stem bronchi, esophagus, and thoracic spinal cord
 - Percentage of cases attributable to cancer varies from 78% to 90% to 97%

- Recent retrospective study reported malignancy the cause of SVCS in 60% of patients
 - Bronchogenic carcinoma 85% to 90% of malignancies in which SVCS presents
 - SVCS develops in 2% to 10% of lung malignancies
 - Risk of SVCS higher in small cell lung cancer
 - Incidence of 6.6% to 12%
 - Because it involves the central mediastinal structures
 - Because of anatomic location of SVC
 - Right-sided lung cancers cause SVCS four times as often as left-sided lung cancers
 - Other neoplasms include:
 - Malignant lymphomas
 - Hodgkin lymphoma often involves mediastinum but rarely causes SVCS
 - Primary germ cell cancers, thymoma, mesothelioma, metastatic disease (primarily breast carcinoma) constitute a small proportion of SVCS cases
- Increasing proportion of benign causes related to presence of IV devices
 - Central venous catheters
 - Pacemaker wires
- Other benign causes of SVCS include:
 - Fibrosing mediastinitis from prior irradiation or histoplasmosis
 - Aortic dissection
 - Complications of surgery, such as aortic dissection repair

Clinical Presentation

- SVCS may be initial presentation of bronchogenic carcinoma and lymphoma
 - May arise in patients with previously documented malignancy
- Severity of signs/symptoms depends on extent, location, and onset rapidity of SVC occlusion
 - In general, obstruction within or below azygos vein results in more dramatic symptoms
 - Azygos venous capacity increases from 11% to 35% to augment head/neck drainage
 - Impedance of flow from obstruction precludes this auxiliary function
 - With slowly developing SVCS
 - Collateral vessels in chest wall and upper extremities are recruited as a diversion for existing SVC engorgement
 - SVCS here of insidious onset, as in fibrosing mediastinitis
- Most commonly reported symptom in SVCS:
 - Dyspnea
 - Followed by head and facial swelling
- Other cardiopulmonary symptoms include:
 - Cough, orthopnea, and chest pain
- Associated signs are:
 - Neck and arm vein distention
 - Plethora or cyanosis of the head and neck
 - Venous collateralization in the arms and upper chest wall
 - Chronic pleural effusions
- More extensive airway or vascular obstruction predicted when positional maneuvers such as lying supine or leaning forward exacerbate respiratory or cardiac symptoms
 - Respiratory insufficiency in supine position worsens as weight of mediastinal structures impinges on tracheobronchial tree
- In the substantially compromised patient with SVCS, cardiopulmonary arrest may ensue with sedative administration or general anesthesia
- Other head and neck signs and symptoms:
 - Conjunctival and periorbital edema, nasal congestion
 - Dysphagia and hoarseness due to laryngeal nerve compression
 - Proptosis, glossal edema, stridor secondary to laryngeal edema
 - Tracheal obstruction
- Central nervous system (CNS) manifestations include:
 - Mild headaches, dizziness, and lethargy with progression to syncope
 - In rapidly developing or complete SVC obstruction
 - Seizures or coma
 - From cerebral edema and increased intracranial pressure
- Bleeding complications such as epistaxis, hemoptysis, and GI hemorrhage from esophageal varices (in longstanding SVC) may occur

Diagnostic Investigations

- **Imaging:** Once clinical diagnosis of SVC syndrome is suspected, confirmation obtained using both radiologic and nuclide techniques
- Chest x-ray (CXR) shows:
 - Widening of superior mediastinum in approximately 60% of patients
 - Pleural effusions, most frequently right-sided, in up to 25% of patients
 - Normal chest radiograph does not exclude diagnosis
- Contrast-enhanced helical computed tomography (CT) accurately delineates site, extent, and cause of occlusion
 - As well as any associated thrombus and collateral vessel development
 - Radiologic diagnosis of SVCS made by demonstrating both decreased or absent venous opacification below level of obstruction and prominent collateral vessel opacification
- Magnetic resonance imaging (MRI) an alternative imaging method in patients with iodinated contrast allergy or without adequate venous access for contrast administration
 - Offers no distinct advantage over CT
- Venography most useful when planning bypass or stenting procedures
 - Superior to CT in identifying site and extent of obstruction and in mapping collateral circulation
 - Does not elucidate underlying cause of SVCS unless SVC thrombosis alone is the causative factor
- Radionuclide ^{99m}technetium venography a less invasive alternative to standard venography
 - Lacks image resolution of the latter
- Although not well established, helical CT phlebography
 - Involves simultaneous bilateral antecubital vein injection with IV contrast
 - Produces both detailed CT images of the mediastinum and CT venogram that correlates well with digital venography
 - Flow artifact (inhomogeneous contrast opacification) created by physiologic mixing of contrast-opacified and nonopacified blood may mimic intraluminal filling defects in patent vessels
 - Remains the major limitation of technique

- **Histologic Diagnosis:** Sputum cytology, thoracentesis, percutaneous needle biopsy, bronchoscopy, mediastinoscopy, or thoracotomy all methods used to obtain pathologic specimens
- Diagnostic yields are as follows:
 - Bronchoscopy, 50% to 70%
 - Transthoracic needle aspiration biopsy, 75%
 - Mediastinoscopy or mediastinotomy, >90%
- Well established that absent tracheal obstruction or severe laryngeal or cerebral edema, SVCS itself results in no life-threatening complications
 - Forgoing pathologic diagnosis unjustified, except in severe airway obstruction or cerebral edema
 - Identification of underlying condition guides appropriate treatment of SVCS in both benign and malignant disease

Treatment

- Primary goals of treatment are symptom relief and eradication or palliation of underlying malignancy
- Initial symptomatic management involves bed rest, head elevation to reduce venous pressure, and supplemental oxygen administration
 - Diuretics and sodium restriction anecdotally may decrease edema
 - Glucocorticoids to minimize inflammatory responses to tumor or radiotherapy (XRT) controversial
 - Steroids are mainstay of treatment in non-Hodgkin lymphoma (NHL)
- **Endovascular Stenting:** If above ineffectual in controlling symptoms, percutaneously placed endovascular stent can be inserted with or without balloon angioplasty
- Relief of symptoms occurs immediately after stent placement in 80% to 95% of patients
 - Morbidity increases with stent insertion if thrombolytics administered
 - Recurrence of SVCS occurs in 10% to 30% of patients after primary therapy with chemotherapy and/or radiation
 - Here, stent placement may be used for palliation
- **Thrombolysis:** With increased use of intravascular devices, thrombus accounts for larger proportion of the benign causes of SVCS
- SVCS attributable to thrombosis of central venous line and catheter preservation desired
 - Thrombolytic therapy given within 5 days of symptom onset associated with an 88% success rate versus 25% after 5 days
- **Radiotherapy and Chemotherapy:** Treatment modality selected individualized to type of malignancy, stage, and performance status of each patient
- Primary management of solid tumors and non–small cell lung cancer (NSCLC) involves XRT
 - NSCLC associated with SVCS carries a poor prognosis
 - 1-year survival 17%
 - In review of 1,635 patients median survival of 5 months
 - Treatment of choice in NSCLC is XRT and possible stent insertion
 - Within 72 hours of XRT, patients have relief of symptoms
 - Within 2 weeks, 70% to 90% of patients are symptom free
- Chemotherapy prolongs survival and improves quality of life in patients with small cell lung cancer (SCLC)
 - Addition of thoracic irradiation may reduce recurrence risk of SVCS
 - SVCS relieved in 77% of patients receiving chemotherapy and/or radiation
 - Relapse in 17% of patients
- Lymphoma and germ cell tumors usually treated with chemotherapy based on histologic type, grade, and stage of disease
- Hodgkin lymphoma, chemotherapy followed by XRT to areas of bulky disease may be indicated
- NHL, XRT alone may be used in early-stage disease, and chemotherapy is treatment for higher-stage tumors
- Whether to irradiate areas of bulky disease in NHL after chemotherapeutic remission unclear
 - With residual tumor or progression of disease after chemotherapy, radiotherapy is administered
- **Surgery:** Surgical bypass of obstruction with vein grafts or prosthetic grafts may be appropriate in benign SVCS
 - In patients with malignancy, surgical intervention, when no further treatment options are possible is palliative measure with poor long-term survival

ACUTE AIRWAY OBSTRUCTION

Oropharyngeal and Tracheal Obstruction

- Sudden upper airway obstruction (UAO) of the larynx, pharynx, or extrathoracic trachea is uncommon with cancers of the head and neck
- Tumors of larynx, pharynx, base of tongue, and thyroid are primarily slow growing
- Obvious signs and symptoms of airway compromise usually evident prior to development of acute obstruction
- Tracheal masses, which take years to be discovered, first become symptomatic when the airway lumen is narrowed by 75%
- Mechanisms of UAO include:
 - Direct tracheal invasion
 - Extrinsic tracheal compression
- Direct tracheal invasion seen with:
 - Locally advanced oropharyngeal tumors, laryngeal neoplasms associated with bulky or supraglottic lesions, and rarely, thyroid cancer and primary tracheal tumors
 - Tracheal impingement in lung cancer occurs with tracheal ingrowth of primary tumor
 - Originating in a main stem bronchus or from enlarging paratracheal or subcarinal lymph nodes
 - Bilateral vocal cord paralysis with recurrent laryngeal nerve paralysis associated with lung malignancies
 - Extrathoracic malignancies may metastasize to mediastinal and endobronchial lymph nodes, causing airway obstruction
 - Renal cell carcinoma, sarcomas, breast cancer, and colon cancer most commonly involved
 - Melanoma may arise as a primary tracheal tumor
 - More often is a metastatic lesion
- Tracheal compression
 - Usually attributable to benign disease
 - A secondary mechanism of UAO in neoplastic disease

- Often the initial presentation of mediastinal tumors and extensive lymphoma

Clinical Presentation

- Patients present with dysphagia, hoarseness, intractable cough, hemoptysis, dyspnea, or stridor
- Important goals during physical examination are:
 - To determine whether impending airway obstruction present
 - To localize site of lesion
- Once stridor apparent, airway caliber has narrowed to approximately 6 mm
 - Without intervention, complete UAO imminent
 - Inspiratory stridor implies an extrathoracic lesion at the level of the glottis or above
 - Expiratory stridor suggests an intrathoracic lesion
 - Biphasic stridor may be indicative of a subglottic or tracheal mass
 - Voice alteration, such as muffling and hoarseness, accompanies subglottic lesions and unilateral vocal cord paralysis, respectively

Diagnostic Investigations

- CXR may identify an obstructive neck mass and consequent tracheal deviation
- Flexible oropharyngeal or nasopharyngeal endoscopy performed to assess airway
- Once the airway stabilized, high-resolution CT of head and neck obtained
 - Provides comprehensive evaluation of sites of narrowing and size and extent of tumor in relation to adjacent structures
 - Spirometry demonstrates a plateau in inspiratory limb of flow-volume loop if there is a fixed obstructive lesion in extrathoracic trachea

Treatment

- Initial management includes head elevation and administration of cool humidified oxygen
- Inhalation of helium-oxygen mixture reduces the work of breathing
- Airway obstruction in patients with bulky oropharyngeal, laryngeal, or thyroid carcinomas will require emergent or elective tracheostomy.
 - Endotracheal intubation not recommended as it may exacerbate existing airway edema and hemorrhage.
- For intraluminal tracheal lesions, bronchoscopy with interventions such as laser therapy, brachytherapy, photodynamic therapy, or stenting may be performed to rapidly alleviate symptoms.
 - Stents also useful in palliating symptomatic extrinsic compression
 - Endotracheal intubation or stenting used to maintain airway when there is extrinsic compression from lymphoma or other highly radiosensitive or chemosensitive tumors with anticipation of rapid reduction of tumor mass
- Surgical resection indicated for primary airway tumors and for lung cancers without mediastinal lymph node involvement
 - In lung and thyroid cancers directly invading trachea, surgery may be curative

- Metastatic disease to the trachea requires palliative treatment

Intrathoracic Obstruction

- Intrathoracic airway obstruction may be present with intrinsic primary endobronchial tumors:
 - Bronchogenic carcinoma and carcinoid
 - With metastatic tumors or their associated lymphadenopathy (lung, renal, breast, thyroid, and colon cancers, and sarcoma or melanoma)
 - With bulky disease causing airway compression
- Symptoms often progress slowly over time
 - Patients complain of dyspnea, wheezing, or chest discomfort
 - Leading to misdiagnosis of asthma or bronchitis prior to development of fulminant airway obstruction
 - Postobstructive pneumonia a finding on initial presentation
 - With impending obstruction, patients may exhibit:
 - Hypertension, tachycardia, tachypnea, and significant pulsus paradoxus
 - Poor air movement, use of accessory muscles, and mental status changes, indicators of severe obstruction
 - Progressive symptoms may result in negative pressure pulmonary edema and anoxic brain injury
- Chest examination may reveal a prolonged expiratory time and wheezing
 - Respiratory symptoms unilateral with lesions below the carina
 - The CXR shows asymmetric lung fields, particularly on end expiration
- Stable patients should have a flow-volume loop performed
 - Intrathoracic, mobile tracheal lesion above the carina will demonstrate airway compression during expiratory phase
 - Producing flattening of expiratory limb of flow-volume loop
 - Whereas a plateau in both inspiratory and expiratory limbs will be observed with fixed obstructive lesions
- Chest CT defines tumor extent and location
 - Rigid bronchoscopy usually necessary to evaluate airway in impending obstruction
 - When obstruction severe, flexible bronchoscopy hazardous
 - Does not permit ventilatory support
 - Bronchoscope may obstruct the already narrowed airway lumen
- Treatment proceeds with general measures:
 - Oxygen or helium/oxygen supplementation, and possibly, steroids
 - If endotracheal intubation required, must recognize potential for hemodynamic compromise associated with asymmetric obstruction and significant increases in airway pressure distal to obstruction
 - Bronchoscopy with various interventions, including debridement, dilation, endotracheal stent placement, laser ablation, photodynamic therapy, and placement of brachytherapy catheters, may relieve symptoms.
 - External beam radiotherapy may also play a role.
 - In lung cancer, tracheal and carinal resection indicated in patients without mediastinal lymph node involvement for a potential cure

NEUROLOGIC SYNDROMES

Spinal Cord Compression

Etiology and Pathophysiology

- Malignant spinal cord compression (MSCC) a profoundly debilitating, but usually nonfatal, manifestation of metastatic cancer
 - Occurs in 5% to 10% of cancer patients
 - Term *malignant spinal cord compression* refers to epidural, intramedullary, and leptomeningeal disease
 - Focus of this section is on epidural spinal cord compression (ESCC)
 - Literature primarily discusses this population
 - Any malignancy capable of metastatic spread may give rise to MSCC
 - Prostate, breast, and lung cancers most commonly involved
 - Each accounting for 15% to 20% of cases
 - In combination, 60% of cases
 - Cumulative incidence of MSCC is specific to tumor type
 - Highest rates occurring in multiple myeloma (8%), prostate cancer (7%), and nasopharyngeal cancer (6.5%)
 - Other tumors include:
 - NHL and renal cell carcinoma, each representing 5% to 10% of cases
 - GI cancers, sarcoma, melanoma, thyroid cancer, and unknown primary carcinoma
 - Enlarging meningiomas, nerve sheath tumors, and leptomeningeal metastases may also compress the spinal cord
 - Nonmalignant causes of MSCC in cancer patients are:
 - Epidural abscesses in presence of immune compromise
 - Hematoma with bleeding diatheses
- MSCC has proclivity for thoracic spine
 - Estimated to occur in this location in approximately 60% to 66% of cases
 - 20% of cases involve lumbar spine
 - Prostate and colorectal carcinomas
 - Cervical spine is uncommon, 7% to 10% of cases
 - MSCC the initial manifestation of malignancy in 20% of patients
 - Carcinomas of the lung and unknown primary, multiple myeloma, and NHL accounted for 78% of patients with MSCC presenting with malignancy
 - Compared to 26% in patients with previously established malignancy
- Mechanisms by which MSCC occurs include:
 - Vertebral body invasion by tumor with possible vertebral collapse causing encroachment on anterior spinal cord (85%)
 - Direct extension into intervertebral space by paraspinal lymphoma, sarcoma, or lung cancer (10% to 15%)
 - Epidural or intramedullary space invasion (<5%)
- Mechanism of injury to the spinal cord mediated by white matter vasogenic edema and axonal swelling that result from cord compression
 - Venous hypertension, decreased spinal cord blood flow, and cord infarction ensue
 - Resulting in ischemic hypoxic neuronal injury

- Vascular endothelial growth factor (VEGF) generated in association with spinal cord hypoxia
 - Dexamethasone may down-regulate VEGF expression
 - Resulting in the beneficial actions of steroids in MSCC

Clinical Presentation

- Pain the primary presenting symptom in MSCC, occurring in 83% to 95% of patients
 - Characterized as localized, radicular, or referred
 - Seen for a median of 8 weeks prior to diagnosis
 - Focal bony pain is typically localized, dull or aching, and constant
 - Direct tenderness of involved vertebral body seen with periosteal destruction
 - With time, radicular pain occurs in dermatome of affected nerve root
 - Is severe, deep, and lancinating
 - Radicular symptoms occur most often in lumbosacral spine
 - May be unilateral or bilateral
 - The latter more frequent with thoracic spine involvement
 - Referred pain does not radiate, but appears in a region distal to the area of pathology
 - Sacroiliac pain may result from L1 compression
 - Pain of MSCC typified by worsening with recumbency
 - Secondary to distention of epidural venous plexus
 - Coughing, sneezing, or Valsalva maneuvers also exacerbate pain
 - Straight-leg raising identifies a lumbosacral radiculopathy
 - Neck flexion reproduces symptoms of thoracic radiculopathy
- Motor weakness present in 60% to 85% of patients on diagnosis of MSCC
 - Only one-third of patients complain of lower extremity weakness on initial presentation
 - Two-thirds are not ambulatory at time of diagnosis
 - Motor deficits at level of conus medullaris or above have a symmetric distribution
 - Paresis usually seen in extensors of upper extremities
 - Or flexors of the lower extremities, depending on location of lesion in spine
 - Upper motor neuron signs such as spasticity, hyperreflexia, and Babinski responses, may be present
 - Cervical lesions may lead to quadriplegia and respiratory collapse
- Sensory deficits, varying degrees of paresthesias, less common than motor deficits
 - Found in 40% to 90% of patients
 - Level of hypesthesia on examination occurs 1 to 5 levels below anatomic level of cord compression
 - Sensation of electric shock radiating through spine and extremities with neck flexion—*Lhermitte sign*—seen infrequently with cervical or thoracic neoplasms
 - Perineal paresthesias occur with cauda equina lesions
 - Gait ataxia may follow sensory loss impairment
 - In absence of sensory findings, impairment of spinocerebellar tract is considered
- Bowel and bladder dysfunction reflect autonomic dysfunction
 - A late manifestation of MSCC
 - Patients report urinary hesitancy and frequency
 - Both incontinence of urine, from poor sphincter tone or overflow of urine, and urinary retention may ensue

- At diagnosis, 50% of patients incontinent or catheter dependent
- Patients may also exhibit erectile dysfunction and impotence
- Constipation and incontinence of stool with diminished sphincter tone may be present
- Narcotics widely used in cancer patients
 - Are capable of precipitating urinary retention and constipation
 - Spinal lesions must be excluded before narcotic use is implicated

Diagnostic Investigation

- Imaging study of choice in evaluating MSCC is MRI
 - Noninvasive and provides high resolution of the tissues, including bony metastases and intramedullary pathology
 - MRI has sensitivity, specificity, and overall accuracy of 93%, 97%, and 95%, respectively
 - In detecting MSCC in patients with known malignancies, excluding primary CNS tumors
 - When entire spine is imaged beyond area of clinically determined cord compression
 - Multiple epidural metastases (MEMs) found in 30% of patients
 - Presence of MEMs may alter treatment strategy
 - Using whole-spine MRI in all patients undergoing imaging may be needed
 - Relative paucity of cervical spine metastases
 - If clinical presentation does not suggest cervical disease
 - May be acceptable to image thoracolumbar spine alone
 - Myelography with or without CT myelogram a more invasive tool than MRI
 - Used in imaging MSCC when MRI contraindicated
 - CT alone does not adequately define soft tissues and spinal cord
 - Plain radiographs and radionuclide testing have low sensitivity and specificity for MSCC
 - Plain films detect vertebral metastases at site of known cord compression only 80% of the time
 - Many metastases missed
 - The ability to visualize lesions requires that 30% to 40% of bone be eroded
 - Bone scintigraphy the most cost-effective and sensitive technique in imaging vertebral metastases
- Followed by 16 mg divided four times daily
 - Tapered over 2 weeks
- High-dose regimens (100-mg bolus)
 - Then 96 mg divided four times daily
 - Tapered over 2 weeks reserved for patients with paresis or paraplegia
- Ambulatory asymptomatic patients undergoing XRT may have corticosteroids withheld
- **Surgery and Radiation:** Direct decompressive surgery followed by XRT superior to XRT alone for patients with MSCC
 - 84% of surgery group versus 57% of XRT group were ambulatory after therapy
 - Those in surgery group were ambulatory for 122 days compared to 13 days in XRT group after treatment
 - Of patients unable to ambulate on entering study:
 - 62% of those receiving surgery and radiation versus 19% receiving XRT alone regained ability to ambulate
 - XRT alone should be used only for patients who are not surgical candidates
 - Radiotherapy useful in preserving neurologic function in subclinical MSCC
 - Most tumors causing MSCC are not chemosensitive

Prognosis

- Median survival in MSCC patients receiving XRT is 3 to 6 months
- Patients who initially present with paralysis or become paralyzed after treatment
 - Have shorter life expectancy than those who are ambulatory
- Ambulatory function on diagnosis of MSCC the most important predictor of outcome of ambulatory function after XRT
 - Underscores need for education of both clinician and patient to enable prompt recognition of MSCC
 - Delay in diagnosis attributed to patient's failure to identify symptoms AND diagnostic delays by the generalist and hospital practitioner
 - Leading to deterioration in motor or bladder function

CARDIAC TAMPONADE

- Goals of therapy are pain control and preservation of neurologic function
 - To improve quality of life
 - Narcotic and corticosteroids administration, XRT, and surgery may all be used
- **Corticosteroids:** 81% of patients receiving corticosteroids and XRT versus 63% of those receiving XRT alone remained ambulatory
 - At 6 months percentages were 59% and 33% in the two groups, respectively
 - Less well-established data regarding use of high-dose dexamethasone regimens
 - Although higher doses (100-mg vs. 10-mg boluses) may have greater clinical efficacy in improving posttreatment ambulation
 - Associated with higher proportion of adverse effects
 - Typical regimens include a 10-mg bolus
- Primary neoplasms of myocardium and pericardium are uncommon
 - Metastatic disease to pericardial space is frequently seen
- Primary pericardial tumors
 - Mesothelioma represents largest proportion
 - 40 times less common than metastatic disease
- Secondary malignancies include most frequently:
 - Lung
 - Breast and ovarian carcinomas
 - Melanoma
 - Lymphoma and leukemia
- Malignancy a primary cause of pericardial effusion in the United States
 - Pericardial tamponade resulting from malignant pericardial effusion (MPCE) represents at least 50% of reported cases of pericardial fluid collection requiring intervention
 - Autopsy series report MPCE seen in 2% to 22% of cancer patients

- These effusions are clinically quiescent, remaining unrecognized
- In some patients, MPCE the initial presentation of cancer
 - It signifies dismal prognosis, with most patients dying within 1 year
- Pericardial effusions in some cancer patients due to comorbid conditions
 - Radiation-induced pericarditis
 - Infection
 - Uremia
 - Myocardial infarction
 - Congestive heart failure
 - Pneumonia

Pathophysiology

- Mechanisms by which malignant disease generates MPCEs include:
 - Direct invasion of the pericardium or myocardium
 - Disruption of lymphatic flow from lymph node metastases or from prior radiotherapy to chest or mediastinum
 - Tumors that invade the pericardium directly or hematogenously, most often:
 - Lung cancer
 - Followed by lymphoma and breast cancer
- With either of aforementioned mechanisms
 - Pericardial fluid accumulates
 - Inhibits passive diastolic filling of normally low-pressure right heart structures
 - Producing jugular and abdominal venous hypertension
 - As pericardial effusion expands, the heart is further compressed
 - Leading to reduced diastolic compliance, decreased diastolic filling, and decreased stroke volume, cardiac output, and blood pressure
 - Right atrial and right ventricular collapse ensues
 - Resulting in frank tamponade, which, untreated, will lead to shock
 - *Pericardial reserve volume* is about 10 to 20 mL
 - Defined as volume that will just distend the pericardium
 - As pericardial effusion enlarges, capacity for stretch is exceeded
 - When fluid accumulates rapidly pericardium cannot stretch rapidly enough to accommodate added volume, and heart becomes compressed
 - Acute tamponade may occur with as little as 50 mL of fluid
 - When effusions develop chronically pericardium is able to compensate by stretching slowly over time
 - Phenomenon of stretch relaxation
 - In cancer patients, MPCE develops slowly
 - 2 L of pericardial fluid may be present before critical symptoms occur

Clinical Presentation

- Patients may be asymptomatic with small pericardial effusions
- Symptoms correlate with compressive effect of effusion on surrounding structures

- Including lung, trachea, and esophagus
- Symptoms include dyspnea, cough, chest pain, hoarseness, hiccups, and dysphagia
 - Patients may report feeling of uneasiness
- Most commonly reported physical sign is distension of jugular veins
 - Classic finding of the Beck's triad of hypotension, increased jugular venous pressure, and quiet heart sounds may be present in addition to the Kussmaul sign
 - Paradoxical jugular venous distention and increased jugular venous pressure on inspiration
 - Sinus tachycardia, hepatomegaly, and peripheral edema may be apparent
 - On cardiac examination, dullness beyond apical impulse and rales noted
 - In patients with inflammatory effusions pericardial rub often heard
 - Narrow pulse pressure frequently noted
 - Pulsus paradoxus observed in 77% of patients with acute tamponade
 - Decrease in systolic blood pressure >10 mm Hg
 - When low-output shock results from failure of compensatory mechanisms to maintain cardiac output
 - Patient exhibits cold, clammy skin, cyanosis, oliguria, and altered mental status

Diagnostic Investigations

- CXR shows water bottle-shaped heart
 - With widening of cardiac silhouette and, occasionally, pericardial calcifications
 - Pleural effusions present in one-third of cases
- ECG may demonstrate low-voltage QRS or nonspecific ST-T wave changes
 - Electrical alternans in the P wave and QRS complex rare noted in 0% to 10% of patients
 - Every other QRS complex has a lower voltage and/or reversed polarity
 - Echocardiogram precisely localizes pericardial fluid
 - Discerns quality of effusion (homogeneous vs. heterogeneous)
 - Determines whether loculations or bulky tumor are present
 - Assesses right and left ventricular function
 - Ascertain whether right atrial and right ventricular diastolic collapse present
 - On echocardiography, heart may swing in pendular fashion within pericardial fluid
 - Right heart catheterization the definitive standard for further defining pericardial effusion
 - Classically equalization of diastolic pressures across all cardiac chambers

Treatment

- Cardiac tamponade a class I indication for performing pericardiocentesis
 - Initial emergent intervention in malignant cardiac tamponade is to drain the effusion
 - Usually in conjunction with echocardiographic guidance

- Fluid sent for chemical analysis, microbiology, and cytology
- Effusion removed successfully in 97% of patients
- In absence of tamponade, systemic chemotherapy is administered as baseline treatment
- Precluding recurrences in 67% of cases
- Effective in controlling malignant effusions when tumors are chemosensitive
 - As in lymphoma, leukemia, and breast cancer
 - XRT highly effective (93%) in controlling malignant pericardial effusions in patients with lymphoma and leukemia
 - Radiation myocarditis or pericarditis a complication of radiotherapy
- Pericardiocentesis is performed in MPCE for symptomatic relief and to establish a cause
 - Fluid reaccumulates within 48 hours of initial pericardiocentesis
 - Intrapericardial sclerosing or cytostatic agents according to tumor type
 - Administered to prevent recurrence
 - Mechanism of action of sclerosing agents effect symphysis of visceral and parietal pericardium
 - Surgical approach to MPCE management:
 - Subxiphoid pericardiotomy for a pericardial window
 - Performed using local anesthesia
 - Has low recurrence rate
 - Tissue can be obtained for pathologic review
 - Small risk of myocardial laceration, pneumothorax, and mortality with procedure
 - 12% recurrence at 1 year and 4% reoperation rate for subxiphoid pericardiotomy
 - Pleuropericardiotomy and pericardiectomy have higher morbidity and mortality rates
 - Require general anesthesia
 - Rarely used in MPCE management
 - Percutaneous balloon pericardiotomy may become procedure of choice in future
 - Requires only local anesthesia
 - Facilitates passage of pericardial fluid into left pleural or peritoneal spaces
 - Have greater resorptive capacity
 - Major side effect is asymptomatic pleural effusion in most patients
 - Appears to be safe and effective technique in patients with large MPCEs and recurrent tamponade (90% to 97%)
 - Reaccumulation rates 0% to 6%
- Reaccumulation rates for other therapies administered after initial pericardiocentesis performed are:
 - Radiotherapy, 33%
 - Systemic chemotherapy, 30%
 - Sclerotherapy with tetracycline, 15% to 30%
 - Mechanical therapies, including indwelling pericardial catheter placement, balloon pericardiotomy, and thoracotomy with pericardiostomy, 0% to 15%
- Even if no reaccumulation of fluid
 - Cardiac function may remain impaired in presence of epicardial tumor infiltration
 - Diastolic dysfunction occurs due to constrictive effect of diseased epicardium surrounding heart
 - Effusive-constrictive pericarditis results in combination of tamponade and cardiac restriction

- Considered in differential diagnosis when patient develops hemodynamic collapse a few days after pericardiocentesis
- Pericardiectomy useful in alleviating constrictive component
- Mortality extremely high

Prognosis

- Survival after development of MPCE extremely poor
- Pericardial lesions contribute to or directly cause death in 86% of untreated patients with symptomatic MPCE
 - In a 275 patient series with MPCE
 - Median survival was 135 days
 - Chance of surviving the first year was 26%
 - Findings of male gender, lung cancer, positive fluid cytology for malignant cells, and clinical presentation of cardiac tamponade or hemodynamic collapse independently associated with poor survival
 - Another series concluded that poor prognosis was associated with positive fluid cytology
 - Median survival was 7.3 weeks versus 29.7 weeks in positive cytology and negative cytology groups, respectively
 - MPCE and abnormal cytology found to be independent predictors of death
 - These prognostic factors used to make practical and realistic treatment decisions

GASTROINTESTINAL EMERGENCIES

Neutropenic Enterocolitis (NE)

- NE is also known as necrotizing enteropathy, ileocecal syndrome, or typhlitis
- First described in adult patients with leukemia and lymphoma over 40 years ago
- Typhlitis recognized in 1970 as equivalent entity involving the cecum in children undergoing induction therapy for acute leukemia
- A life-threatening inflammatory syndrome in immunocompromised patient involving the terminal ileum, ascending colon, and cecum
- Disease affects both small and large bowel *neutropenic enterocolitis* most commonly used
- Cardinal features defining the syndrome are:
 - Fever, abdominal pain, and bowel wall thickening in patient with neutropenia
 - *Neutropenia* defined as neutrophil count of either:
 - <500 neutrophils/ μ L
 - Or <1,000 neutrophils/ μ L with expected precipitous decline to <500 neutrophils/ μ L
 - Disease may progress to bowel ulceration, necrosis, and perforation, and ultimately, sepsis and death
- NE occurs primarily in patients following aggressive cytotoxic therapy for:
 - Acute leukemia and other hematologic malignancies such as lymphoma, chronic leukemia, multiple myeloma
 - Rarely in solid tumors, such as colon, breast, testicular, lung, and pancreatic cancers

- Administration of drugs toxic to bowel mucosa can result in NE, such as:
 - Cytosine arabinoside
 - Cytarabine
 - Cisplatin
 - Fluorouracil
 - Vincristine
 - Doxorubicin
 - 5-fluorouracil
 - Thioguanine
 - Mercaptopurine
- NE rare in solid tumors
 - Case reports identifying syndrome in breast cancer patients receiving taxanes
 - Case reports of acute leukemia patients presenting with NE in absence of chemotherapy
 - Indicating that drug toxicity a predisposing factor not a prerequisite in the disease pathogenesis
- Other immunocompromised patients in whom NE occurs include:
 - Aplastic anemia
 - Cyclic neutropenia
 - Agranulocytosis
 - Felty syndrome
 - Thalassemia minor
 - Systemic lupus erythematosus
 - Human immunodeficiency virus (HIV) disease
 - Patients receiving immunosuppressive therapy for bone marrow/renal transplantation also at risk
- Incidence of NE in adults varies widely, ranging from 0.8% to 26%
 - Pooled incidence rate for adults hospitalized for treatment of hematologic malignancies and solid tumors and for aplastic anemia was 5.3%
 - In acute leukemia group receiving myelosuppressive therapy, with exclusion of transplant patients, it was 5.6%
 - Extrapolating from these findings, neutropenia rather than acute leukemia the primary risk factor for NE
 - Elsewhere, 88 (6%) of 1,450 consecutive patients treated for leukemia had clinical manifestations of NE
 - While incidence low, the high mortality rate associated with NE underscores its designation as an oncologic emergency
 - Initially mortality rates ranged from 50% to 100%
 - The above systematic review noted an observed rate of 50% or higher
 - Other published figures ranging between 40% and 50%

Pathogenesis

- NE has a predilection for the terminal ileum, cecum, and appendix
 - An explanatory factor is overall decreased blood supply to colon
 - Inherent to cecum is decreased vascularity and increased distensibility compared to other colonic segments
 - Progressive cecal distention may cause increasing intraluminal pressure and exacerbation of submucosal edema
 - Pathogenesis of NE is multifactorial and remains unclear
 - Drug-induced cytotoxic mucosal injury initiates the process

- Limiting cellular proliferation and generating glandular epithelial atypia and necrosis (cytosine arabinoside)
- Producing myenteric plexus degeneration (vincristine)
- Subsequently, mucosal barrier integrity is breached
 - Cells cannot rapidly regenerate to repair the damaged surface
- Bacterial translocation occurs, resulting in microbial infection and sepsis
- Marked neutropenia impairs host defense and promotes further microbial invasion
 - Bowel flora becomes altered
- Blood cultures are often positive for:
 - *Clostridium septicum*, *C. difficile*
 - *Escherichia coli*
 - *Pseudomonas*
 - *Klebsiella*
 - *Enterobacter*
 - *Staphylococcus*
 - Candidiasis, primarily *Candida albicans*, which colonizes mucosal surfaces, the most common fungal infection in neutropenic patients
 - Associated with high morbidity and mortality
 - These microbial infections lead to inflammation and edema
- With sustained profound neutropenia
 - Bacterial invasion is unconstrained
 - Results in transmural necrosis, hemorrhage, ulceration, and perforation
 - In addition to drug-induced mucosal injury, infiltration of mucosa with leukemic and lymphoproliferative cells and mucosal ischemia from sepsis-related hypotension may also participate in initiating and perpetuating mucosal injury

Symptoms

- Onset of NE is 7 to 10 days after treatment, when neutropenia is evident
- Clinical presentation includes:
 - Fever, occurring in 90% of all hospitalized neutropenic patients at any time
 - Nausea and vomiting
 - Abdominal pain
 - Watery or bloody diarrhea
- Physical examination may show:
 - Stomatitis with diffuse mucositis
 - Abdominal tenderness
 - Abdominal distention
 - Peritoneal signs suggestive of bowel perforation
 - In 60% to 80% of patients
 - Right lower quadrant tenderness is elicited
 - Palpation of a right lower quadrant mass usually indicates a thickened, dilated, fluid-filled cecum

Differential Diagnosis

- NE included in differential diagnosis whenever a neutropenic patient presents with fever and abdominal pain, particularly right lower quadrant pain
- Other entities that may mimic NE are:

- Pseudomembranous colitis
- Acute appendicitis
- Acute cholecystitis
- Acute pancreatitis
- Diverticulitis
- Ischemic colitis
- Ogilvie syndrome (colonic pseudo-obstruction)
- Chemotherapy-induced abdominal pain
- Ileus secondary to vincristine toxicity
- GI bleeding may occur in 35% of typhlitis cases
- Hemorrhage should suggest NE rather than appendicitis

Diagnostic Investigation

- On laboratory analysis, in addition to neutropenia, thrombocytopenia often seen
- Blood cultures positive in 50% to 82% of cases for bowel organisms
- Stool studies notable for absence of *C. difficile* toxin A
- Plain abdominal radiographs usually normal or nonspecific
- Findings may include:
 - Decreased right lower quadrant gas with dilated small bowel loops and air fluid levels consistent with distal bowel obstruction
 - Free intraperitoneal air after perforation
 - Pneumatosis coli
 - Localized or diffuse “thumb-printing” characteristic of mucosal edema
- Sonography assists in confirming diagnosis of NE
 - Excluding other differential diagnoses by detecting bowel wall thickening
 - Ultrasound useful in following clinical course of disease
 - Sonographic manifestations of NE include:
 - Rounded mass with dense central echoes and a wider hyperechoic periphery
 - Pseudopolypoid changes of the cecal mucosa
 - Pericolic fluid collections
 - Patients with sonographically detected bowel wall thickness >10 mm had significantly higher mortality rate (60%) than did those with bowel wall thickness ≤10 mm (4.2%)
- CT a more accurate modality for assessing cecal wall thickening and evaluating the extent of the colitis
 - Has utility in differentiating NE from appendicitis, appendiceal abscess, or pseudomembranous colitis
 - CT findings include:
 - Diffuse submucosal thickening and edema of the terminal ileum and ascending colon
 - Mural hemorrhage
 - Pericolic fluid collections
 - Abscess formation
 - Pneumatosis coli
 - Intraperitoneal free air
 - False-negative rates in identifying NE for CT, ultrasound, and plain radiographs are 15%, 23%, and 48%, respectively
- Barium enema unsafe because it may result in bowel perforation in presence of severely damaged, necrotic bowel
- Endoscopic evaluation generally avoided because it involves a high risk of perforation
 - In addition to hemorrhagic and infectious complications
 - May precipitate fulminant mural necrosis

- Colonoscopy has been performed in a few patients and shows irregular nodular mucosa, ulcerations, hemorrhagic friability, and a masslike lesion resembling carcinoma

Histopathology

- With difficulty of obtaining biopsy specimens, a tissue diagnosis is not required to confirm NE

Management

- Prospective trials or case control studies evaluating therapeutic interventions in NE lacking
- Management strategy remains controversial regarding decision to proceed with early surgical intervention versus conservative approach
 - Conservative management involves:
 - Bowel rest
 - IV fluid and blood product resuscitation
 - Broad-spectrum antibiotics, granulocyte colony-stimulating factor (G-CSF)
 - Parenteral nutrition
 - Use of omeprazole and gastric decompression not advocated
 - Antidiarrheal and narcotic agents should be avoided – Perpetuate ileus and promote bacterial overgrowth
 - Chemotherapy-induced NE may recur with future treatment
 - Further chemotherapy withheld until NE has completely resolved
 - Bowel decontamination helpful before subsequent chemotherapy
 - Selection of broad-spectrum antibiotics incorporates:
 - Infectious Diseases Society of America 2002 recommendations for febrile neutropenia
 - 2003 ISDA guidelines for complicated intra-abdominal infections
 - Without prompt antibiotic therapy, neutropenic patients with Gram-negative bacteremia have 40% mortality rate – Antibiotic(s) of choice in NE must have activity against both Gram-negative and anaerobic organisms
 - Options include:
 - Monotherapy
 - Carbapenem or piperacillin—tazobactam
 - Duotherapy
 - Antipseudomonal β -lactam plus aminoglycoside
 - Cefepime or ceftazidime plus metronidazole
 - Antifungal therapy with amphotericin B therapy
 - Considered for empiric therapy
 - In profoundly neutropenic patients with fevers beyond 5 days
 - ◻ Despite appropriately dosed antibiotics
 - G-CSF:
 - Increases cell division in myeloid precursor cells
 - Decreases bone marrow transit time
 - Modulates activity and function of developing and mature neutrophils
 - G-CSF recommended in febrile neutropenic patients with:
 - High risk for infection-associated complications

- Poor prognostic factors, such as:
 - Profound neutropenia (<100 cells/ μ L)
 - Sepsis
 - Pneumonia
 - Hypotension
 - Invasive fungal infection
 - Uncontrolled primary disease
 - NE undisputedly meets these criteria
- G-CSF administration in chemotherapy-related febrile neutropenia:
 - Reduces hospitalization time and time to neutrophil recovery
 - May have impact on infection-related mortality
 - Warrants further study
- Clinical improvement in NE patients usually seen:
 - After normalization of neutrophil count with discontinuation of chemotherapy
 - Symptoms start as white blood cell (WBC) count declines after chemotherapy
 - Recovery begins after the nadir when WBC is increasing
- No standard recommendations regarding surgical intervention in NE
 - Most patients unlikely to be surgical candidates
 - Surgery with laparotomy alone for patients with perforation and ileus
 - Patients who fail to improve or worsen (bowel perforation, peritonitis) after 2 or 3 days of conservative therapy warrant consideration for surgery
 - Surgery recommended for severe complications:
 - Abscess, necrotic bowel, and obstruction
 - Definitive indications for surgery include:
 - Intraperitoneal free air/perforation
 - Generalized peritonitis
 - Persistent bleeding in spite of correction of coagulopathy
 - Important considerations influencing decision to surgically intervene:
 - Patient's prognosis and comorbidities
 - Postoperative morbidity/mortality greater with coexistent disease
 - If surgery warranted, the procedure of choice is colectomy with ileostomy and mucous fistula
 - Primary anastomosis used in few patients
 - Extent of mucosal necrosis may be underestimated by the appearance of the serosa
 - Ensure complete resection of edematous bowel
 - Even in absence of necrosis and inflammation, to preclude fatal outcome

TOXICITY OF CHEMOTHERAPY

- Most antineoplastic agents therapeutic actions target rapidly proliferating malignant cells
- Agents interrupt fundamental cellular processes such as DNA, RNA, and protein synthesis
- Not completely specific to malignant cells and will also act on normal tissues
 - Causing multiple toxicities
- Rapidly regenerating cells, hematopoietic, GI mucosa, spermatogonia, and hair follicles may suffer transient toxicity

Pulmonary Toxicities

- Pulmonary toxicity—both acute and chronic—increasingly seen
- Chemotherapy-induced lung disease (CLD) describes:
 - Lung injury with multiple etiologic agents
 - Varying pathophysiologic mechanisms, including
 - Direct lung toxicity
 - Immunologic response
 - Increased capillary permeability
 - Corresponding clinical presentations are:
 - Interstitial pneumonitis/fibrosis
 - Hypersensitivity syndrome
 - Capillary leak syndrome
 - Each may result in fulminant respiratory failure
 - Symptoms can appear immediately or months after termination of therapy

Antitumor Antibiotics

- **Bleomycin:** An antitumor antibiotic used in treatment of lymphoma, germ cell tumors, cervical carcinoma, and head and neck squamous cell carcinoma
- Absence of bleomycin hydrolase in skin and lungs prevents deactivation of drug, accounting for selective toxicity
- Bleomycin interstitial pneumonitis the most ominous toxicity
 - Associated with 3% mortality rate
 - Occurring in 0% to 46% of patients receiving bleomycin-containing regimens
 - Either during treatment or up to 6 months after discontinuation
 - Toxicity mediated by mechanism of direct lung injury via generation of cytokines and free radicals
 - Sequelae are endothelial damage, inflammatory cell infiltration, fibroblast activation, and fibrosis
 - Conflicting evidence whether perioperative $\text{FiO}_2 > 0.24$ causes synergistic toxicity with bleomycin through production of free radicals
- **Mitomycin C:** Antibiotic used in treating solid tumors, primarily breast and lung carcinomas
- Mechanism of injury alkylation of endothelial cell DNA, precluding cell division
 - Associated with development of an interstitial pneumonitis/fibrosis
 - Usually 3 to 12 months after therapy
 - With 3% to 14% incidence
 - Mortality as high as 14% to 50%
 - Risk factors include:
 - Oxygen exposure
 - Prior irradiation
 - Other cytotoxic drug administration, such as:
 - Bleomycin
 - Cisplatin
 - Vinca alkaloids
 - Cyclophosphamide
 - Doxorubicin
 - Drug withdrawal, steroids, and avoidance of supplemental oxygen may be helpful
- Mitomycin–vinca alkaloid syndrome a unique entity
 - Occurs with 6% incidence after vinca alkaloid administered to patients receiving combination therapy with mitomycin and vinblastine
 - Not with vinca alkaloid alone

- Severe hypoxemia ensues with development of interstitial infiltrates on CXR
- Most patients show acute improvement within 24 hours with:
 - Oxygen
 - Diuretics
 - Occasionally, mechanical ventilation
- Chronic lung damage occurs in 60% of patients

Alkylating Agents

- **Carmustine (BCNU):** A nitrosourea used in management of CNS tumors and in induction therapy for bone marrow transplant (BMT)
 - Cytotoxicity mediated by alkylation of guanine in DNA
 - Carmustine causes dose-dependent pulmonary fibrosis
 - Carries highest incidence of fibrosis among nitrosoureas
 - Mortality rate ranges from 24% to 90%
 - In 1% and 30% of patients receiving high- and low-dose carmustine, respectively, early-onset fibrosis and alveolitis occurs
 - In up to 40% of patients undergoing induction for BMT, pulmonary fibrosis develops within 2 years
 - Late fibrosis observed up to 17 years after exposure
 - Concomitant radiotherapy, chronic obstructive pulmonary disease, and pneumoconiosis increase risk of carmustine toxicity
 - 60% of patients will respond dramatically to steroids

Microtubule-Targeting Agents

- **Taxanes:** Paclitaxel inhibits microtubule disassembly
 - Has activity against solid tumors such as non-small cell lung carcinoma, breast carcinoma, and ovarian carcinoma
 - Prepared in Cremophor, a castor oil-based solution
 - A type I hypersensitivity reaction, characterized by urticaria, bronchospasm, angioedema, and hypotension, occurs within 2 to 10 minutes of infusion of paclitaxel with a 3% to 10% incidence
 - Attributable to Cremophor vehicle rather than paclitaxel itself
 - Premedication with steroids and H₁ and H₂ blockers can curtail reaction

Antimetabolites

- **Cytosine Arabinoside:** Ara-C is a substituted nucleoside antimetabolite that disrupts DNA replication
 - Used in therapy of leukemia and NHL
 - One toxicity is abrupt onset of endothelial inflammation and capillary leak syndrome
 - Causing noncardiogenic pulmonary edema, acute dyspnea, and a diffuse interstitial and alveolar pattern
 - Management supportive and includes oxygen, diuretics, and mechanical ventilation when needed
- **Gemcitabine:** A pyrimidine analogue, structurally similar to ara-C
 - Has activity against tumors of the pancreas, lung (NSCLC), breast, and ovaries
 - Incidence of lung toxicity <1% to 1.4%
 - Proposed mechanism of injury involves pulmonary endothelial cell damage resulting in capillary leak syndrome
 - Symptoms of gemcitabine pulmonary toxicity range from:
 - Mild dyspnea to a fatal acute respiratory distress syndrome (ARDS)

- Increasing age, pulmonary neoplasm, and prior radiotherapy may be contributing risk factors
- Patients respond rapidly to corticosteroids, but fatalities do occur

Differentiation Agents

- **All-trans-Retinoic Acid:** ATRA is a differentiation agent used for the treatment of acute promyelocytic leukemia (APL)
 - It is associated with retinoic acid syndrome
 - Develops in 20% to 50% of APL patients receiving ATRA
 - Median of 7 days (range 0–35 days) after induction therapy
 - Clinical presentation includes fluid retention, weight gain, fever, and musculoskeletal pain, with progression to respiratory distress, pulmonary infiltrates, pleural and pericardial effusions, renal insufficiency, skin infiltrates, hypotension, and death
 - Corticosteroids highly effective when syndrome commences
 - Have limited utility once pulmonary symptoms apparent
 - Mechanism of pulmonary toxicity of ATRA is capillary leak syndrome

Monoclonal Antibodies

- **Trastuzumab:** A humanized monoclonal antibody targeting epidermal growth factor type 2 (HER2) receptor
 - In approximately 25% of breast cancers HER2 receptor overexpressed
 - Associated with a poor prognosis
 - Analysis of 25,000 patients identified bronchospasm as only manifestation of pulmonary toxicity
 - Nine cases (0.04%) were fatal
 - Most serious reactions commenced within 2 hours of infusion
 - Most fatalities were observed in patients with poor performance status and severe underlying pulmonary disease
- **Bevacizumab:** Recombinant humanized monoclonal antibody directed against VEGF
 - Inhibits binding of VEGF to receptors impairing angiogenesis
 - Approved for first-line treatment of advanced colorectal cancer in combination therapy
- **Alemtuzumab:** Monoclonal antibody to lymphocyte and monocyte CD52 antigen
 - Salvage therapy for chronic lymphocytic leukemia
 - In 16 patients with B-cell chronic lymphocytic leukemia, associated pulmonary toxicity in one patient was severe bronchospasm, responding to corticosteroids

Cardiac Toxicities

Antitumor Antibiotics

- **Anthracyclines:** Red-pigmented antibiotics (rhodomycins), which include doxorubicin, daunorubicin, idarubicin, and epirubicin
 - Active against broad spectrum of tumors, such as breast and esophageal carcinomas, Hodgkin and non-Hodgkin lymphomas, osteosarcomas, Kaposi sarcoma, and soft-tissue sarcomas

- Three mechanisms that lead to oxidative stress contribute to cardiac toxicity:
 - Mitochondrial dysfunction and consequent adenosine triphosphate depletion
 - Free radical lipid peroxidation by iron–doxorubicin complexes
 - Glutathione peroxidase depletion
 - Histopathology demonstrates myofibril dropout, vacuolization of myocardial cells, and necrosis
- Acute cardiotoxicities include nonspecific ST-T wave changes, supraventricular tachycardia (SVT), ventricular arrhythmias, myopericarditis, cardiomyopathy, and sudden death
- Cardiomyopathy is dose dependent
 - Classified as subacute and late
 - Subacute cardiomyopathy presents within 8 months of therapy, with a peak onset of 3 months
 - Late cardiomyopathy is observed after 5 or more years
- Continual decline in left ventricular function results in CHF
- Liposomal doxorubicin may reduce cardiotoxicity
- Dexrazoxane, an iron chelator with cardioprotective properties substantially reduces toxicity
- Toxic effects compounded by other therapies:
 - Trastuzumab, cyclophosphamide, dactinomycin, mithramycin, mitomycin, etoposide, melphalan vincristine, bleomycin, dacarbazine, and taxanes
- **Mitoxantrone:** Agent has structural similarity to anthracyclines
 - Used in metastatic breast cancer, acute myeloid leukemia, and NHL
 - Cardiac injury, like the anthracyclines, may involve iron chelation complexes
 - Arrhythmias and dose-dependent heart failure are toxicities
 - Incidence of moderate to severe decrease in left ventricular ejection fraction (LVEF) and of CHF is 13% and 2.6%, respectively, with cumulative dose ≤ 140 mg/m²
 - Doses below 110 mg/m² decrease incidence of heart failure
 - Incidence increases with doses > 160 mg/m²
- **Mitomycin C:** In addition to lung toxicity, mitomycin is cardiotoxic
 - Results in increased incidence of cardiac failure with cumulative doses > 30 mg/m²
 - Additive cardiotoxicity occurs when used in conjunction with anthracyclines
 - Superoxide free radicals may mediate toxicity

Alkylating Agents

- **Cyclophosphamide:** A nitrogen mustard alkylating agent effective in treating leukemia, lymphoma, multiple myeloma, mycosis fungoides, neuroblastoma, and ovarian cancer
 - Acute cardiotoxicity may develop with doses of 120 to 170 mg/kg given over 1 to 7 days in preparation for bone marrow transplantation
 - ECG may reveal decreased QRS amplitude, nonspecific T-wave abnormalities, poor R-wave progression, SVT and VT, and second-degree atrioventricular block
 - Acute fulminant CHF may occur in up to 28% treated with high-dose cyclophosphamide
 - CHF usually short lived and reversible
 - Drug is metabolized to its active form in the liver by the cytochrome P-450
 - More rapid metabolism amplifies the risk of CHF

- Another cardiotoxicity is hemorrhagic myocarditis
 - Putatively mediated by endothelial capillary injury
 - Results in pericardial effusion, tamponade, and death
 - Most effusions are treatable with corticosteroids and analgesics
- When purine analogue pentostatin used in bone marrow conditioning regimens in combination with cyclophosphamide
 - An increased incidence of fatal cardiac toxicity that includes myocardial infarction, CHF, and arrhythmias
- Possible additive effect of cyclophosphamide and anthracycline-induced cardiomyopathy, but data are conflicting
- **Iphosphamide:** An alkylating agent, with similar properties to cyclophosphamide
 - Used to treat lymphoma, leukemia, and testicular and bladder tumors
 - Arrhythmias and transient, reversible, dose-dependent CHF may be seen
- **Cisplatin:** Cross-links interstrand DNA
 - Used in treating cancers of the testes, bladder, ovaries, and other tumors
 - Bradycardia, SVT, acute ischemia, myocardial infarction (MI), and ischemic cardiomyopathy observed
 - Acute chest pain and palpitations associated with cisplatin infusion
 - Late complications occur 10 to 20 years after therapy
 - Hypomagnesemia and hypokalemia generated by cisplatin-induced tubular defects may exacerbate arrhythmias

Microtubule-Targeting Agents

- **Vinca Alkaloids:** Vinca alkaloids include vincristine and vinblastine
 - Used for management of hematologic malignancies and solid tumors
 - Vinorelbine, a semisynthetic derivative used in NSCLC therapy
 - Exert toxicity by inhibiting microtubule assembly
 - All possess vasoconstrictive properties
 - Hypertension, vasospastic myocardial ischemia, and myocardial infarction seen
 - Vinorelbine toxicity is more common in women than men
- **Taxanes:** Hypertension and cardiac arrhythmias, most commonly transient asymptomatic bradycardia observed with paclitaxel
 - Incidence of more significant bradyarrhythmias—Mobitz type I and II heart block and complete heart block—was 0.1%
 - Rarely see atrial and ventricular tachycardias, myocardial ischemia, and MI
 - Often in patients with underlying cardiac disease or electrolyte derangements
 - Docetaxel may lead to the potentiation of anthracycline cardiomyopathy

Antimetabolites

- **5-Fluorouracil and Capecitabine:** 5-FU a synthetic pyrimidine antimetabolite used in regimens for managing multiple solid tumors including gastrointestinal, breast, ovarian, and head and neck malignancies
 - Myocardial ischemia, possibly triggered by coronary vasospasm, well-known cardiac toxicity occurring with increased frequency in combination with cisplatin

- Silent ischemic ECG changes identified during 24 hours of observation in up to 68% of patients receiving a continuous 5-FU infusion
- Other cardiac manifestations include chest pain, angina, atrial and ventricular arrhythmias, MI, persistent ventricular dysfunction, sudden death, and cardiogenic shock requiring inotropic support
- Preexisting cardiac morbidity significantly increases risk of cardiotoxicity
 - Compared to no prior cardiac disease (15.1% vs. 1.5%)
- Given potential for severe cardiotoxicity, infusions terminated when chest pain occurs
- Oral equivalent of infused 5-FU is capecitabine
- Exhibits a similar cardiotoxicity profile to 5-FU

Topoisomerase Inhibitors

- **Etoposide:** A topoisomerase II inhibitor used primarily for treatment of refractory testicular tumors and small cell lung carcinoma
 - Hypotension the most common side effect
 - MI and vasospastic angina may also occur
 - Prior chemotherapy or mediastinal irradiation may increase MI risk after etoposide therapy

Biologic Response Modifiers (BRM)

- **Interferons:** Glycoprotein BRM classified according to their respective derivations:
 - Interferon-*alfa* (leukocytes)
 - Interferon-*beta* (fibroblasts)
 - Interferon-*gamma* (lymphocytes)
 - Used to treat various tumors including renal cell carcinoma, metastatic melanoma, multiple myeloma, Kaposi sarcoma, and some leukemias and lymphomas
 - Cardiovascular toxicities include hypertension or hypotension, ischemia in patients with coronary artery disease (CAD), MI, arrhythmias (20% incidence), sudden death, and cardiomyopathy characterized by resolution with termination of the infusion
- **Interleukin-2 (IL-2):** A glycoprotein BRM derived from helper T-lymphocytes
 - Approved for treatment of metastatic renal cell cancer
 - Most patients develop capillary leak syndrome and hypotension associated with decreased peripheral vascular resistance necessitating vasopressors
 - In 423 treatment courses with IL-2, 65% of patients required pressor support
 - In patients with CAD, direct myocardial toxicity precipitates ischemia, MI, arrhythmias, and death
 - IL-2 may also predispose to ventricular and supraventricular arrhythmias
 - Seen in 14% to 21% of patients

Differentiation Agents

- **All-*trans*-Retinoic Acid:** (See also Pulmonary Toxicities.) Pericardial effusions, cardiac tamponade, myocardial ischemia, fatal infarction, and thrombosis
- **Arsenic Trioxide:** A differentiation agent effective in treating relapsed acute promyelocytic leukemia
 - Like all-*trans*-retinoic acid, may cause the retinoic acid syndrome
 - Prolongation of QT interval is another complication seen in up to 63% of patients

- Leading to torsades de pointes and sudden death
- Degree of QT prolongation higher in presence of hypokalemia
 - Careful monitoring of electrolytes and maintaining levels in high normal range is prudent

Monoclonal Antibodies

- **Trastuzumab:** (See also Pulmonary Toxicities.) An increased risk of cardiotoxicity associated with trastuzumab
 - Highest in patients receiving concurrent:
 - Anthracycline plus cyclophosphamide (27%)
 - Concomitant trastuzumab and paclitaxel (13%)
 - Trastuzumab alone (3%–7%)
 - Mechanism of cardiac toxicity not well understood
 - Cardiac *erbB2* essential for myocyte function
 - Trastuzumab targets both *HER2* and *erbB2* receptors
 - Early symptom following initial treatment may be an asymptomatic decline in LVEF
 - With late progression to dilated cardiomyopathy
 - Risk factors for cardiovascular toxicity include older age, cumulative doxorubicin dosage 400 mg/m² or greater, and concurrent anthracycline and trastuzumab administration, rather than temporally separated dosing
- **Rituximab:** The CD20 antigen, present on normal and malignant B cells, the target of the chimeric murine/human monoclonal antibody rituximab
 - Used to treat leukemias and lymphomas, as well as benign diseases
 - Cardiac toxicity involves dysrhythmias and angina in <1% of infusions
 - Most adverse effects infusion related, usually occurring within 2 hours of first infusion
 - Acute infusion-related deaths reported in 0.04% to 0.07% of cases
 - Clinical presentation in these patients includes hypoxia, pulmonary infiltrates, ARDS, MI, ventricular fibrillation, and cardiogenic shock
 - Hypersensitivity reactions, including hypotension, angioedema, hypoxia, or bronchospasm, occur in up to 10% of cases
 - Management is supportive, using IV fluids, antihistamines, acetaminophen, bronchodilators, and vasopressors
- **Cetuximab:** Agent is human/mouse chimeric monoclonal antibody designed to target human epidermal growth factor receptor
 - Used alone or in combination therapy with irinotecan to treat metastatic colorectal cancer
 - Life-threatening infusion reactions occur in 3% of patients with:
 - Bronchospasm, urticaria, and hypotension
 - Interstitial pneumonitis with noncardiogenic pulmonary edema a rare toxicity
- **Bevacizumab:** (See also Pulmonary Toxicities.) Associated with CHF, hypertension, and arterial thromboembolism
 - With monotherapy, 2% of patients developed moderate to life-threatening (grades 2 to 4) left ventricular dysfunction
 - CHF developed in 14% of patients concurrently receiving anthracyclines, and in 4% of patients previously receiving anthracyclines or left chest wall irradiation
 - Clinical trials documented hypertension in 5% of patients, with reports of hypertensive crisis, hypertensive encephalopathy, and subarachnoid hemorrhage

- U.S. Food and Drug Administration warning to health care providers announcing demonstrated increased risk of arterial thromboembolic events, which include cerebrovascular accident, transient ischemic attack, MI, and angina
- Risk of fatal arterial thrombotic events doubled to 5% in patients receiving intravenous 5-FU and bevacizumab

Hematologic Toxicities

Thalidomide

- A sedative-hypnotic with anti-inflammatory properties
- Used in multiple myeloma patients to treat advanced and chemotherapy-refractory disease
- Mechanism of action is unclear
 - Immune modulation, antiangiogenesis, and tumor necrosis factor- α may play role
- Increased risk of venous thromboembolism (VTE) associated with agent
 - Occurs at a mean of 2 months of therapy
 - Lower extremity deep vein thrombosis (DVT) the most frequent thrombotic complication
 - Approximately 50% of patients will develop pulmonary embolism (PE)
 - Mechanism of thalidomide-induced DVT not well defined
 - Thalidomide may exert direct effect on endothelial cells injured by other chemotherapy agents such as doxorubicin
 - VTE rates with thalidomide monotherapy, thalidomide-dexamethasone, thalidomide-doxorubicin, and thalidomide-dexamethasone-doxorubicin
 - Were <5%, 9%, 12%, and 22%, respectively
 - This suggests role for VTE prophylaxis

Hormones

- **Estramustine:** Estramustine phosphate has hormonal properties because it contains nor-nitrogen mustard linked to 17 beta-estradiol.
 - Used in treatment of prostate cancer
 - Up to 10% of patients receiving estramustine have:
 - VTE and PE
 - Myocardial and cerebrovascular ischemia
- **Tamoxifen and Aromatase Inhibitors:** Tamoxifen and the aromatase inhibitors—anastrozole, letrozole, and exemestane—adjuvant therapy for early-stage estrogen receptor-positive breast carcinoma
 - Increased risk of VTE with tamoxifen
 - Incidence of VTE in general population is 0.12% per year and 0.09% per year in women
 - In women with early-stage breast cancer and no adjuvant treatment, compared to those receiving tamoxifen
 - Incidence increases to 0.4% over 5 years and 1.4% to 1.7% over 5 years, respectively
 - Incidence escalates to 10.8% over 5 years in same population of women
 - Receiving concurrent tamoxifen and chemotherapy
 - Aromatase inhibitors (AI) generally associated with lower risk of VTE than tamoxifen
 - At 5 years incidence of VTE with anastrozole 1.6% versus 2.4% with tamoxifen

Gastrointestinal Toxicities

Bevacizumab

- Associated with both bowel perforation and GI hemorrhage
 - In patients with metastatic colon cancer receiving irinotecan, fluorouracil, and leucovorin (IFL) plus bevacizumab, or IFL alone
 - GI perforation observed in six patients (1.5%) treated with IFL plus bevacizumab with one fatality compared to none in IFL group
 - More recent phase II trial adding bevacizumab to bolus 5-FU and leucovorin
 - Bowel perforation in 2% of cases
 - In advanced refractory colorectal cancer, severe to life-threatening GI hemorrhage (grades 3 and 4) seen in 3.8% patients

Genitourinary Toxicities

Cyclophosphamide and Ifosfamide

- Cyclophosphamide and ifosfamide induce early (within 72 hours of administration) hemorrhagic cystitis via their metabolite, acrolein
 - Causes denudation of bladder mucosa and bleeding
 - Early hemorrhagic cystitis was observed in over 40% of bone marrow transplants
 - Rate dramatically declined to 5% with aggressive hydration regimens and administration of the thiol mesna
 - Mesna a type of thiol that inactivates acrolein in bladder after being converted to active form in kidney
 - Must be administered prior to cyclophosphamide infusion and continued after infusion terminated consequent to its shorter half-life
 - Cases of hemorrhagic cystitis progressing to intractable or profuse bleeding
 - Bladder irrigation and cystoscopy with clot extraction and fulguration may be necessary to achieve hemostasis
 - Cystectomy, vascular ligation, or hyperbaric therapy required in recalcitrant cases
 - Late occurring hemorrhagic cystitis starts 72 hours after administration of preparatory regimens in bone marrow transplantation
 - Risk factors including viral infections, busulfan use, pelvic irradiation, older age at transplantation, allogeneic transplantation, and graft versus host disease

Mitomycin C

- One life-threatening manifestation of mitomycin is thrombotic thrombocytopenic purpura-hemolytic uremic syndrome (TTP-HUS)
 - A distinct multiorgan disorder distinguished by:
 - Thrombocytopenia
 - Microangiopathic hemolytic anemia (MAHA)
 - Tissue ischemia
 - Precipitated by platelet agglutination in the arterial microvasculature
 - Classic pentad no longer required to make the diagnosis
 - Fever, thrombocytopenia, MAHA, renal failure, neurologic dysfunction

- New definition encompasses a broad spectrum of conditions in which unexplained thrombocytopenia and MAHA are present
- Of chemotherapeutic agents associated with TTP-HUS, mitomycin the most common
 - Bleomycin, cisplatin, and gemcitabine also causes of syndrome
- Pathogenic mechanism of mitomycin C-induced TTP-HUS may involve:
 - Chemotherapy-induced endothelial cell injury
 - Circulating immune complexes against tumor-related antigens
- In some cancer patients difficult to attribute TTP-HUS to mitomycin
 - Because malignancy-induced TTP-HUS clinically indistinguishable from mitomycin-induced disease
- TTP-HUS typically seen 4 to 8 weeks following final dose of mitomycin
 - Usually present with dyspnea from noncardiogenic pulmonary edema
 - May progress to ARDS and may mimic mitomycin lung toxicity
 - Renal failure generally present
 - Neurologic symptoms infrequent
- Patients with mitomycin-induced TTP-HUS do not respond to plasmapheresis
 - Immunoadsorption of plasma over a staphylococcal protein A column to remove immune complexes may be effective
 - Prognosis of mitomycin-induced TTP-HUS is poor
 - Most patients succumb to pulmonary or renal failure or to underlying malignancy within 4 months

Na, sodium; Cl, chloride; K, potassium; Ca, calcium; Mg, magnesium; D₅W, 5% dextrose in water; NaCl, sodium chloride; NS, normal saline.

OSMOLALITY

Calculated serum osmolality

$$= 2[\text{Na}^+] + \frac{[\text{glucose}]}{18} + \frac{[\text{BUN}]}{2.8} + \frac{[\text{mannitol}]}{18} + \frac{[\text{EtOH}]}{4.6} + \frac{[\text{ethylene glycol}]}{6.2} + \frac{[\text{methanol}]}{3.2}$$

[Normal 275–290 mmol/kg]

Osmolar gap =

Measured serum osmolality – Calculated serum osmolality

[0–5 mOsm/kg]

Sodium (Na^+)

Pseudohyponatremia with hyperglycemia

Each 100-mg/dL increase in serum glucose (above 100 mg/dL) decreases Na^+ by 1.6 mmol/L

Free water deficit in hypernatremia

$$= (0.6) (\text{body weight in kg}) \left(\frac{[\text{Na}^+]}{140} - 1 \right)$$

Free water excess in hyponatremia

$$= (0.6) (\text{body weight in kg}) \left(1 - \frac{[\text{Na}^+]}{140} \right)$$

POTASSIUM (K^+)

$[\text{K}^+]$ increases 0.6 mmol/L for each 0.1-unit decrease in pH

APPENDIX B: ACID-BASE

TABLE B.1

ANTICIPATED CHANGES IN SIMPLE DISTURBANCES

Primary disorder	Primary	Secondary	Compensation	Limit	Net effect
Metabolic acidosis	↓ $[\text{HCO}_3^-]$	↓ PaCO_2	$\Delta \text{PaCO}_2 = 1.0\text{--}1.4 \times \delta [\text{HCO}_3^-]$	10 mm Hg	↑ $[\text{H}^+]$ (↓ pH)
Metabolic alkalosis	↑ $[\text{HCO}_3^-]$	↑ PaCO_2	$\Delta \text{PaCO}_2 = 0.5\text{--}1.0 \times \delta [\text{HCO}_3^-]$	55 mm Hg No hypoxia	↓ $[\text{H}^+]$ (↑ pH)

CAUSES OF SIMPLE ACID-BASE DISTURBANCES

A. Metabolic acidosis

1. Increased anion gap (usually decreased chloride)

a. Acidosis

1. Alcoholic ketoacidosis
2. Diabetic ketoacidosis
3. Starvation ketoacidosis
4. Ethylene glycol ingestion
5. Paraldehyde
6. Methanol ingestion

7. Lactic acidosis

8. Uremic acidosis

9. Hyperosmolar nonketotic coma

b. Nonacidosis

1. Hypokalemia
2. Hypocalcemia
3. Hypomagnesemia
4. Hyperalbuminemia
5. Nitrate usage
6. Penicillin/carbenicillin
7. Pseudohyponatremia
8. Pseudohypochloremia
9. False decrease in serum HCO_3^-

2. Normal anion gap (usually increased chloride)
 - a. Acidosis
 1. Carbonic anhydrase inhibitors
 2. Ureterosigmoidostomy
 3. Ileostomy
 4. Diarrhea
 5. Pancreatic fistula
 6. Parenteral nutrition
 7. Ingestion of NH_4Cl
 8. Ingestion of HCl or other acid
 9. Renal tubular acidosis
 10. Dilutional acidosis
 11. Following respiratory alkalosis
 12. Cholestyramine
 13. Normal saline infusions
 - b. Nonacidosis
 1. Hyperkalemia
 2. Hypocalcemia
 3. Hypomagnesemia
 4. Hypoalbuminemia
 5. IgG
 6. Lithium
 7. Pseudohyponatremia
 8. Pseudohyperchloremia
 9. False increase in serum HCO_3^-
- B. Metabolic alkalosis
 1. Loss of H^+
 - a. Gastrointestinal loss
 1. Vomiting, nasogastric suction
 2. Antacids
 3. Chloride-depleting diarrhea
 - b. Renal loss
 1. Diuretics
 2. Excess mineralocorticoid
 3. Postchronic hypercapnia
 4. Decreased chloride intake
 5. High-dose penicillins
 6. Hypercalcemia
 - c. Intracellular H^+ shift
 1. Hypokalemia
 2. Refeeding
 2. HCO_3^- retention
 - a. Massive transfusions
 - b. NaHCO_3 therapy
 - c. Milk-alkali syndrome
 3. Volume contraction
 - a. Diuretics
 - b. Gastrointestinal losses in patients with achlorhydria
 - c. Sweat losses in cystic fibrosis
- C. Respiratory acidosis
 1. Central nervous system (CNS) depression
 2. Chronic obstructive lung disease
 3. Severe asthma
 4. Pneumothorax
 5. Abdominal distention
 6. Pulmonary edema
 7. Mechanical underventilation
 8. Idiopathic hypoventilation
 9. Neuromuscular disease
- D. Respiratory alkalosis
 1. Salicylate toxicity
 2. Hepatic failure
 3. Psychogenic hyperventilation
 4. Pulmonary edema
 5. Asthma
 6. Systemic inflammatory response syndrome
 7. Restrictive lung disease
 8. Primary CNS disease
 9. Mechanical overventilation
 10. Hypoxemia

APPENDIX C: FORMULAS

CEREBRAL/NEUROLOGIC FORMULAS

Intracranial pressure (ICP)

[<20 cm H_2O , <15 mm Hg]

Cerebral perfusion pressure (CPP) = MAP – ICP

[70–100 mm Hg]

Cerebral vascular resistance (CVR)

[1.5–2.1 mm Hg/100 g/min/mL]

Cerebral blood flow (CBF) = CPP/CVR

[75 mL/100 g gray matter/min]

[45 mL/100 g white matter/min]

Jugular bulb saturation ($\text{S}_{\text{JV}}\text{O}_2$)

[55%–70%]

Cerebral metabolic rate (CMRO_2) = (CBF) ($\text{CaO}_2 - \text{C}_{\text{JV}}\text{O}_2$)

[3–3.5 mL/100 g/min]

Cerebral oxygen extraction = $\frac{\text{CMO}_2}{(\text{CBF})(\text{CaO}_2)} = \frac{\text{CaO}_2 - \text{C}_{\text{JV}}\text{O}_2}{\text{CaO}_2}$

HEMODYNAMIC FORMULAS

Pulse pressure = systolic BP – diastolic BP

Mean arterial pressure (MAP) = $\frac{\text{SBP} + 2(\text{DBP})}{3}$

[70–105 mm Hg]

Central venous pressure (CVP)

[0–8 mm Hg]

Mean pulmonary artery pressure ($\overline{\text{PA}}$)

[10–20 mm Hg]

Pulmonary artery occlusion pressure (PAOP)

[4–12 mm Hg]

Cardiac output (CO) = Stroke volume (SV) × Heart rate (HR)

[4–8 L/min]

Cardiac index (CI) = $\frac{\text{CO}}{\text{BSA}}$

[2.5–4.0 L/min/ m^2]

$$\text{Pulmonary vascular resistance (PVR)} = \frac{(\overline{PA} - PAOP)80}{CO}$$

[150–250 dyne/s/cm⁻⁵]

$$\text{Pulmonary vascular resistance index (PVRI)} = \frac{(\overline{PA} - PAOP)80}{CI}$$

[100–240 dyne/s/cm⁻⁵/m²]

$$\text{Systemic vascular resistance (SVR)} = \frac{(MAP - CVP)80}{CO}$$

[800–1,200 dyne/s/cm⁻⁵]

$$\text{Systemic vascular resistance index (SVRI)} = \frac{(MAP - CVP)80}{CI}$$

[1,300–2,900 dyne/s/cm⁻⁵/m²]

$$\text{Stroke volume index (SVI)} = \frac{CI}{HR}$$

[40 ± 7 mL/beat/m²]

Right ventricular stroke work index (RVSWI)

$$= SVI(\overline{PA} - CVP)(0.0136)$$

[6–10 g · meter/m² per beat]

Left ventricular stroke work index (LVSWI)

$$= SVI(MAP - PAOP)(0.0136)$$

[43–56 g · meter/m² per beat]

Arterial O₂ content (CaO₂) = O₂ combined with hemoglobin + O₂ dissolved in the plasma

[1 g Hb binds 1.36 mL O₂]

$$= (1.36)(Hb)(SaO_2) + 0.0031(PaO_2)$$

[20 mL O₂/dL]

Mixed venous O₂ saturation (SvO₂)

[75%]

$$\begin{aligned} \text{Mixed venous O}_2 \text{ content (CvO}_2) &= (1.36)(Hb)(SvO_2) \\ &+ 0.0031(PvO_2) \end{aligned}$$

[15 mL O₂/dL]

$$\text{O}_2 \text{ delivery } (\dot{D}O_2) = CO \times CaO_2 \times 10$$

[600–1,000 mL O₂/min]

$$\text{Oxygen delivery indexed (DO}_2\text{I)} = CI \times CaO_2 \times 10$$

[500–600 mL/min/m²]

$$\text{O}_2 \text{ consumption } (\dot{V}O_2) = CI(CaO_2 - CvO_2)$$

[110–150 mL/min/m²]

$$\text{O}_2 \text{ extraction ratio} = \frac{(CaO_2 - CvO_2)}{CaO_2}$$

[25%]

RESPIRATORY FORMULAS

Oxygenation

Fraction of inspired O₂ (FIO₂)

[0.21–1.0]

Respiratory quotient (R) = VCO₂ expired/VO₂ inspired

[Normal: 0.8]

Barometric pressure (PB)

[760 mm Hg at sea level]

Partial pressure of H₂O (PH₂O)

[47 mm Hg at 37°C]

Partial pressure of inspired O₂ (PIO₂) = FIO₂ (PB – PH₂O)

[150 mm Hg at sea level]

Partial pressure of alveolar O₂ (PAO₂) (alveolar gas equation)

$$\begin{aligned} PAO_2 &= FIO_2 (PB - PH_2O) - \frac{PaCO_2}{R} \\ &= (FIO_2 \times 713) - (PaCO_2/0.8) \text{ (at sea level)} \\ &= 150 - (PaCO_2/0.8) \text{ (at sea level on room air)} \end{aligned}$$

[Range: 100 mm Hg on room air; 673 mm Hg on 100% O₂]

Partial pressure of arterial O₂ (PaO₂)

[70–100 mm Hg]

Increased: hyperventilation, increased FIO₂, contaminated sample

Decreased: hypoventilation, decreased FIO₂, \dot{V}/\dot{Q} mismatch, intrapulmonary or anatomic R → L shunt, diffusion abnormalities

Alveolar–arterial O₂ gradient (P(A – a)O₂) = PAO₂ – PaO₂

[3–16 mm Hg on room air; 25–65 mm Hg on 100% O₂]

Ventilation

Partial pressure of arterial CO₂ (PaCO₂)

[46 mm Hg]

Partial pressure of alveolar (expired) CO₂ (P \bar{E} CO₂)

Dead-space ventilation (VD): Portion of VT that does not participate in gas exchange

VD = anatomic dead space + physiologic dead space

[150 mL]

Engelhoff modification of the Bohr formula for dead space

$$\frac{VD}{VT} = \frac{PaCO_2 - PECO_2}{PaCO_2}$$

Minute ventilation (VE) = respiratory rate × VT

Pulmonary capillary blood O₂ content (CcO₂)

$$= 1.36 (Hb) (SaO_2) (FIO_2) + 0.003 (PBH_2O - PaCO_2) (FIO_2)$$

$$\text{Shunt fraction } (\dot{Q}_s/\dot{Q}_t) = \frac{CcO_2 - CaO_2}{CcO_2 - CvO_2}$$

Lung Volumes

Tidal volume (VT): Volume inspired/expired with each breath
[500 mL; 6–7 mL/kg lean body weight]

Inspiratory reserve volume (IRV): Maximal inspired volume end-tidal inspiration

[25% of vital capacity (VC)]

Inspiratory capacity (IC): Maximal volume inspired from resting expiratory level

$$IC = IRV + VT$$

[1–2.4 L]

Expiratory reserve volume (ERV): Maximal expired volume from end-tidal inspiration

[25% of vital capacity (VC)]

Residual volume (RV): Volume remaining in lungs after maximal expiration

[1–2.4 L]

Functional residual capacity (FRC): Volume remaining in lungs at end-tidal expiration

$$FRC = ERV + RV$$

[1.8–3.4 L]

Vital capacity (VC): Maximal volume expelled by forceful effort after maximal inspiration

$$VC = IRV + ERV + VT$$

[3–5 L; 50–60 mL/kg lean body weight in females; 70 mL/kg lean body weight in males]

Total lung capacity (TLC): Volume in lungs at end of maximal inspiration

$$TLC = VC + RV$$

[4–6 L]

Lung Mechanics

Plateau pressure (Pplat)

Peak inspiratory pressure (PIP)

Positive end-expiratory pressure (PEEP)

Compliance = change in volume/change in pressure

$$\text{Static compliance (Cst)} = \frac{VT}{P_{\text{plat}} - \text{PEEP}}$$

[70–160 mL/cm H₂O (paralyzed/anesthetized and supine)]

$$\text{Dynamic compliance (Cdyn)} = \frac{VT}{PIP - \text{PEEP}}$$

[50–80 mL/cm H₂O (paralyzed/anesthetized and supine)]

RENAL FORMULAS

$$\text{Creatinine clearance (Cl}_{\text{Creat}}) = \frac{(U_{\text{Creat}})(\text{urine volume})}{P_{\text{Creat}}}$$

Fractional excretion of sodium (FeNa⁺)

$$= \frac{\text{urine [Na}^+]}{\text{plasma [Na}^+]} \times \frac{\text{plasma [creatinine]}}{\text{urine [creatinine]}} \times 100$$

Free water clearance

$$= \text{urine vol} - \frac{\text{urine osmolality}}{\text{plasma osmolality}} \times \text{urine vol}$$

TABLE C.1

DAILY RENAL EXCRETION OF CATIONS AND ANIONS IN NORMALS

Electrolyte	Urinary excretion (mmol/d)
CATIONS	
Na	127 ± 6
K	49 ± 2
Ca	4 ± 1
Mg	11 ± 1
NH ₄	28 ± 2
Total	219 ± 3
ANIONS	
Cl	135 ± 5
SO ₄	34 ± 1
PO ₄	20 ± 1
Organic anions	29 ± 1
Total	221 ± 6

Na, sodium; K, potassium; Ca, calcium; Mg, magnesium; NH₄, ammonia; Cl, chloride; SO₄, sulfate; H₂PO₄, phosphate.

From Goldstein MB, Bear R, Richardson RMA, et al. The urine anion gap: a clinically useful index of ammonium excretion. *Am J Med Sci.* 1986;292:198, with permission.

TABLE C.2

USE OF URINE ELECTROLYTES

Diagnostic problem	Urinary value	Primary diagnostic possibilities
Volume depletion	Na = 0–10 mmol/L	Extrarenal sodium loss
	Na > 10 mmol/L	Renal salt wasting or adrenal insufficiency
Acute oliguria	Na = 0–10 mmol/L	Prerenal azotemia
	Na > 30 mmol/L	Acute tubular necrosis
Hyponatremia	Na = 0–10 mmol/L	Severe volume depletion, edematous
	Na > dietary intake	Inappropriate antidiuretic hormone secretion; adrenal insufficiency
Hypokalemia	K = 0–10 mmol/L	Extrarenal K loss
	K > 10 mmol/L	Renal K loss
Metabolic alkalosis	Cl = 0–10 mmol/L	Cl-responsive alkalosis
	Cl = dietary intake	Cl-resistant alkalosis

Na, sodium; K, potassium; Cl, chloride.

TABLE C.3

INTERPRETATION OF URINE ELECTROLYTES

Electrolyte	Normal response	Patient response	Potential pitfalls
Na ⁺	Reflects diet and ECF volume; <10 mmol if ECF vol contracted	>20 mmol in ECF vol contraction suggests renal tubular damage	Diuretic use No reabsorbed anions Recent vomiting, drugs
Cl ⁻	Reflects diet and ECF volume; <10 mmol if ECF vol contracted	>20 mmol with ECF vol contraction suggests renal damage	Diuretic Diarrhea
K ⁺	Reflects diet, plasma [K], aldosterone action	If hypokalemia and urine [K] >20 mM or rate of K excretion >30 mmol/d then K excretion too high	K-sparing diuretics Low urine [Na] Water diuresis
pH	Depends on acid-base status Useful for bicarbonaturia	Useful once low NH ₄ ⁺ excretion confirmed to define cause of low NH ₄ ⁺	Unreliable for urine NH ₄ ⁺ Urinary tract infection
HCO ₃ ⁻	Depends on diet and acid-base status; >10 mM indicates HCO ₃ ⁻ load 0 in acidemia	High urine HCO ₃ ⁻ with chronic metabolic alkalosis indicates vomiting or HCO ₃ ⁻ input High urine HCO ₃ with acidemia in pRTA	Urinary tract infection Carbonic anhydrase inhibitors
(Na ⁺ , K ⁺ , Cl ⁻)	Depends on diet and acid-base status	Na + K > Cl = low urine NH ₄ ⁺ Cl > Na + K = high urine NH ₄ ⁺	Ketonuria Drug anions Alkaline urine

Na⁺, sodium; Cl, chloride; K⁺, potassium; HCO₃⁻, carbonate; NH₄, ammonia; ECF, extracellular fluid; pRTA, partial renal tubular acidosis; vol, volume.

From Halperin ML, Goldstein MB. *Fluid, Electrolyte and Acid-Base Emergencies*. Philadelphia: WB Saunders; 1988, with permission.

TOXICOLOGY FORMULAS

Serum methanol concentration [MeOH] in mg/dL

$$= 3.2(\text{Osm}_s - (2 \times [\text{Na}^+]) - ([\text{BUN}]/2.8) - ([\text{glucose}]/18) - ([\text{EtOH}]/4.6) - 10)$$

$$\text{Ethylene glycol concentration} = 6.2(\text{Osm}_s - (2 \times [\text{Na}^+]) - ([\text{BUN}]/2.8) - ([\text{glucose}]/18) - ([\text{EtOH}]/4.6) - 10)$$

INFECTIOUS DISEASES FORMULAS

Antibiotic kinetics:

The *volume of distribution* (V_D) of an antimicrobial is calculated as:

$$V_D = \frac{A}{C_p}$$

where A = total amount of antibiotic in the body and C_p = antibiotic plasma concentration.

Repetitive dosing of antibiotics depends on the principle of *minimal plasma concentrations* (C_{\min}):

$$C_{\min} = \frac{D}{(V_D)(2^n - 1)}$$

where D = dose and n = dosing interval expressed in half-lives.

The *plasma concentration at steady state* (C_{ss}) of an antimicrobial can be estimated utilizing the following formula:

$$C_{ss} = \frac{\text{Dose per half-life}}{(0.693)(V_D)}$$

Antibiotic adjustments:

Renal dysfunction in critically ill patients is common. In those patients receiving aminoglycosides, dosage modification is required according to the *aminoglycoside clearance*:

$$\text{Aminoglycoside clearance} = (C_{cr})(0.6) + 10$$

where C_{cr} = creatinine clearance in mL/minute.

In order to estimate the *creatinine clearance*, the *Cockcroft and Gault formula* is utilized:

$$C_{cr} (\text{mL/min}) = \frac{(140 - \text{age}) \times \text{weight}}{\text{Cr} \times 72}$$

where Cr = serum creatinine in mg/dL. Another modification to this formula is the *Spyker and Guerrant method*:

$$C_{cr} (\text{mL/min}) = \frac{(140 - \text{age}) \times (1.03 - 0.053 \times \text{Cr})}{\text{Cr}}$$

APPENDIX D: PHARMACOLOGY

DRUG FORMULAS

$$\text{Drug clearance} = V_d \times K_{el}$$

$$\text{Drug half-life } (T_{1/2}) = 0.693/K_{el}$$

$$\text{Drug elimination constant } (K_{el}) = \frac{\ln ([\text{peak}]/[\text{trough}])}{t_{\text{peak}} - t_{\text{trough}}}$$

$$\text{Drug loading dose} = V_d \times [\text{target peak}]$$

$$\text{Drug dosing interval}$$

$$= (-1/K_{el}) \times \ln ([\text{desired trough}]/[\text{desired peak}]) + \text{infusion time (h)}$$

TABLE D.1

DRUG DOSAGE ADJUSTMENTS IN RENAL FAILURE

	Dose adjustment	GFR (mL/min)			Removed by

APPENDIX E: DERMATOMES

FIGURE E.1.

FIGURE E.2. BURNS: To estimate the extent of burn, the *rule of nines* for body surface area (BSA) is commonly used: Children: arms 9% each; legs 9% each; head 13%; trunk 18% anterior, 18% posterior; genitalia 1%. Lund and Browder chart for estimation of burn extent. (From Artz CP and Yarbrough DR III. Burns: including cold, chemical, and electric injuries. In: Sabiston CC Jr, ed. *Textbook of Surgery: The Biological Basis of Modern Surgical Practice*, 11th ed. Philadelphia: WB Saunders; 1977, with permission.)

APPENDIX F: ORGAN INJURY SCALING, TRAUMA SCORING SYSTEMS

TRAUMA SCORING SYSTEMS

TABLE F.1
ABBREVIATED INJURY SCORE (AIS)

Score	Injury ^a
1	Minor
2	Moderate
3	Serious
4	Severe
5	Critical
6	Unsurvivable

^aInjuries are ranked on a scale of 1 to 6, with 1 being minor, 5 severe, and 6 an unsurvivable injury. This represents the “threat to life” associated with an injury and is not meant to represent a comprehensive measure of severity.

From Copes WS, Sacco WJ, Champion HR, et al. Progress in characterizing anatomic injury. In *Proceedings of the 33rd Annual Meeting of the Association for the Advancement of Automotive Medicine*, Baltimore, with permission.

TABLE F.2
GLASGOW COMA SCORE (GCS)^a

Score ^b	Best eye response (E)
1	No eye opening
2	Eye opening to pain
3	Eye opening to verbal command
4	Eyes open spontaneously
Score ^b	Best Verbal Response (V)
1	No verbal response
2	Incomprehensible sounds
3	Inappropriate words
4	Confused
5	Orientated
Score ^b	Best Motor Response (M)
1	No motor response
2	Extension to pain
3	Flexion to pain
4	Withdrawal from pain
5	Localizing pain
6	Obeys commands

^aNote that the phrase “GCS of 11” is essentially meaningless, and it is important to break the figure down into its components, such as E3V3M5 = GCS 11.

^bA coma score of 13 or higher correlates with a mild brain injury, 9–12 is a moderate injury, and 8 or less a severe brain injury. From Teasdale G, Jennett B. Assessment of coma and impaired consciousness. *Lancet*. 1974;ii:81–83, with permission.

TABLE F.3
REVISED TRAUMA SCORE (RTS)^a

Glasgow coma score (GCS) ^b	Systolic blood pressure (SBP)	Respiratory rate (RR)	Coded value
13–15	>89	10–29	4
9–12	76–89	>29	3
6–8	50–75	6–9	2
4–5	1–49	1–5	1
3	0	0	0

^aThe coded form of the RTS is calculated as follows: $RTS = 0.9368 \text{ GCS} + 0.7326 \text{ SBP} + 0.2908 \text{ RR}$. Values for the RTS are in the range 0 to 7.8408. The RTS is heavily weighted toward the GCS to compensate for major head injury without multisystem injury or major physiologic changes. A threshold of $RTS < 4$ has been proposed to identify those patients who should be treated in a trauma center, although this value may be somewhat low.

From Champion HR, Sacco JW, Copes WS. A revision of the trauma score. *J Trauma*. 1989;29:623–629, with permission.

TABLE F.4
INJURY SEVERITY SCORE (ISS)^a

Region	Injury description	Abbreviated injury score (AIS ^b)	Square top three
Head and neck	Cerebral contusion	3	9
Face	No injury	0	
Chest	Flail chest	4	16
Abdomen	Minor contusion of liver	2	25
	Complex rupture of spleen	5	
Extremity	Fractured femur	3	
External	No injury	0	
Injury severity score:			50

^aThe ISS takes values from 0 to 75. If an injury is assigned an AIS^b of 6 (unsurvivable injury), the ISS is automatically assigned to 75. The ISS is virtually the only anatomic scoring system in use and correlates linearly with mortality, morbidity, hospital stay, and other measures of severity.

From Baker SP, O'Neill B, Haddon W, et al. The injury severity score: a method for describing patients with multiple injuries and evaluating emergency care. *J Trauma*. 1974;14:187–196.

APPENDIX G: SEDATION SCORES

TABLE G.1
RAMSAY SCALE

Level	Characteristics ^a
1	Patient awake, anxious, agitated, or restless
2	Patient awake, cooperative, orientated, and tranquil
3	Patient drowsy, with response to commands
4	Patient asleep, brisk response to glabella tap or loud auditory
5	Patient asleep, sluggish response to stimulus
6	Patient has no response to firm nailbed pressure or other noxious stimuli

From Ramsay MAE, Savege TM, Simpson BRJ, et al. Controlled sedation with alphaxalone/alphadolone. *BMJ*. 1974;iii:656–659, with permission.

TABLE G.2
RICHMOND AGITATION-SEDATION SCALE (RASS)

Score	Term	Description
+4	Combative	Overtly combative or violent; immediate danger to staff
+3	Very agitated	Pulls on or removes tube(s) or catheter(s) or has aggressive behavior toward staff
+2	Agitated	Frequent nonpurposeful movement or patient–ventilator dyssynchrony
+1	Restless	Anxious or apprehensive but movements not aggressive or vigorous
0	Alert and calm	
–1	Drowsy	Not fully alert, but has sustained (>10 seconds) awakening, with eye contact, to voice
–2	Light sedation	Briefly (<10 seconds) awakens with eye contact to voice
–3	Moderate sedation	Any movement (but no eye contact) to voice
–4	Deep sedation	No response to voice, but any movement to physical stimulation
–5	Unarousable	No response to voice or physical stimulation

From Sessler CN, Gosnell MS, Grap MJ, et al. The Richmond agitation-sedation scale: validity and reliability in adult intensive care unit patients. *Am J Respir Crit Care Med*. 2002;166:1338–1344, with permission.

APPENDIX H: SEVERITY SCORING SYSTEMS

TABLE H.1

ACUTE PHYSIOLOGIC AND CHRONIC HEALTH EVALUATION (APACHE II)

A: Acute physiologic score (APS; 12 variables)

Physiologic variable	High abnormal range					Low abnormal range			
	+4	+3	+2	+1	0	+1	+2	+3	+4
Temperature rectal (°C)	≥41	39–40.9		38.5–38.9	36–38.4	34–35.9	32–33.9	30–31.9	≤29.0
Mean arterial pressure (mm Hg)	≥160	130–159	110–129		70–109		50–69		≤49
Heart rate—ventricular response	≥180	140–179	110–139		70–109		55–69	40–54	≤39
Respiratory rate—nonventilated or ventilated	≥50	35–49		25–34	12–24	10–11	6–9		≤5
Oxygen: A-a DO ₂ or PaO ₂ (mm Hg)									
a. FiO ₂ ≥0.5 record A-a DO ₂	≥500	350–499	200–349		≤200	PO ₂ 61–70		PO ₂ 55–60	PO ₂ <55
b. FiO ₂ <0.5 record only PaO ₂					PO ₂ >70				
Arterial pH	≥7.7	7.6–7.69		7.5–7.59	7.33–7.49		7.25–7.32	7.15–7.24	<7.15
Serum HCO ₃ —only if no ABGs	≥52	41–51.9		32–40.9	23–31.9		18–21.9	15–17.9	<15
Serum sodium (mmol/L)	≥180	160–179	155–159	150–154	130–149		120–129	111–119	≤110
Serum potassium (mmol/L)	≥7	6–6.9		5.5–5.9	3.5–5.4	3–3.4	2.5–2.9		≤2.5
Serum creatinine (μmol/L)	≥350	200–340	150–190		60–140		<60		≤20
Hematocrit (%)	≥60		50–50.9	46–49.9	30–45.9		20–29.9		<1
White blood cell count (×1,000/mm ³)	≥40		20–39.9	15–19.9	3–14.9		1–2.9		
Glasgow coma score (GCS) Score = 15 minus actual GCS									

B: Age points			C: Chronic health points			Apache II score	
Age (years)	Points	History	Points for elective surgery		Points for emergency surgery	Sum of A + B + C	
≤44	0	Liver: Biopsy-proven cirrhosis and documented portal hypertension or prior episodes of hepatic failure	2		5	A: APS	
45–54	2	Cardiovascular: NYHA Class IV	2		5	B: Age points score	
55–64	3	Respiratory: e.g., severe COPD, hypercapnia, home O ₂ , pulmonary hypertension	2		5	C: Chronic health points score	
65–74	5	Immunocompromised	2		5		
≥75	6	Renal: Chronic dialysis	2		5	Total:	

ABG, arterial blood gas; NYHA, New York Heart Association; COPD, chronic obstructive pulmonary disease. From Knaus WA, Draper EA, Wagner DP, et al. APACHE II: a severity of disease classification system. *Crit Care Med*. 1985;13:818–829, with permission.

TABLE H.2

SIMPLIFIED ACUTE PHYSIOLOGY (SAPS II) (SCORE)

Variable	26	13	12	11	9	7	6	5	4	3	2	0	1	2	3	4	6	7	8	9	10	12	15	16	17	18
Age in years																										
Heart rate (beat/min)				<40								40–69	70–119													
Systolic blood pressure (mm Hg)													100–199	≥200												
Body temperature (°C)												<39°C														
PaO ₂ /FiO ₂ (mm Hg) only if VENT or CPAP				<100								100–199														
Urinary output (L/d)				<0.500																						
Blood urea (mmol/L) (g/L)																										
WBC count (10 ³ /mL)																										
Serum K ⁺ (mEq/L)																										
Serum Na ⁺ (mEq/L)																										
Serum HCO ₃ (mEq/L)																										
Bilirubin (if jaundice) (mg/L)																										
Glasgow coma score (points)																										
Chronic diseases																										
Type of admission																										

VENT, ventilator; CPAP, continuous positive airway pressure; WBC, white blood cell; Met Cancer, metastatic carcinoma; Met, metastatic; hem mal, hematologic malignancy; AIDS, acquired immunodeficiency syndrome.

The SAPS II score registers the worst value of selected variables, within the first 24 hours after admission.

From Le Gall JR, Lemeshow S, Saulnier F, et al. A new simplified acute physiology score (SAPS II) based on a European/North American multicenter study. *JAMA*. 1993;270:2957–2963, with permission.

TABLE H.3

SEQUENTIAL ORGAN FAILURE ASSESSMENT (SOFA) SCORE

Organ system		Score				
		Score 0	Score 1	Score 2	Score 3	Score 4
Respiration	Lowest PaO ₂ /FiO ₂ (mm Hg) or (Kpa)	>400 >53.33	≤400 40–53.33	≤300 26.67–40	≤200 13.33–26.67 and yes	≤100 ≤13.33 and yes
	Respiratory support (yes/no)					
Coagulation	Lowest platelet (10 ³ /mm ³)	>150	≤150	≤100	≤50	≤20
Hepatic	Highest bilirubin (mg/dL)	<1.2	1.2–1.9	2.0–5.9	6.0–11.9	≥12
	or (μmol/L)	<20	20–32	33–101	102–204	>204
Circulatory	Lowest mean arterial pressure (mmHg)	>70	<70			
	Highest dopamine dose (μg/kg/min)			≤5	>5	>15
	Highest epinephrine dose (μg/kg/min)				≤0.1	>0.1
	Highest norepinephrine dose (μg/kg/min)				≤0.1	>0.1
	Dobutamine (yes/no)			Any dose ^a		
	(GCS, see Table H-2)	15	13–14	10–12	6–9	<6
Renal	Highest creatinine level (mg/dL)	<1.2	1.2–1.9	2.0–3.4	3.0–4.9	≥5.0
	or (μmol/L)	<110	110–170	171–299	300–440	>440
	Total urine output (mL/24 h)				<500	<200

GCS, Glasgow Coma Score.

SOFA total (Σ 6 items). The SOFA score assesses the function of 6 different organ systems: respiratory (partial arterial oxygen pressure (PaO₂)/fraction of inspired oxygen [FiO₂]), cardiovascular (blood pressure, vasoactive drugs), renal (creatinine and diuresis), hepatic (bilirubin), neurological (Glasgow Coma Score), and hematological (platelet count).

From Vincent JL, Moreno R, Takala J, et al. The SOFA (Sepsis-related Organ Failure Assessment) score to describe organ dysfunction/failure. On behalf of the Working Group on sepsis-related problems of the European Society of Intensive Care Medicine. *Intensive Care Med.* 1996;22:707–710, with permission.

TABLE H.4

MULTIPLE ORGAN DYSFUNCTION SCORE (MODS)

Variables	Points				
	0	1	2	3	4
PaO ₂ /FiO ₂	<300	226–300	151–225	76–150	≤75
Creatinine serum	≤100	101–200	201–350	351–500	≥500
Bilirubin	≤20	21–60	61–120	121–240	>240
Heart rate	≤10	10.1–15	15.1–20	20.1–30	>30
Platelet count	>120	81–120	51–80	21–50	≤20
Glasgow coma score	15	13–14	10–12	7–9	≤6

From Marshall JC, Cook DJ, Christou NV, et al. Multiple organ dysfunction score: a reliable descriptor of a complex clinical outcome. *Crit Care Med.* 1995;23:1638–1652, with permission.

TABLE I.1
AMINOPENICILLINS

Drug	Drug class	Adults (usual dose ^a)	Actions, interactions, and others	Spectrum of activity, indications, and active against most strains of	Route, reduce dose, and contraindications
Ampicillin	Aminopenicillin	Usual dose: IV: 2.0 g IV q4h PO: 500 mg q6h	Allopurinol (increased frequency of rash) Warfarin (increased INR)	<i>Streptococcus pneumoniae</i> ; <i>Staphylococcus aureus</i> (penicillinase and nonpenicillinase producing); <i>Haemophilus influenzae</i> , and group A β -hemolytic <i>Streptococci</i> Bacterial meningitis caused by <i>Escherichia coli</i> , group B <i>Streptococci</i> , and other gram-negative bacteria (<i>Listeria monocytogenes</i> , <i>Neisseria meningitidis</i>) Endocarditis caused by susceptible gram-positive organisms including <i>Streptococcus</i> sp., penicillin G-susceptible <i>Staphylococci</i> , and <i>Enterococci</i> . Endocarditis due to enterococcal strains usually respond to intravenous therapy Gram-negative sepsis caused by <i>E. coli</i> , <i>Proteus mirabilis</i> , and <i>Salmonella</i> sp. Gastrointestinal infections caused by <i>Salmonella typhosa</i> (typhoid fever), other <i>Salmonella</i> sp., and <i>Shigella</i> sp. Urinary tract infections caused by <i>E. coli</i> and <i>Proteus mirabilis</i>	Primary mode of elimination: Renal Reduce dose in moderate to severe renal impairment
Amoxicillin	Aminopenicillin	Usual dose: IV: 500 mg–1 g tds (higher doses: 2 g 4 hourly in endocarditis PO: 1 g q8h	Bactericide Some gram-negative activity	<ul style="list-style-type: none"> • <i>Streptococcus pneumoniae</i> • <i>Haemophilus influenzae</i> (except COPD patients) • β-Hemolytic <i>Streptococci</i> • <i>Streptococcus pyogenes</i> do not produce β-lactamase • <i>Enterococcus faecalis</i> 	<ul style="list-style-type: none"> • Primary mode of elimination: Renal • Reasonable oral absorption (oral preparation) • Reduce dose in moderate to severe renal impairment
Amoxicillin/clavulanate	Aminopenicillin/ β -lactam inhibitor combination	Usual dose: 500/125 mg (PO) q8h or 875/125 mg (PO) q12h for severe infections or respiratory tract infections		<p>Aerobic gram-positive microorganisms <i>Streptococcus pneumoniae</i> (including isolates with penicillin MICs ≤ 2 μg/mL)</p> <p>Aerobic gram-negative microorganisms <i>Haemophilus influenzae</i> (including β-lactamase-producing isolates) <i>Moraxella catarrhalis</i> (including β-lactamase-producing isolates)</p> <p>The following <i>in vitro</i> data are available, but their clinical significance is unknown.</p> <p>Aerobic gram-positive microorganisms <i>Staphylococcus aureus</i> (including β-lactamase-producing isolates)</p> <p>NOTE: <i>Staphylococci</i> that are resistant to methicillin/oxacillin must be considered resistant to amoxicillin/clavulanic acid <i>S. pyogenes</i></p>	<ul style="list-style-type: none"> • Primary mode of elimination: Renal • Reduce dose in moderate to severe renal impairment • 875/125 mg formulation should not be used in patients with CrCl <30 mL/min

(continued)

TABLE I.1

CONTINUED

Drug	Drug class	Adults (usual dose ^a)	Actions, interactions, and others	Spectrum of activity, indications, and active against most strains of	Route, reduce dose, and contraindications
Ampicillin/sulbactam	Aminopenicillin/ β -lactam inhibitor combination	<p>Usual dose: IV: 1.5–3.0 g q6h Remember: Na⁺ content = 4.2 mEq/g</p> <p>Total dose of sulbactam should not exceed 4 g/day</p>	<p>Bactericide</p> <p>Broad-spectrum antibiotic and a β-lactamase inhibitor</p> <p>For mild or moderate infection, 1.5 g IV q6h</p> <p>Pseudoresistance with <i>E. coli</i></p> <p><i>Klebsiella (in vitro)</i></p>	<p>Gram-negative bacteria</p> <p><i>Haemophilus influenzae</i> (β-lactamase and non-β-lactamase producing); <i>Moraxella</i> (Branhamella) <i>catarrhalis</i> (β-lactamase and non-β-lactamase producing); <i>Escherichia coli</i> (β-lactamase and non-β-lactamase producing); <i>Klebsiella</i> spp. (all known strains are β-lactamase producing); <i>Proteus mirabilis</i> (β-lactamase and non-β-lactamase producing); <i>Proteus vulgaris</i>; <i>Providencia rettgeri</i>; <i>Providencia stuartii</i>; <i>Morganella morganii</i>; <i>Neisseria gonorrhoeae</i> (β-lactamase and non-β-lactamase producing).</p> <p>Anaerobes</p> <p><i>Clostridium</i> sp.; <i>Peptococcus</i> sp.; <i>Peptostreptococcus</i> sp.; <i>Bacteroides</i> sp., including <i>B. fragilis</i></p>	<ul style="list-style-type: none"> • Primary mode of elimination: Renal and hepatic • Ampicillin and sulbactam for injection may be administered by either the IV or the IM routes • In patients with impairment of renal function, the elimination kinetics of ampicillin and sulbactam are similarly affected

INR, international normalized ratio; COPD, chronic obstructive pulmonary disease; MIC, minimum inhibitory concentration; CrCl, creatinine clearance.

TABLE I.2

ANTIPSEUDOMONAL PENICILLINS

Drug	Drug class	Adults (usual dose ^a)	Actions, interactions, and others	Spectrum of activity, indications, and active against most strains of	Route, reduce dose, and contraindications
Piperacillin	Antipseudomonal penicillin	Usual dose: IV: 34 g q48h	Drug interaction with aminoglycosides in renal failure	<p>Prophylaxis: Piperacillin is indicated for prophylactic use in surgery including intra-abdominal (gastrointestinal and biliary) procedures, vaginal hysterectomy, abdominal hysterectomy, and cesarean section. Piperacillin should only be used to treat or prevent infections that are proven or strongly suspected to be caused by susceptible bacteria.</p> <p>Indications and use</p> <p>Intra-abdominal infections including hepatobiliary and surgical infections caused by <i>E. coli</i>, <i>Pseudomonas aeruginosa</i>, <i>Enterococci</i>, <i>Clostridium</i> spp., anaerobic cocci, or <i>Bacteroides</i> spp., including <i>B. fragilis</i>.</p> <p>Urinary tract infections caused by <i>E. coli</i>, <i>Klebsiella</i> spp., <i>P. aeruginosa</i>, <i>Proteus</i> spp. including <i>P. mirabilis</i>, or <i>Enterococci</i></p> <p>Gynecologic infections including endometritis, pelvic inflammatory disease, pelvic cellulitis caused by <i>Bacteroides</i> spp. including <i>B. fragilis</i>, anaerobic cocci, <i>Neisseria gonorrhoeae</i>, or <i>Enterococci</i> (<i>E. faecalis</i>)</p> <p>Septicemia including bacteremia caused by <i>E. coli</i>, <i>Klebsiella</i> spp., <i>Enterobacter</i> spp., <i>Serratia</i> spp., <i>P. mirabilis</i>, <i>S. pneumoniae</i>, <i>Enterococci</i>, <i>P. aeruginosa</i>, <i>Bacteroides</i> spp., or anaerobic cocci.</p> <p>Lower respiratory tract infections caused by <i>E. coli</i>, <i>Klebsiella</i> spp., <i>Enterobacter</i> spp., <i>P. aeruginosa</i>, <i>Serratia</i> spp., <i>H. influenzae</i>, <i>Bacteroides</i> spp., or anaerobic cocci.</p> <p>Skin and skin structure infections caused by <i>E. coli</i>, <i>Klebsiella</i> spp., <i>Serratia</i> spp., <i>Acinetobacter</i> spp., <i>Enterobacter</i> spp., <i>P. aeruginosa</i>, <i>Morganella morganii</i>, <i>Providencia rettgeri</i>, <i>Proteus vulgaris</i>, <i>P. mirabilis</i>, <i>Bacteroides</i> spp. including <i>B. fragilis</i>, anaerobic cocci, or <i>Enterococci</i></p> <p>Bone and joint infections caused by <i>P. aeruginosa</i>, <i>Enterococci</i>, <i>Bacteroides</i> spp., or anaerobic cocci</p> <p>Indicated for nosocomial pneumonia (moderate to severe) caused by piperacillin-resistant, β-lactamase-producing strains of <i>Staphylococcus aureus</i> and by piperacillin/tazobactam-susceptible <i>Acinetobacter baumannii</i>, <i>Haemophilus influenzae</i>, <i>Klebsiella pneumoniae</i>, and <i>Pseudomonas aeruginosa</i> (nosocomial pneumonia caused by <i>P. aeruginosa</i> should be treated in combination with an aminoglycoside)</p> <p>Community-acquired pneumonia (moderate severity only) caused by piperacillin-resistant, β-lactamase-producing strains of <i>H. influenzae</i></p> <p>Appendicitis (complicated by rupture or abscess) and peritonitis caused by piperacillin-resistant, β-lactamase-producing strains of <i>Escherichia coli</i> or the following members of the <i>Bacteroides fragilis</i> group: <i>B. fragilis</i>, <i>B. ovatus</i>, <i>B. thetaiotaomicron</i>, or <i>B. vulgatus</i></p>	<ul style="list-style-type: none"> Primary mode of elimination: Renal Reduce dose in moderate to severe renal impairment
Piperacillin/tazobactam	Antipseudomonal penicillin	Usual dose: IV: 4.5 g q8h Pneumonia nosocomial, use 4.5 g (IV) q6h	Drug interaction with aminoglycosides and vecuronium	<p>Bone and joint infections caused by <i>P. aeruginosa</i>, <i>Enterococci</i>, <i>Bacteroides</i> spp., or anaerobic cocci</p> <p>Indicated for nosocomial pneumonia (moderate to severe) caused by piperacillin-resistant, β-lactamase-producing strains of <i>Staphylococcus aureus</i> and by piperacillin/tazobactam-susceptible <i>Acinetobacter baumannii</i>, <i>Haemophilus influenzae</i>, <i>Klebsiella pneumoniae</i>, and <i>Pseudomonas aeruginosa</i> (nosocomial pneumonia caused by <i>P. aeruginosa</i> should be treated in combination with an aminoglycoside)</p> <p>Community-acquired pneumonia (moderate severity only) caused by piperacillin-resistant, β-lactamase-producing strains of <i>H. influenzae</i></p> <p>Appendicitis (complicated by rupture or abscess) and peritonitis caused by piperacillin-resistant, β-lactamase-producing strains of <i>Escherichia coli</i> or the following members of the <i>Bacteroides fragilis</i> group: <i>B. fragilis</i>, <i>B. ovatus</i>, <i>B. thetaiotaomicron</i>, or <i>B. vulgatus</i></p>	<ul style="list-style-type: none"> Mode of elimination: 20% in bile, 80% unchanged in urine Reduce dose in moderate to severe renal impairment

(continued)

TABLE I.2
CONTINUED

Drug	Drug class	Adults (usual dose ^a)	Actions, interactions, and others	Spectrum of activity, indications, and active against most strains of	Route, reduce dose, and contraindications
Ticarcillin disodium	Antipseudomonal penicillin	Usual dose: IV: 3 g q6h	Drug interaction with aminoglycosides in renal failure	Uncomplicated and complicated skin and skin structure infections, including cellulitis, cutaneous abscesses, and ischemic/diabetic foot infections caused by piperacillin-resistant, β -lactamase-producing strains of <i>S. aureus</i> Infections caused by piperacillin-susceptible organisms for which piperacillin has been shown to be effective are also amenable to piperacillin tazobactam content. Postpartum endometritis or pelvic inflammatory disease caused by piperacillin-resistant, β -lactamase-producing strains of <i>E. coli</i> Ticarcillin is a semisynthetic antibiotic with a broad spectrum of bactericidal activity against many gram-positive and gram-negative aerobic and anaerobic bacteria.	<ul style="list-style-type: none"> Primary mode of elimination: Renal Reduce dose in moderate to severe renal impairment
Ticarcillin/clavulanate	Ticarcillin disodium (Antipseudomonal penicillin) + β -lactamase inhibitor clavulanate potassium (the potassium salt of clavulanic acid), for intravenous administration	Usual dose: IV: 3.1 g q4–6h (3.1 g vial containing 3 g ticarcillin and 100 mg clavulanic acid) Moderate infections 200 mg/kg/d in divided doses every 6 h Severe infections 300 mg/kg/d in divided doses every 4 h For patients weighing <60 kg, the recommended dosage is 200–300 mg/kg/d, based on ticarcillin content, given in divided doses every 4–6 hours.	Drug interaction with aminoglycosides in renal failure	Ticarcillin is, however, susceptible to degradation by β -lactamases, and therefore, the spectrum of activity does not normally include organisms that produce these enzymes. Ticarcillin is a semisynthetic antibiotic with a broad spectrum of bactericidal activity against many gram-positive and gram-negative aerobic and anaerobic bacteria. Ticarcillin is, however, susceptible to degradation by β -lactamases, and therefore, the spectrum of activity does not normally include organisms that produce these enzymes. Gram-positive aerobes <i>Staphylococcus aureus</i> ; <i>Staphylococcus epidermidis</i> Gram-negative aerobes <i>Citrobacter</i> sp.; <i>Enterobacter</i> sp., including <i>E. cloacae</i> ; <i>Escherichia coli</i> ; <i>Haemophilus influenzae</i> ; <i>Klebsiella</i> sp. including <i>K. pneumoniae</i> ; <i>Pseudomonas</i> sp. including <i>P. aeruginosa</i> ; <i>Serratia marcescens</i> Anaerobic bacteria <i>Bacteroides fragilis</i> group; <i>Prevotella</i> (formerly <i>Bacteroides melaninogenicus</i>) Gram-positive aerobes <i>Staphylococcus saprophyticus</i> ; <i>Streptococcus agalactiae</i> (group B); <i>Streptococcus bovis</i> ; <i>Streptococcus pneumoniae</i> (penicillin-susceptible strains only); <i>Streptococcus pyogenes</i> ; <i>Viridans</i> group <i>streptococci</i> Gram-negative aerobes <i>Acinetobacter baumannii</i> ; <i>Acinetobacter calcoaceticus</i> ; <i>Acinetobacter haemolyticus</i> ; <i>Acinetobacter lwoffii</i> ; <i>Moraxella catarrhalis</i> ; <i>Morganella morganii</i> ; <i>Neisseria gonorrhoeae</i> ; <i>Pasteurella multocida</i> ; <i>Proteus mirabilis</i> ; <i>Proteus penneri</i> ; <i>Proteus vulgaris</i> ; <i>Providencia rettgeri</i> ; <i>Providencia stuartii</i> ; <i>Stenotrophomonas maltophilia</i> Anaerobic bacteria <i>Clostridium</i> sp. including <i>C. perfringens</i> , <i>C. difficile</i> , <i>C. sporogenes</i> , <i>C. ramosum</i> , and <i>C. bifermentans</i> ; <i>Eubacterium</i> sp.; <i>Fusobacterium</i> sp. including <i>F. nucleatum</i> and <i>F. necrophorum</i> ; <i>Peptostreptococcus</i> sp.; <i>Veillonella</i> sp.	<ul style="list-style-type: none"> Primary mode of elimination: Renal Reduce dose in moderate to severe renal impairment

TABLE 1.3

CARBAPENEMS

Drug	Drug class	Adults (usual dose ^a)	Actions, interactions, and others	Spectrum of activity, indications, and active against most strains of	Route, reduce dose, and contraindications
Ertapenem	Carbapenem	Usual dose: IV/IM: 1 g q24h	Not a substrate/inhibitor of cytochrome P450 enzymes Probenecid (decrease clearance of ertapenem)	Aerobic and facultative gram-positive microorganisms <i>Staphylococcus aureus</i> (methicillin-susceptible isolates only); <i>Streptococcus agalactiae</i> ; <i>Streptococcus pneumoniae</i> (penicillin susceptible isolates only); <i>Streptococcus pyogenes</i> Note: Methicillin-resistant <i>Staphylococci</i> and <i>Enterococcus</i> spp. are resistant to ertapenem. Aerobic and facultative gram-positive microorganisms <i>Escherichia coli</i> ; <i>Haemophilus influenzae</i> (β -lactamase negative isolates only); <i>Klebsiella pneumoniae</i> ; <i>Moraxella catarrhalis</i> ; <i>Proteus mirabilis</i> Anaerobic microorganisms <i>Bacteroides fragilis</i> ; <i>Bacteroides distasonis</i> ; <i>Bacteroides ovatus</i> ; <i>Bacteroides thetaotaomicron</i> ; <i>Bacteroides uniformis</i> ; <i>Clostridium clostridioforme</i> ; <i>Eubacterium lentum</i> ; <i>Peptostreptococcus</i> sp.; <i>Porphyromonas asaccharolytica</i> ; <i>Prevotella bivia</i>	Primary mode of elimination: Renal Reduce dose in moderate to severe renal impairment.
Imipenem/ cilastatin	Carbapenem	Usual dose: IV: 1,000 mg q6h (4 g) only in severe life-threatening infections (mainly in some <i>Pseudomonas</i> species) no more than 50 mg/kg/24h IV: 250 mg q6h in mild infections IV: 500 mg q8h (1.5 g) or q6h (2.0 g) in moderate infections Total dose of sodium 37.5 mg (1.6 mEq) by 500 mg Imipenem	The bactericidal activity of imipenem results from the inhibition of cell wall synthesis	Conditions: Bacterial septicemia. Lower respiratory tract infections. Urinary tract infections (complicated and uncomplicated). Nosocomial pneumonia, peritonitis, sepsis. Gynecologic infections. Bone and joint infections. Skin and skin structure infections. Endocarditis. Polymicrobial infections. Gram-positive aerobes <i>Enterococcus faecalis</i> (formerly <i>S. faecalis</i>) (NOTE: Imipenem is inactive <i>in vitro</i> against <i>Enterococcus faecium</i> [formerly <i>S. faecium</i>]); <i>Staphylococcus aureus</i> including penicillinase-producing strains; <i>Staphylococcus epidermidis</i> including penicillinase-producing strains; <i>Streptococcus agalactiae</i> (group B streptococci); <i>Streptococcus pneumoniae</i> ; <i>Streptococcus pyogenes</i> Gram-negative aerobes <i>Acinetobacter</i> spp.; <i>Citrobacter</i> spp.; <i>Enterobacter</i> spp.; <i>Escherichia coli</i> ; <i>Gardnerella vaginalis</i> ; <i>Haemophilus influenzae</i> ; <i>Haemophilus parainfluenzae</i> ; <i>Klebsiella</i> spp.; <i>Morganella morganii</i> ; <i>Proteus vulgaris</i> ; <i>Providencia rettgeri</i> ; <i>Pseudomonas aeruginosa</i> (NOTE: Imipenem is inactive <i>in vitro</i> against <i>Xanthomonas</i> [<i>Pseudomonas</i>] <i>malophilia</i> and some strains of <i>P. cepacia</i>); <i>Serratia</i> spp., including <i>S. marcescens</i>	Central nervous system adverse experiences such as confusional states, myoclonic activity, and seizures have been reported during treatment with imipenem. Reduce dose in moderate to severe renal impairment. For patients on hemodialysis, imipenem is recommended only when the benefit outweighs the potential risk of seizures.

Meropenem	Carbapenem	Usual dose: IV: 500 mg q8h	Pneumonia, urinary tract infection, gynecologic infections, skin and skin structure infections	Gram-positive anaerobes <i>Bifidobacterium</i> spp.; <i>Clostridium</i> spp.; <i>Eubacterium</i> spp.; <i>Peptococcus</i> spp.; <i>Peptostreptococcus</i> spp.; <i>Propionibacterium</i> spp.	
				Gram-negative anaerobes <i>Bacteroides</i> spp., including <i>B. fragilis</i> ; <i>Fusobacterium</i> spp.	
Meropenem	Carbapenem	Usual dose: IV: 500 mg q8h	Pneumonia, urinary tract infection, gynecologic infections, skin and skin structure infections	Gram-positive aerobes <i>Bacillus</i> spp.; <i>Listeria monocytogenes</i> ; <i>Nocardia</i> spp.; <i>Staphylococcus saprophyticus</i> ; group C streptococci; group G streptococci; <i>Viridans group streptococci</i>	
				Gram-negative aerobes <i>Aeromonas hydrophila</i> ; <i>Alcaligenes</i> spp.; <i>Capnocytophaga</i> spp.; <i>Haemophilus ducreyi</i> ; <i>Neisseria gonorrhoeae</i> including penicillinase-producing strains <i>Pasteurella</i> spp.; <i>Providencia stuartii</i> .	
Meropenem	Carbapenem	Usual dose: IV: 500 mg q8h	Pneumonia, urinary tract infection, gynecologic infections, skin and skin structure infections	Gram-negative anaerobes <i>Prevotella bivia</i> ; <i>Prevotella disiens</i> ; <i>Prevotella melaninogenica</i> ; <i>Veillonella</i> spp.	
				<i>In vitro</i> tests show imipenem to act synergistically with aminoglycoside antibiotics against some isolates of <i>Pseudomonas aeruginosa</i> .	
Meropenem	Carbapenem	Usual dose: IV: 500 mg q8h	Pneumonia, urinary tract infection, gynecologic infections, skin and skin structure infections	Meropenem is a broad-spectrum carbapenem antibiotic. It is active against gram-positive and gram-negative bacteria.	Reduce dose in moderate to severe renal impairment.
				Meropenem has significant stability to hydrolysis by β -lactamases of most categories, both penicillinases and cephalosporinases produced by gram-positive and gram-negative bacteria.	
Meropenem	Carbapenem	Usual dose: IV: 500 mg q8h	Pneumonia, urinary tract infection, gynecologic infections, skin and skin structure infections	Meropenem should not be used to treat methicillin-resistant <i>Staphylococcus aureus</i> (MRSA).	
				<i>In vitro</i> tests show meropenem to act synergistically with aminoglycoside antibiotics against some isolates of <i>Pseudomonas aeruginosa</i> .	
Meropenem	Carbapenem	Usual dose: IV: 500 mg q8h	Pneumonia, urinary tract infection, gynecologic infections, skin and skin structure infections

TABLE I.4

MONOBACTAMS

Drug	Drug class	Adults (usual dose ^a)	Actions, interactions, and others	Spectrum of activity, indications, and active against most strains of	Route, reduce dose, and contraindications
Aztreonam	Monobactam It was originally isolated from <i>Chromobacterium violaceum</i> .	Usual dose: IV: 1–2 g q8h Usual dose: IV: 2 g q6h	<ul style="list-style-type: none"> • Synthetic bactericidal antibiotic • Synthetic bactericidal antibiotic • Meningeal dose 	Aerobic gram-negative microorganisms: <i>Citrobacter</i> spp., including <i>C. freundii</i> ; <i>Enterobacter</i> spp., including <i>E. cloacae</i> ; <i>Escherichia coli</i> ; <i>Haemophilus influenzae</i> (including ampicillin-resistant and other penicillinase-producing strains); <i>Klebsiella</i> , <i>Proteus</i> , and <i>Serratia</i> species.	Reduce dose in moderate to severe renal impairment.

Cunha BA. *Antibiotic Essentials*, 5th ed. Royal Oak, MI: Physicians Press; 2006.
From <http://www.drugs.com> (drug information online). Revised from November 2006.

TABLE 1.5
CEPHALOSPORINS (PARENTERAL)

Drug	Drug class	Adults (usual dose ^a)	Actions, interactions, and others	Spectrum of activity, indications, and active against most strains of	Route, reduce dose, and contraindications
Cefazolin	First-generation cephalosporin	Usual dose: IV: 1 g q8h Remember: Na ⁺ content = 46 mg per g cefazolin	<i>In vitro</i> tests demonstrate that the bactericidal action of cephalosporins results from inhibition of cell wall synthesis Drug interactions None	<i>Staphylococcus aureus</i> (including penicillinase-producing strains); <i>Staphylococcus epidermidis</i> ; methicillin-resistant staphylococci are uniformly resistant to cefazolin. Group A β -hemolytic <i>Streptococci</i> and other strains of streptococci (many strains of enterococci are resistant) <i>Streptococcus pneumoniae</i> ; <i>Escherichia coli</i> ; <i>Proteus mirabilis</i> ; <i>Klebsiella</i> sp.; <i>Enterobacter aerogenes</i> ; <i>Haemophilus influenzae</i>	Reduce dose in moderate to severe renal impairment.
Cefuroxime	Second-generation IV/oral cephalosporin	Usual dose: IV: 1.5 g q8h PO: 500 mg q12h Remember: Na ⁺ content = 2.4 mEq/g	Cefuroxime has <i>in vitro</i> activity against a wide range of gram-positive and gram-negative organisms, and it is highly stable in the presence of β -lactamases of certain gram-negative bacteria. The bactericidal action of cefuroxime results from inhibition of cell wall synthesis.	Aerobes, gram-positive <i>Staphylococcus aureus</i> ; <i>Staphylococcus epidermidis</i> ; <i>Streptococcus pneumoniae</i> ; <i>Streptococcus pyogenes</i> (and other streptococci) NOTE: Most strains of enterococci (e.g., <i>Enterococcus faecalis</i> [formerly <i>Streptococcus faecalis</i>]), are resistant to cefuroxime. Methicillin-resistant staphylococci and <i>Listeria monocytogenes</i> are resistant to cefuroxime. Aerobes, gram-negative <i>Citrobacter</i> spp.; <i>Enterobacter</i> spp.; <i>Escherichia coli</i> ; <i>Haemophilus influenzae</i> (including ampicillin-resistant strains); <i>Haemophilus parainfluenzae</i> ; <i>Klebsiella</i> spp. (including <i>Klebsiella pneumoniae</i>); <i>Moraxella (Branhamella) catarrhalis</i> (including ampicillin- and cephalothin-resistant strains); <i>Morganella morganii</i> (formerly <i>Proteus morganii</i>); <i>Neisseria gonorrhoeae</i> (including penicillinase- and non-penicillinase-producing strains); <i>Neisseria meningitidis</i> ; <i>Proteus mirabilis</i> ; <i>Providencia rettgeri</i> (formerly <i>Proteus rettgeri</i>); <i>Salmonella</i> spp.; <i>Shigella</i> spp.	Reduce dose in moderate to severe renal impairment. Do not use for meningitis prophylaxis.
Cefotaxime	Third-generation cephalosporin	Usual dose: 2 g IV q6h	Administer by IV injection or infusion or by deep IM injection.	Lower respiratory tract infections , including pneumonia, caused by <i>Streptococcus pneumoniae</i> (formerly <i>Diplococcus pneumoniae</i>), <i>Streptococcus pyogenes</i> ^b (group A streptococci) and other streptococci (excluding enterococci, e.g., <i>Enterococcus faecalis</i>), <i>Staphylococcus aureus</i> (penicillinase and nonpenicillinase producing), <i>Escherichia coli</i> , <i>Klebsiella</i> sp., <i>Haemophilus influenzae</i> (including ampicillin-resistant strains), <i>Haemophilus parainfluenzae</i> , <i>Proteus mirabilis</i> , <i>Serratia marcescens</i> , ^b <i>Enterobacter</i> sp., indolepositive <i>Proteus</i> and <i>Pseudomonas</i> sp. (including <i>P. aeruginosa</i>).	Reduce dose in moderate to severe renal impairment.

Genitourinary infections

Urinary tract infections caused by *Enterococcus* sp.,^a *Staphylococcus epidermidis*, *Staphylococcus aureus*^b (penicillinase and nonpenicillinase producing), *Citrobacter* sp., *Enterobacter* sp.,^b *Escherichia coli*,^b *Klebsiella* sp., *Proteus mirabilis*, *Proteus vulgaris*,^b *Providencia stuartii*, *Morganella morganii*,^b *Providencia rettgeri*,^b *Serratia marcescens*, and *Pseudomonas* sp. (including *P. aeruginosa*). Also, uncomplicated gonorrhea (cervical/urethral and rectal) caused by *Neisseria gonorrhoeae*, including penicillinase-producing strains.

Gynecologic infections, including pelvic inflammatory disease, endometritis, and pelvic cellulitis caused by *Staphylococcus epidermidis*, *Streptococcus* sp., *Enterococcus* sp., *Enterobacter* sp.,^b *Klebsiella* sp.,^b *Escherichia coli*, *Proteus mirabilis*, *Bacteroides* sp. (including *Bacteroides fragilis*^b), *Clostridium* sp., and anaerobic cocci (including *Peptostreptococcus* sp. and *Peptococcus* sp.) and *Fusobacterium* sp. (including *F. nucleatum*^b)

Bacteremia/septicemia caused by *Escherichia coli*, *Klebsiella* sp., *Serratia marcescens*, *Staphylococcus aureus*, and *Streptococcus* sp. (including *S. pneumoniae*)

Skin and skin structure infections caused by

Staphylococcus aureus (penicillinase and nonpenicillinase producing), *Staphylococcus epidermidis*, *Streptococcus pyogenes* (group A streptococci) and other streptococci, *Enterococcus* sp., *Acinetobacter* sp.,^b *Escherichia coli*, *Citrobacter* sp. (including *C. freundii*^b), *Enterobacter* sp.,^b *Klebsiella* sp., *Proteus mirabilis*, *Proteus vulgaris*,^b *Morganella morganii*, *Providencia rettgeri*,^b *Pseudomonas* sp., *Serratia marcescens*, *Bacteroides* sp., and anaerobic cocci (including *Peptostreptococcus*^b sp. and *Peptococcus* sp.)

Intra-abdominal infections including peritonitis caused by *Streptococcus* sp.,^b *Escherichia coli*, *Klebsiella* sp., *Bacteroides* sp., and anaerobic cocci (including *Peptostreptococcus*^b sp. and *Peptococcus*^b sp.) *Proteus mirabilis*,^b and *Clostridium* sp.^b

Bone and/or joint infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Streptococcus* sp. (including *S. pyogenes*^b), *Pseudomonas* sp. (including *P. aeruginosa*^b), and *Proteus mirabilis*^b

(continued)

TABLE I.5

CONTINUED

Drug	Drug class	Adults (usual dose ^a)	Actions, interactions, and others	Spectrum of activity, indications, and active against most strains of	Route, reduce dose, and contraindications
Ceftazidime	Third-generation cephalosporin	Usual dose: 2 g IV q8h	Ceftazidime is bactericidal in action, exerting its effect by inhibition of enzymes responsible for cell wall synthesis.	<p>Central nervous system infections (e.g., meningitis and ventriculitis), caused by <i>Neisseria meningitidis</i>, <i>Haemophilus influenzae</i>, <i>Streptococcus pneumoniae</i>, <i>Klebsiella pneumoniae</i>,^b and <i>Escherichia coli</i>^b</p> <p>Lower respiratory tract infections, including pneumonia, caused by <i>Pseudomonas aeruginosa</i> and other <i>Pseudomonas</i> spp.; <i>Haemophilus influenzae</i>, including ampicillin-resistant strains; <i>Klebsiella</i> spp.; <i>Enterobacter</i> spp.; <i>Proteus mirabilis</i>; <i>Escherichia coli</i>; <i>Serratia</i> spp.; <i>Citrobacter</i> spp.; <i>Streptococcus pneumoniae</i>; and <i>Staphylococcus aureus</i> (methicillin-susceptible strains).</p> <p>Skin and skin structure infections caused by <i>Pseudomonas aeruginosa</i>; <i>Klebsiella</i> spp.; <i>Escherichia coli</i>; <i>Proteus</i> spp., including <i>Proteus mirabilis</i> and indole-positive <i>Proteus</i>; <i>Enterobacter</i> spp.; <i>Serratia</i> spp.; <i>Staphylococcus aureus</i> (methicillin-susceptible strains); and <i>Streptococcus pyogenes</i> (group A β-hemolytic streptococci).</p> <p>Urinary tract infections, both complicated and uncomplicated, caused by <i>Pseudomonas aeruginosa</i>; <i>Enterobacter</i> spp.; <i>Proteus</i> spp., including <i>Proteus mirabilis</i> and indole-positive <i>Proteus</i>; <i>Klebsiella</i> spp.; and <i>Escherichia coli</i></p> <p>Bacterial septicemia caused by <i>Pseudomonas aeruginosa</i>, <i>Klebsiella</i> spp., <i>Haemophilus influenzae</i>, <i>Escherichia coli</i>, <i>Serratia</i> spp., <i>Streptococcus pneumoniae</i>, and <i>Staphylococcus aureus</i> (methicillin-susceptible strains)</p> <p>Bone and joint infections caused by <i>Pseudomonas aeruginosa</i>, <i>Klebsiella</i> spp., <i>Enterobacter</i> spp., and <i>Staphylococcus aureus</i> (methicillin-susceptible strains)</p> <p>Gynecologic infections, including endometritis, pelvic cellulitis, and other infections of the female genital tract caused by <i>Escherichia coli</i></p> <p>Intra-abdominal infections, including peritonitis caused by <i>Escherichia coli</i>, <i>Klebsiella</i> spp., and <i>Staphylococcus aureus</i> (methicillin-susceptible strains) and polymicrobial infections caused by aerobic and anaerobic organisms and <i>Bacteroides</i> spp. (many strains of <i>Bacteroides fragilis</i> are resistant)</p>	Reduce dose in moderate to severe renal impairment.

Cefepime	Fourth-generation cephalosporin	<p>Usual dose: 1–2 g IV q12h</p> <p>For proven serious systemic <i>P. aeruginosa</i> infections, febrile neutropenia, or cystic fibrosis: 2 g (IV) q8h (max dose)</p> <p>Meningeal dose: 2 g (IV) q8h (max dose)</p>	<p>Local intolerances to IV or IM administration of cefepime were not statistically different from those of ceftazidime administration</p>	<p>Central nervous system infections, including meningitis, caused by <i>Haemophilus influenzae</i> and <i>Neisseria meningitidis</i>. Cefazidime has also been used successfully in a limited number of cases of meningitis due to <i>Pseudomonas aeruginosa</i> and <i>Streptococcus pneumoniae</i>.</p> <p><i>In vitro</i>, activity against gram-positive organisms including <i>Streptococcus agalactiae</i>, <i>Streptococcus pneumoniae</i>, <i>Streptococcus pyogenes</i>, and penicillin-susceptible <i>Staphylococcus aureus</i></p> <p>The broad range of gram-negative organisms sensitive to include family Enterobacteriaceae, <i>Klebsiella pneumoniae</i>, <i>Haemophilus influenzae</i>, <i>Neisseria meningitidis</i>, <i>Neisseria gonorrhoeae</i>, and <i>Pseudomonas aeruginosa</i></p>	<p>Reduce dose in moderate to severe renal impairment</p>
----------	---------------------------------	--	--	--	---

^bUsual dose, assumes normal renal/hepatic function.

TABLE I.6

GLYCOPEPTIDES

Drug	Drug class	Adults (usual dose ^a)	Actions, interactions, and others	Spectrum of activity, indications, and active against most strains of	Route, reduce dose, and contraindications
Vancomycin	Glycopeptide	The initial dose should be no <15 mg/kg, even in patients with mild to moderate renal insufficiency Usual dose IV: 1 g q12h	The bactericidal action of vancomycin results primarily from inhibition of cell wall biosynthesis. In addition, vancomycin alters bacterial cell membrane permeability and RNA synthesis. Concomitant administration of vancomycin and anesthetic agents has been associated with erythema and histamine-like flushing and anaphylactoid reactions.	Indicated for the treatment of serious or severe infections caused by susceptible strains of methicillin-resistant (β -lactam-resistant) staphylococci. It is indicated for penicillin-allergic patients; for patients who cannot receive or who have failed to respond to other drugs, including the penicillins or cephalosporins; and for infections caused by vancomycin-susceptible organisms that are resistant to other antimicrobial drugs. Also indicated for initial therapy when methicillin-resistant staphylococci are suspected, but after susceptibility data are available, therapy should be adjusted accordingly. Effective in the treatment of staphylococcal endocarditis. Its effectiveness has been documented in other infections due to staphylococci, including septicemia, bone infections, lower respiratory tract infections, and skin and skin structure infections. Effective alone or in combination with an aminoglycoside for endocarditis caused by <i>S. viridans</i> or <i>S. bovis</i> . For endocarditis caused by enterococci (e.g., <i>E. faecalis</i>), vancomycin hydrochloride has been reported to be effective only in combination with an aminoglycoside. Effective for the treatment of diphtheroid endocarditis. Has been used successfully in combination with rifampin, an aminoglycoside, or both, in early-onset prosthetic valve endocarditis caused by <i>S. epidermidis</i> or diphtheroids The parenteral form of vancomycin may be administered orally for treatment of antibiotic-associated pseudomembranous colitis produced by <i>C. difficile</i> and for staphylococcal enterocolitis	Dosage adjustment must be made in patients with impaired renal function. Vancomycin dosage schedules should be adjusted in elderly patients Dosage table for vancomycin (adapted from Moellering et al.) ^b Creatine Clearance/ Dose mL/min—mg/24 h 100—1,545 90—1,390 80—1,235 70—1,080 60—925 50—770 40—620 30—465 20—310 10—155

TABLE I.7

CHLORAMPHENICOL, CLINDAMYCIN, ERYTHROMYCIN GROUP, KETOLIDES

Drug	Drug class	Adults (usual dose ^a)	Actions, interactions, and others	Spectrum of activity, indications, and active against most strains of	Route, reduce dose, and contraindications
Chloramphenicol	Chloramphenicol sodium succinate	Chloramphenicol sodium succinate is intended for intravenous use only. It has been demonstrated to be ineffective when given intramuscularly. 0.25–1 g IV q6h (max. of 4 g/d) Administration of 50 mg/kg/d in divided doses will produce blood levels of the magnitude to which the majority of susceptible microorganisms will respond.	The most serious adverse effect of chloramphenicol is bone marrow depression. Serious and fatal blood dyscrasias (aplastic anemia, hypoplastic anemia, thrombocytopenia, and granulocytopenia) are known to occur after the administration of chloramphenicol.	Chloramphenicol must be used only in those serious infections for which less potentially dangerous drugs are ineffective or contraindicated: 1. Acute infections caused by <i>Salmonella typhi</i> 2. Serious infections caused by susceptible strains: <ul style="list-style-type: none"> • <i>Salmonella</i> sp. • <i>H. influenzae</i>, especially meningal infections • <i>Rickettsia</i> • Lymphogranuloma-psittacosis group • Various gram-negative bacteria causing bacteremia, meningitis, or other serious gram-negative infections • Other susceptible organisms that have been demonstrated to be resistant to all other appropriate antimicrobial agents 3. Cystic fibrosis regimens	Total urinary excretion of chloramphenicol in these studies ranged from a low of 68% to a high of 99% over a 3-d period. From 8% to 12% of the antibiotic excreted is in the form of free chloramphenicol
Clindamycin	Clindamycin phosphate	IV or IM: 600–900 mg q8h PO: 0.15–0.45 g q6h	Pseudomembranous colitis has been reported with nearly all antibacterial agents, including clindamycin, and may range in severity from mild to life threatening.	Aerobic gram-positive cocci , including: <i>Staphylococcus aureus</i> (penicillinase- and nonpenicillinase-producing strains); <i>Staphylococcus epidermidis</i> (penicillinase- and nonpenicillinase-producing strains); <i>Streptococci</i> (except <i>Enterococcus faecalis</i>); <i>Pneumococci</i> Anaerobic gram-negative bacilli , including <i>Bacteroides</i> sp. (including <i>Bacteroides fragilis</i> group and <i>Bacteroides melanogenicus</i> group) and <i>Fusobacterium</i> species Anaerobic gram-positive non-spore-forming bacilli , including <i>Propionibacterium</i> , <i>Eubacterium</i> , and <i>Actinomyces</i> sp. Anaerobic and microaerophilic gram-positive cocci , including <i>Peptococcus</i> sp., <i>Microaerophilic streptococci</i> , and <i>Clostridia</i>	The elimination half-life of clindamycin is increased slightly in patients with markedly reduced renal or hepatic function. Hemodialysis and peritoneal dialysis are not effective in removing clindamycin from the serum.

(continued)

TABLE I.7

CONTINUED

Drug	Drug class	Adults (usual dose ^a)	Actions, interactions, and others	Spectrum of activity, indications, and active against most strains of	Route, reduce dose, and contraindications
Clarithromycin	Semisynthetic macrolide antibiotic	Usual dose: PO: 0.5 g q12h	Drug Interactions: Patients who are receiving single doses of clarithromycin and theophylline or carbamazepine may be associated with an increase of serum theophylline and carbamazepine concentrations.	Aerobic gram-positive microorganisms <i>Staphylococcus aureus</i> ; <i>Streptococcus pneumoniae</i> ; <i>Streptococcus pyogenes</i> Aerobic gram-negative microorganisms <i>Haemophilus influenzae</i> ; <i>Haemophilus parainfluenzae</i> ; <i>Moraxella catarrhalis</i> Other microorganisms <i>Mycoplasma pneumoniae</i> ; <i>Chlamydia pneumoniae</i> Mycobacteria <i>Mycobacterium avium</i> complex consisting of <i>Mycobacterium avium</i> and <i>Mycobacterium intracellulare</i> β -Lactamase production should have no effect on clarithromycin activity. Most strains of methicillin-resistant and oxacillin-resistant staphylococci are resistant to clarithromycin.	Contraindications: Any of the following drugs: cisapride, pimozone, astemizole, terfenadine, and ergotamine or dihydroergotamine. If clarithromycin is coadministered with cisapride, pimozone, astemizole, or terfenadine resulting in cardiac arrhythmias (QT prolongation, ventricular tachycardia, ventricular fibrillation, and torsades de pointes), this is most likely due to inhibition of metabolism of these drugs.
Linezolid	Oxazolidinone	Usual dose: PO or IV dose: 600 mg q12h all indications except 400 mg q12h for uncomplicated skin infections	Reversible myelosuppression including anemia, leukopenia, pancytopenia, and thrombocytopenia has been reported in patients. In cases where the outcome is known, when linezolid was discontinued, the affected hematologic parameters have risen toward pretreatment levels. Lactic acidosis has been reported with the use of linezolid. Spontaneous reports of serotonin syndrome associated with the administration of linezolid and serotonergic agents, including antidepressants Peripheral and optic neuropathy have been reported in patients treated with linezolid	Aerobic and facultative gram-positive microorganisms <i>Enterococcus faecium</i> (vancomycin-resistant strains only); <i>Staphylococcus aureus</i> (including methicillin-resistant strains); <i>Streptococcus agalactiae</i> ; <i>Streptococcus pneumoniae</i> (including multidrug-resistant isolates); <i>Streptococcus pyogenes</i> Aerobic and facultative gram-positive microorganisms <i>Enterococcus faecalis</i> (including vancomycin-resistant strains); <i>Enterococcus faecium</i> (vancomycin-susceptible strains); <i>Staphylococcus epidermidis</i> (including methicillin-resistant strains); <i>Staphylococcus haemolyticus</i> ; <i>Viridans group streptococci</i> Aerobic and facultative gram-negative microorganisms <i>Pasteurella multocida</i>	Linezolid is primarily metabolized by oxidation of the morpholine ring, which results in two inactive ring-opened carboxylic acid metabolites: The aminoethoxyacetic acid metabolite (A) and the hydroxyethyl glycine metabolite (B). Nonrenal clearance accounts for approximately 65% of the total clearance of linezolid. Under steady-state conditions, approximately 30% of the dose appears in the urine as linezolid, 40% as metabolite B, and 10% as metabolite A.

Cunha BA. *Antibiotic Essentials*, 5th ed. Royal Oak, MI: Physicians Press; 2006.

TABLE 1.8

TETRACYCLINES

Drug	Drug class	Adults (usual dose ^a)	Actions, interactions, and others	Spectrum of activity, indications, and active against most strains of	Route, reduce dose, and contraindications
Doxycycline	Derived from oxytetracycline	Usual dose: PO: 0.1 g q12h IV: 0.1 g q12h	The tetracyclines are primarily bacteriostatic and are thought to exert their antimicrobial effect by the inhibition of protein synthesis.	Wide range of gram-positive and gram-negative microorganisms Aerobic gram-positive microorganisms <i>Bacillus anthracis</i> ; <i>Listeria monocytogenes</i> ; <i>Staphylococcus aureus</i> Aerobic gram-negative microorganisms <i>Bartonella bacilliformis</i> ; <i>Brucella</i> sp.; <i>Calymmatobacterium granulomatis</i> ; <i>Campylobacter fetus</i> ; <i>Francisella tularensis</i> ; <i>Haemophilus ducreyi</i> ; <i>Haemophilus influenzae</i> ; <i>Neisseria gonorrhoeae</i> ; <i>Vibrio cholerae</i> ; <i>Yersinia pestis</i> . Anaerobic microorganisms <i>Actinomyces israelii</i> ; <i>Fusobacterium fusiforme</i> ; <i>Clostridium</i> sp. Other microorganisms <i>Borrelia recurrentis</i> ; <i>Chlamydia psittaci</i> ; <i>Chlamydia trachomatis</i> ; <i>Mycoplasma pneumoniae</i> ; <i>Rickettsiae</i> ; <i>Treponema pallidum</i> ; <i>Treponema pertenue</i>	Can be used in patients with renal failure Hemodialysis does not alter serum half-life.
Oxytetracycline	Tetracycline	Usual dose: PO: 0.25–0.5 g q6h IV: 0.5–1.0 g q12h	Primarily bacteriostatic	Wide range of gram-positive and gram-negative microorganisms, similar to other tetracyclines	Contraindicated in pregnancy, hepatotoxicity in mother, transplacental to fetus. Intravenous dosage over 2.0 g/d may be associated with fatal hepatotoxicity

Cunha BA. *Antibiotic Essentials*, 5th ed. Royal Oak, MI: Physicians Press; 2006.

TABLE I.9

FLUOROQUINOLONES

Drug	Drug class	Adults (usual dose ^a)	Actions, interactions, and others	Spectrum of activity, indications, and active against most strains of	Route, reduce dose, and contraindications
Ciprofloxacin	Fluoroquinolone	Usual dose: IV: 400 mg q8–12h (infusion over a period of 60 min) PO: 500–750 mg q 12h	Inhibition of bacterial topoisomerase IV and DNA gyrase (both of which are type II topoisomerases), enzymes required for DNA replication, transcription, repair, and recombination Drug interactions with theophylline, caffeine, warfarin, phenytoin, sulfonyleurea, glyburide, metronidazole, probenecid, piperacillin sodium, and cyclosporine	Aerobic gram-positive microorganisms <i>Enterococcus faecalis</i> (many strains are only moderately susceptible); <i>Staphylococcus aureus</i> (methicillin-susceptible strains only); <i>Staphylococcus epidermidis</i> (methicillin-susceptible strains only); <i>Staphylococcus saprophyticus</i> ; <i>Staphylococcus pneumoniae</i> (penicillin-susceptible strains); <i>Staphylococcus pyogenes</i> Aerobic gram-negative microorganism <i>Citrobacter (diversus, freundii)</i> ; <i>Enterobacter cloacae</i> ; <i>Escherichia coli</i> ; <i>Haemophilus (influenzae, parainfluenzae)</i> ; <i>Klebsiella pneumoniae</i> ; <i>Moraxella catarrhalis</i> ; <i>Morganella morganii</i> ; <i>Proteus (mirabilis, vulgaris)</i> ; <i>Providencia (rettingeri, stuartii)</i> ; <i>Pseudomonas aeruginosa</i> ; <i>Serratia marcescens</i> . Also ciprofloxacin has been shown to be active against <i>Bacillus anthracis</i> both <i>in vitro</i> and by use of serum levels as a surrogate marker.	Contraindications: Concomitant administration with tizanidine Patients with impaired renal function: Creatinine clearance (mL/min): <ul style="list-style-type: none"> • >30 (see usual dose) • 5–29 (200–400 mg q18–24h)

Levofloxacin	Fluoroquinolone	Usual dose: 250–750 mg qd PO or IV	Inhibition of bacterial topoisomerase IV and DNA gyrase (both of which are type II topoisomerases), enzymes required for DNA replication, transcription, repair, and recombination Drug interactions with theophylline, caffeine, warfarin, phenytoin, sulfonyleurea glyburide, metronidazole, probenecid, piperacillin sodium, and cyclosporine	<p>Acute bacterial sinusitis due to <i>Streptococcus pneumoniae</i>, <i>Haemophilus influenzae</i>, or <i>Moraxella catarrhalis</i></p> <p>Acute bacterial exacerbation of chronic bronchitis due to <i>Staphylococcus aureus</i>, <i>Streptococcus pneumoniae</i>, <i>Haemophilus influenzae</i>, <i>Haemophilus parainfluenzae</i>, or <i>Moraxella catarrhalis</i>.</p> <p>Nosocomial pneumonia due to methicillin-susceptible <i>Staphylococcus aureus</i>, <i>Pseudomonas aeruginosa</i>, <i>Serratia marcescens</i>, <i>Escherichia coli</i>, <i>Klebsiella pneumoniae</i>, <i>Haemophilus influenzae</i>, or <i>Streptococcus pneumoniae</i>. Adjunctive therapy should be used as clinically indicated. Where <i>Pseudomonas aeruginosa</i> is a documented or presumptive pathogen, combination therapy with an antipseudomonal β-lactam is recommended.</p> <p>Community-acquired pneumonia due to <i>Staphylococcus aureus</i>, <i>Streptococcus pneumoniae</i> (including multidrug-resistant strains [MDRSP]),^a <i>Haemophilus influenzae</i>, <i>Haemophilus parainfluenzae</i>, <i>Klebsiella pneumoniae</i>, <i>Moraxella catarrhalis</i>, <i>Chlamydia pneumoniae</i>, <i>Legionella pneumophila</i>, or <i>Mycoplasma pneumoniae</i></p> <p>Complicated skin and skin structure infections due to methicillin-susceptible <i>Staphylococcus aureus</i>, <i>Enterococcus faecalis</i>, <i>Streptococcus pyogenes</i>, or <i>Porteus mirabilis</i>.</p> <p>Uncomplicated skin and skin structure infections (mild to moderate) including abscesses, cellulites, furuncles, impetigo, pyoderma, and wound infections, due to <i>Staphylococcus aureus</i> or <i>Streptococcus pyogenes</i></p> <p>Chronic bacterial prostatitis due to <i>Escherichia coli</i>, <i>Enterococcus faecalis</i>, or <i>Staphylococcus epidermidis</i></p> <p>Complicated urinary tract infections (mild to moderate) due to <i>Enterococcus faecalis</i>, <i>Enterobacter cloacae</i>, <i>Escherichia coli</i>, <i>Klebsiella pneumoniae</i>, <i>Proteus mirabilis</i>, or <i>Pseudomonas aeruginosa</i></p> <p>Acute pyelonephritis (mild to moderate) caused by <i>Escherichia coli</i></p> <p>Uncomplicated urinary tract infections (mild to moderate) due to <i>Escherichia coli</i>, <i>Klebsiella pneumoniae</i>, or <i>Staphylococcus saprophyticus</i></p>	<p>Clearance of levofloxacin is substantially reduced and plasma elimination half-life is substantially prolonged in patients with impaired renal function (creatinine clearance <50 mL/min), requiring dosage adjustment in such patients to avoid accumulation. Neither hemodialysis nor continuous ambulatory peritoneal dialysis (CAPD) is effective in removal of levofloxacin from the body, indicating that supplemental doses of levofloxacin are not required following hemodialysis or CAPD.</p> <p>Adverse reactions: Opiate screen false positives; photosensitivity; QTc interval prolongation and tendinopathy</p>
Moxifloxacin	Fluoroquinolone	Usual dose: 400 mg PO or IV qd	The bactericidal action of moxifloxacin results from the interference with topoisomerase II and IV.	<p>Community-acquired pneumonia (CAP), including CAP caused by multidrug-resistant <i>Streptococcus pneumoniae</i>^b</p> <p>Complicated skin and skin structure infections, including diabetic foot infections</p> <p>Complicated intra-abdominal infections, including polymicrobial infections such as abscesses</p>	<p>Similar to other fluoroquinolones</p>

^aMDRSP (multidrug-resistant *Streptococcus pneumoniae*) are strains resistant to two or more of the following antibiotics: Penicillin (minimum inhibitory concentration [MIC] = 2 μ g/mL), second-generation cephalosporins (e.g., cefuroxime, macrolides, tetracyclines, and trimethoprim/sulfamethoxazole).

^bMultidrug-resistant *S. pneumoniae* includes isolates previously known as PRSP (penicillin-resistant *S. pneumoniae*), and are strains resistant to two or more of the following antibiotics: Penicillin (MIC \geq 2 mg/mL), second-generation cephalosporins (e.g., cefuroxime), macrolides, tetracyclines, and trimethoprim/sulfamethoxazole.

TABLE I.10
POLYMYXINS

Drug	Drug class	Adults (usual dose ^d)	Actions, interactions, and others	Spectrum of activity, indications, and active against most strains of	Route, reduce dose, and contraindications
Polymyxin B	Phospholipid cell membrane-altering antibiotic	0.75–1.25 mg/kg (IV) q12 h (1 mg = 10,000 units)	Colistin is polycationic and has both hydrophilic and lipophilic moieties. These interact with the bacterial cytoplasmic membrane, changing its permeability. This effect is bactericidal. The main toxicities described with intravenous treatment are nephrotoxicity and neurotoxicity. At a dose of 160 mg colistimethate IV q8h, very little nephrotoxicity is seen. (Conway SP, Etherington C, Munday J, et al. Safety and tolerability of bolus intravenous colistin in acute respiratory exacerbation in adults with cystic fibrosis. <i>Am J Pharmacother</i> 2000;34:1238–1242.)	Colistin is effective against gram-negative bacilli, except <i>Proteus</i> and <i>Burkholderia cepacia</i> , and is used as a polypeptide antibiotic. Multidrug-resistant <i>Acinetobacter baumannii</i> , even in <i>Acinetobacter meningitis</i> with intrathecal polymyxin E Mycobacterium aurum was susceptible to the antibiotic colistin (polymyxin E), which had an MIC of 5 µg/mL and an apparent bactericidal effect at concentrations above 50 µg/mL. Cited from David HL, Rastogi N. Antibacterial action of colistin (polymyxin E) against <i>Mycobacterium aurum</i> . <i>Antimicrob Agents Chemother</i> . 1985;27(5):701–707	Usage in pregnancy: The safety of this drug in human pregnancy has not been established.
Polymyxin E	Colistin (Polymyxin E) is a polymyxin antibiotic produced by certain strains of <i>Bacillus polymyxa</i> var. <i>colistinus</i> . There are 2 forms of colistin available commercially: colistin sulfate and colistimethate sodium (colistin methanesulfonate sodium, colistin sulfomethate sodium).	Colomycin 1,000,000 units is 80 mg colistimethate Coly-Mycin M 150 mg “colistin base” is 360 mg colistimethate or 4,500,000 units	Polymyxins bind to the cell membrane and alters its structure making it more permeable. The resulting water uptake leads to cell death. They are cationic, basic proteins that act like detergents. Interactions: Amphothericin B, amikacin, gentamicin, tobramycin, vancomycin. Adverse effects: Renal failure (tubular necrosis). Neurotoxicity associated with very prolonged or high serum levels; neuromuscular blockade with renal failure and or neuromuscular disorders	Bactericidal for gram-negative; little to no effect on gram-positive since cell wall is too thick to permit access to membrane	Colistin sulfate and colistimethate sodium are eliminated from the body by different routes.

Cunha BA. *Antibiotic Essentials*, 5th ed. Royal Oak, MI: Physicians Press; 2006.
From <http://www.drugs.com> (drug information online). Revised from November 2006.

TABLE I.11

AMINOGLYCOSIDES

Drug	Drug class	Adults (usual dose ^a)	Actions, interactions, and others	Spectrum of activity, indications, and active against most strains of	Route, reduce dose, and contraindications
Gentamicin	Aminoglycoside antibiotic, derived from <i>Micromonospora purpurea</i> , an actinomycete	Usual dose: Gentamicin sulfate 3 mg/kg/d q8h In patients with life-threatening infections: 5 mg/kg/d q24h (preferred over q8h dosing) Intravenous use only for gentamicin sulfate in 0.9% sodium chloride.	Bactericidal antibiotic that acts by inhibiting normal protein synthesis in susceptible microorganisms Drug interactions: Amphotericin B, cephalothin, cyclosporine, enflurane, methoxyflurane, polymyxin B, radiographic contrast, vancomycin (increase nephrotoxicity), cisplatin, etc. (see specifications of the product)	<i>Escherichia coli</i> ; <i>Proteus</i> sp. (indole-positive and indole-negative); <i>Pseudomonas aeruginosa</i> ; species of <i>Klebsiella-Enterobacter-Serratia</i> group; <i>Citrobacter</i> sp.; and <i>Staphylococcus</i> sp. (including penicillin and methicillin-resistant strains) Gentamicin is also active <i>in vitro</i> against species of <i>Salmonella</i> and <i>Shigella</i> .	To adjust the doses for patients with renal impairment Adverse reactions: Nephrotoxicity: Adverse renal effects have been reported. They occur more frequently in patients with a history of renal impairment and in patients treated for longer periods or with larger dosages than recommended. Others such as neurotoxicity (serious adverse effects on both vestibular and auditory branches of the eighth nerve), peripheral neuropathy, or encephalopathy, including numbness, skin tingling, muscle twitching, convulsions, and a myasthenia gravis-like syndrome, have been reported. (See specifications of the product.)
Amikacin	Semisynthetic aminoglycoside antibiotic, derived from kanamycin	Usual dose: Amikacin sulfate IV: 15 mg/kg or 1 g q24h (preferred to q12h dosing)	Drug interactions: See gentamicin sulfate.	Gram negative Amikacin is active <i>in vitro</i> against <i>Pseudomonas</i> sp., <i>Escherichia coli</i> , <i>Proteus</i> sp. (indole-positive and indole-negative), <i>Providencia</i> sp., <i>Klebsiella-Enterobacter-Serratia</i> sp., <i>Acinetobacter</i> (formerly <i>Mima-Herellea</i>) sp., and <i>Citrobacter freundii</i> When strains of the above organisms are found to be resistant to other aminoglycosides, including gentamicin, tobramycin, and kanamycin, many are susceptible to amikacin <i>in vitro</i> . Gram positive Amikacin is active <i>in vitro</i> against penicillinase and nonpenicillinase-producing <i>Staphylococcus</i> sp. including methicillin-resistant strains. However, aminoglycosides in general have a low order of activity against other gram-positive organisms.	See gentamicin sulfate.
Tobramycin	Aminoglycoside antibiotic, derived from the actinomycete <i>Streptomyces tenebrarius</i>	Usual dose: Tobramycin sulfate: IV: 5 mg/kg q24h or 240 mg q24h (preferred over q8h dosing). The dosage should be reduced to 3 mg/kg/d as soon as clinically indicated.	Tobramycin acts by inhibiting synthesis of protein in bacterial cells. Drug interactions: See gentamicin sulfate.	Gram-positive aerobes <i>Staphylococcus aureus</i> Gram-negative aerobes <i>Citrobacter</i> sp., <i>Enterobacter</i> sp., <i>Escherichia coli</i> , <i>Klebsiella</i> sp., <i>Morganella morganii</i> , <i>Pseudomonas aeruginosa</i> , <i>Proteus mirabilis</i> , <i>Proteus vulgaris</i> , <i>Providencia</i> sp., <i>Serratia</i> sp. Aminoglycosides have a low order of activity against most gram-positive organisms, including <i>Streptococcus pyogenes</i> , <i>Streptococcus pneumoniae</i> , and <i>Enterococci</i>	See gentamicin sulfate.

Cunha BA. *Antibiotic Essentials*, 5th ed. Royal Oak, MI: Physicians Press; 2006.
From <http://www.drugs.com> (drug information online). Revised from November 2006.

TABLE I.12

MISCELLANEOUS

Drug	Drug class	Adults (usual dose ^a)	Actions, interactions, and others	Spectrum of activity, indications, and active against most strains of	Route, reduce dose, and contraindications
Metronidazole	Nitroimidazole antiparasitic/antibiotic	Usual dose: IV: 1 g q/24h PO: 500 mg q12h	Metronidazole is a synthetic antibacterial compound. Drug interactions: Warfarin and other oral coumarin anticoagulants, phenytoin or phenobarbital, cimetidine, and disulfiram	Anaerobic gram-negative bacilli , including <i>Bacteroides</i> sp., including the <i>Bacteroides fragilis</i> group (<i>B. fragilis</i> , <i>B. distasonis</i> , <i>B. ovatus</i> , <i>B. thetaiotaomicron</i> , <i>B. vulgatus</i>); <i>Fusobacterium</i> sp. Anaerobic gram-positive bacilli , including <i>Clostridium</i> sp. and susceptible strains of <i>Eubacterium</i> Anaerobic gram-positive cocci , including <i>Peptococcus</i> sp.; <i>Peptostreptococcus</i> sp.	Primary mode of elimination: Hepatic
Trimethoprim (TMP)/sulfamethoxazole (SMX) or cotrimoxazole	Synthetic folate antagonist/sulfonamide	Usual dose: IV or PO: 2.5–5 mg/kg q6h	Sulfamethoxazole is bacteriostatic and trimethoprim is bactericidal Drug interactions: Warfarin (monitoring carefully); phenytoin (folate deficiencies when is used concomitantly); thiazides increased incidence of thrombocytopenia with purpura in elderly patients; cyclosporine (nephrotoxicity reversible); digoxin; indomethacin; pyrimethamine; tricyclic antidepressants; amantadine; methotrexate; and oral hypoglycemic agents	Primary agent in the treatment of <i>Pneumocystis carinii pneumonia</i> (PCP), an opportunistic infection in patients with HIV/AIDS, and as secondary prophylaxis of PCP in patients who have already had at least one episode of PCP. Also is indicated for the treatment of chronic bronchitis, enterocolitis caused by strains of <i>Shigella</i> (<i>flexneri</i> and <i>sonnei</i>), acute otitis media in children, traveler's diarrhea caused by enterotoxigenic <i>Escherichia coli</i> and <i>Shigella</i> sp., and bacterial urinary tract infections	SMX-TMP is metabolized in the liver. Urinary concentrations of both active drugs are decreased in patients with impaired renal function. Only small amounts of trimethoprim are excreted in feces via biliary elimination. Trimethoprim and active sulfamethoxazole are moderately removed by hemodialysis.

Cunha BA. *Antibiotic Essentials*, 5th ed. Royal Oak, MI: Physicians Press; 2006.

TABLE I.13

ANTIFUNGALS

Drug	Drug class	Adults (usual dose ^a)	Actions, interactions, and others	Spectrum of activity, indications, and active against most strains of	Route, reduce dose, and contraindications
Amphotericin B	Antifungal Polyene macrolide antibiotic produced by soil bacteria <i>Strepto- myces nodosus</i>	Usual dose: IV: 0.5–0.8 mg/kg q24h	Amphotericin B is the gold standard for the treatment of serious and invasive systemic mycosis as well as for Kala-Azar. Drug interactions: Avoid concomitant administration of nephrotoxic drugs and bone marrow suppressants.	Amphotericin B has useful activity against candidiasis, cryptococcosis, histoplasmosis, blastomycosis, paracoccidioidomycosis, coccidioidomycosis, aspergillosis, extracutaneous sporotrichosis, zygomycosis (mucormycosis), penicilliosis (<i>Penicilliosis marneffei</i>) pseudallescheriasis, hyalohyphomycosis (including infection due to <i>Acremonium</i> , <i>Fusarium</i> , <i>Penicillium</i> , etc.) and phaeohyphomycosis (including infection due to <i>Alternaria</i> , <i>Bipolaris</i> , <i>Cladosporium</i> , <i>Cladophialophora</i> , <i>Curvularia</i> , <i>Exophiala</i> , <i>Exserohilum</i> , <i>Fonsecaea</i> , <i>Phialophora</i> , <i>Wangiella</i> , etc.). Empirical antifungal therapy is useful to granulocytopenic patients with persistent or recurrent fever. ^a	Primary mode of elimination: Metabolized The most common cause for withdrawal of or failure to continue amphotericin B therapy is its severe renal toxicity in nearly half of all the patients. The second problem, which is a major one, is the nephrotoxicity of amphotericin B.
Liposomal amphotericin B	Antifungal Polyene macrolide antibiotic True liposomal preparation of amphotericin B in which lipid complex of liposomes is constituted of lecithin and cholesterol	Usual dose: IV: 3–6 mg/kg q24h	Is the most effective and affordable drug for treatment of both systemic mycosis and Kala-Azar. Drug interactions: As with conventional amphotericin B, avoid concomitant administration of nephrotoxic drugs and bone marrow suppressants, only and in patients with hypokalemia.	Amphotericin B shows a high order of <i>in vitro</i> activity against many species of fungi <i>viz.</i> <i>Histoplasma capsulatum</i> , <i>Cryptococcus immitis</i> , <i>Candida</i> sp., <i>Blastomyces dermatitidis</i> , <i>Rhodotorula</i> , <i>Cryptococcus neoformans</i> , <i>Sporothrix schenckii</i> , <i>Mucor</i> sp., <i>Aspergillus fumigatus</i> , <i>Malassezia furfur</i> , <i>Trichosporon beigeli</i> , <i>Saccharomyces cerevisiae</i> , <i>Scedosporium</i> sp., <i>Paecilomyces</i> sp., <i>Penicillium</i> sp., <i>Fusarium</i> sp., <i>Bipolaris</i> sp., <i>Exophiala</i> sp., <i>Cladophialophora</i> sp., <i>Absidia</i> sp., <i>Apophysomyces</i> sp., <i>Cunninghamella</i> sp., <i>Rhizomucor</i> sp., <i>Rhizopus</i> sp., and <i>Saksenaea</i> sp. These fungi are inhibited by concentrations of amphotericin B ranging from 0.03 to 1 µg/mL <i>in vitro</i> . Amphotericin B also has activity against species of <i>Leishmania</i> and is found to be effective in the treatment of Kala-Azar.	Primary mode of elimination: Metabolized

(continued)

TABLE I. 13
CONTINUED

Drug	Drug class	Adults (usual dose ^a)	Actions, interactions, and others	Spectrum of activity, indications, and active against most strains of	Route, reduce dose, and contraindications
Fluconazole	Triazole antifungal agent	Usual dose: 400 mg (IV/PO) × 1 dose, then 200 mg (IV/PO) q24h Usual dose for candidemia: 400 mg (IV/PO) q24h after loading dose of 800 mg (IV/PO) Meningeal dose: 400 mg (IV/PO) q24h	Fluconazole is a highly selective inhibitor of fungal cytochrome P450 sterol C-14 α -demethylation. Drug interactions: Oral contraceptives, cimetidine, antacid, hydrochlorothiazide, rifampin, warfarin, phenytoin, cyclosporine, zidovudine, theophylline, terfenadine, oral hypoglycemic agents, tolbutamide, glipizide, glyburide, rifabutin, tacrolimus, cisapride, midazolam, azithromycin (not significant)	Prophylaxis Fluconazole is also indicated to decrease the incidence of candidiasis in patients undergoing bone marrow transplantation who receive cytotoxic chemotherapy and/or radiation therapy. Fluconazole exhibits <i>in vitro</i> activity against <i>Cryptococcus neoformans</i> and <i>Candida</i> spp. Fungistatic activity has also been demonstrated in normal and immunocompromised animal models for systemic and intracranial fungal infections due to <i>Cryptococcus neoformans</i> and for systemic infections due to <i>Candida albicans</i> . Fluconazole is indicated for the treatment of: 1. Vaginal candidiasis (vaginal yeast infections due to <i>Candida</i>) 2. Oropharyngeal and esophageal candidiasis. In open noncomparative studies of relatively small numbers of patients, fluconazole was also effective for the treatment of <i>Candida</i> urinary tract infections, peritonitis, and systemic <i>Candida</i> infections including candidemia, disseminated candidiasis, and pneumonia. 3. Cryptococcal meningitis Invasive aspergillosis Indicated for the primary treatment of acute invasive aspergillosis (<i>Aspergillus</i> spp.) Also with <i>Fusarium</i> spp. and <i>Scedosporium</i> spp. Other disease-causing agents Voriconazole was shown to be effective against both <i>Scedosporium apiospermum</i> and <i>Fusarium</i> spp. For <i>Scedosporium apiospermum</i> , a successful response to Vfend was reported in 15 of 24 subjects (63%). In those with <i>Fusarium</i> spp., 9 of 21 (43%) were successfully treated with voriconazole.	Primary mode of elimination: Renal Contraindications: Terfenadine and cisapride Fluconazole has been associated with rare cases of serious hepatic toxicity.
Voriconazole	Triazole antifungal agent	Usual dose: IV dosing: Loading dose of 6 mg/kg (IV) q12h × 1 day, then maintenance dose of 4 mg/kg (IV) q12h. It is possible to switch to weight-based PO maintenance IV dose. PO dosing: 1. If weight ≥40 kg: Loading dose of 400 mg (PO) q12h × 1 day, then maintenance dose of 200 mg (PO) q12h. If response is inadequate, increase dose to 300 mg (PO) q12h. 2. If weight <40 kg: Loading dose of 200 mg (PO) × 1 day, then maintenance dose of 100 mg (PO) q12h. If response is inadequate, increase dose to 150 mg (PO) q12h. In patients with chronic and/or non life-threatening infections, loading dose may be given PO.	Mode of action of voriconazole is the inhibition of fungal cytochrome P450-mediated 14 α -lanosterol demethylation, an essential step in fungal ergosterol biosynthesis. Drug interactions: Benzodiazepines, vinca alkaloids, carbamazepine, ergo alkaloids, rifampin, rifabutin, sirolimus, long-acting barbiturates (see contraindications), cyclosporine, omeprazole, tacrolimus, phenytoin, warfarin, statins, dihydropyridine, calcium channel blockers (low arterial pressure), sulfonyleureas (hypoglycemia). Potential hepatotoxicity risk	Primary mode of elimination: Hepatic Contraindications: Long-acting barbiturates	

Itraconazole	Antifungal agent	<p>Usual dose: 200 mg (IV/PO) q24h 200 mg capsule/solution (PO) q24h.</p> <p>Begin itraconazole for acute/severe infections with a loading regimen of 200 mg (IV) q12h × 2 days (4 doses), then give 200 mg (IV or PO) q24h maintenance dose. Each IV dose should be infused over 60 minutes.</p>	<p>Drug interactions: Coadministration of cisapride, pimozone, quinidine, dofetilide, or levacetylmethadol (levomethadyl) with itraconazole.</p>	<p>Itraconazole exhibits <i>in vitro</i> activity against <i>Blastomyces dermatitidis</i>, <i>Histoplasma capsulatum</i>, <i>Histoplasma duboisii</i>, <i>Aspergillus flavus</i>, <i>Aspergillus fumigatus</i>, <i>Candida albicans</i>, and <i>Cryptococcus neoformans</i>. Itraconazole also exhibits varying <i>in vitro</i> activity against <i>Sporothrix schenckii</i>, <i>Trichophyton species</i>, <i>Candida krusei</i>, and other <i>Candida</i> species.</p> <p>Fungistatic activity has been demonstrated against disseminated fungal infections caused by <i>Blastomyces dermatitidis</i>, <i>Histoplasma duboisii</i>, <i>Aspergillus fumigatus</i>, <i>Coccidioides immitis</i>, <i>Cryptococcus neoformans</i>, <i>Paracoccidioides brasiliensis</i>, <i>Sporothrix schenckii</i>, <i>Trichophyton rubrum</i>, and <i>Trichophyton mentagrophytes</i>.</p>	<p>Primary mode of elimination: Hepatic; metabolized predominantly by the cytochrome P450 3A4 isoenzyme system (CYP3A4) Patients with impaired hepatic function should be carefully monitored when taking itraconazole. If signs or symptoms of congestive heart failure appear during administration of itraconazole, monitor carefully and consider other treatment alternatives. Contraindications: Cisapride, oral midazolam, pimozone, quinidine, dofetilide, triazolam, and levacetylmethadol (levomethadyl) are contraindicated with itraconazole.</p>
Caspofungin	Echinocandin antifungal	<p>Usual dose: 70 mg (IV) × 1 dose, then 50 mg (IV) q24h</p> <p>In patients weighing more than 80 kg it is recommended that 70 mg/d is given rather than 50 mg/d. Patients with moderate liver insufficiency should receive a dose of 35 mg/d.</p>	<p>Caspofungin is not an inhibitor and is a poor substrate for cytochrome people P450 enzymes.</p> <p>Drug interactions: Cyclosporine, tacrolimus, carbamazepine, rifampin, dexamethasone, efavirenz, nelfinavir, nevirapine, phenytoin</p>	<p>Caspofungin is active against all species of <i>Candida</i>. It is extremely active against all species except <i>Candida parapsilosis</i>, <i>Candida guilliermondii</i>, and <i>Candida lusitanae</i>, against which it is moderately active.</p> <p>Caspofungin is also very active against all <i>Aspergillus</i> sp. It does not kill <i>Aspergillus</i> completely in test tubes. There is a very limited amount of activity against <i>Coccidioides immitis</i>, <i>Blastomyces dermatitidis</i>, <i>Scedosporium</i> sp., <i>Paecilomyces variotii</i>, and <i>Histoplasma capsulata</i> but it is likely that the activity is not sufficient for clinical use.</p>	<p>Primary mode of elimination: Hepatic</p>

Unfractionated heparin (UFH), 843, 896–898
 monitoring, 898
 in STEMI, 628–629
 uses of, 897–898
 for anticoagulation, guidelines for, 897*t*
 vs. LMWH, 901*t*
- Unstable angina, 615
 antiplatelet and anticoagulant agents in, 622*t*
 dosages of nitroglycerin and nitrates in, 622*t*
 principal presentations of, 615*t*
- Unusual infections, 604–614
UPET. *See* Urokinase pulmonary embolism trial (UPET)
- Upper airway obstruction (UAO), 81, 940–941
 clinical presentation of, 941
 diagnosis of, 941
 in flexible bronchoscopy, 81
 treatment of, 941
- Upper gastrointestinal bleeding (UGIB), 787–792
 with cirrhosis, 809
 clinical presentation, 787–788
 diagnostic evaluation, 788–789
 amount of blood loss, 788
 diagnostic workup, 789
 gastric lavage, 788
 endoscopic treatment, 790–91
 epidemiology, 787
 etiology of, 787*t*
 gastric acid suppression, 790
 management, 789–792
 angiographic treatment, 791
 endoscopic treatment, 790–791
 hemodynamic resuscitation, 790
 pharmacologic treatment, 790
 surgery, 791–792
 management of, 789–792
 pharmacologic treatment, 790
 predictors of outcome and risk stratification, 789
 splanchnic vasoconstrictors for, 790
 stress-related mucosal damage, 792
- Upper tract endoscopy, in urologic surgery, 345
Uptake of inhaled agents from the lungs, 228
Uremia, 892–893
Ureterointestinal diversion, 109
Urethral catheters, types of, 556
Urethral injuries, in urologic surgery, 347
Urinary anion gap, 104
Urinary drainage system, in UTI, 555–556
Urinary excretion, of fixed acid, 103–104
Urinary reagent strips, in UTI, 554*t*
Urinary tract infections (UTI), 551–560
 alternatives to urinary catheter, 556–557
 antibiotic irrigation, 556
 antimicrobial agents, 557
 antimicrobial treatment of, 557, 559*t*
 assessing urinary reagent strips in, 554*t*
 criteria for, 553*t*
 cystitis and, 557–558
 definitions of symptomatic, 551, 552*t*
 impact in ICU, 554
 management of Candiduria, 559–560
 meatal care of, 556
 microbiology of, 552
 pathogens associated with nosocomial, 553*t*
 pathophysiology of, 551–552
 prevention in ICU, 554–555
 prostatitis, 558
 pyelonephritis, 558–559
 in renal transplantation, 374
 risk factors for, 553–554
 specificities of complicated
 in ICU, 559–560
 symptomatic
 treatment of, 557–559
 treatment of, 557–560
 urinary drainage system in, 555–556
 antiseptic in, 556
- Urinary tract infection (UTI), 447
Urine output, in CPB, 313
Urodelatin, for ARF, 836
Urokinase, 906
Urokinase pulmonary embolism trial (UPET), 751*t*
Urologic surgery
 bowel injury in, 346
 damage control strategies in, 348–349
 extraperitoneal bladder injuries in, 347
 genital injuries in, 347–348
 genital surgery and, 346
 gross hematuria in, 343
 iatrogenic injury in, 346–348
 intraperitoneal bladder injuries in, 347–348
 laparoscopy in, 345
 oncologic emergencies in, 344
 pelvic surgery and, 344–345
 renal injuries in, 347
 upper abdominal surgery and, 344
 upper tract endoscopy in, 345
 urethral injuries in, 347
 of urinary tract, 343
 urosepsis, 343, 349–350
U.S. Acute Liver Failure Study Group (ALFSG), 800
- VAC. *See* Vacuum-assisted closure (VAC)
Vacuum-assisted closure (VAC), 480
7-valent conjugate vaccine
 for meningitis, 502
Valvular heart disease (VHD), 656–665
 clinical signs in, 657*t*
 critical illnesses and, 656–664
 aortic regurgitation, 656–659
 aortic stenosis, 656–659
 cause of, 656
 mitral regurgitation, 659–661
 mitral stenosis, 661–662
 mixed valve lesions, 664
 prosthetic valve dysfunction, 664
 pulmonic insufficiency, 663–664
 pulmonic stenosis, 663
 with specific valvular abnormalities, 656–664
 tricuspid regurgitation, 662–663
 tricuspid stenosis, 662
 immediate concerns in, 656
 Vancomycin, in brain abscess, 506
 Vancomycin-resistant enterococcus, 442–443
 VAP. *See* Ventilator-associated pneumonia (VAP)
 Variable decelerations, 413
 classification of, 413*t*
 in relation to contraction, 413*t*
 Variceal bleeding, 791
 risk factors for recurrent, 791*t*
 Varicella-Zoster virus (VZV), 575
 Vascular access, for RRT, 844
 Vascular cannulation, 66–74
 central venous catheter, 66
 inferior vena cavae filter, 66
 Vascular occlusion, in liver transplantation, 366–367
 Vascular surgery, 329–334
 Vascular system
 pancreatitis and, 815–816
 RRT and, 844
 Vasoconstrictor therapy
 in CPB, 312
 for HRS, 808
 Vasodilators, in CPB, 312
 Vasodilatory neurogenic shock, 143
 Vasodilatory shock, 141
 Vasopressin, 852, 855*t*
 in CPR, 5
 Vasopressin, in CPB, 312
 Vasopressors, for sepsis and septic shock, 133
 VCV. *See* Volume-controlled ventilation (VCV)
 Vecuronium, 150
 Vein catheterization, 68–69
 femoral vein cannulation, 68
 internal jugular vein cannulation, 68
- Veno-occlusive disease of liver
 clinical criteria of, 380*t*
 stem cell transplantation, 380
Venous access, in temporary cardiac pacing, 24–25
Venous thromboembolism, 421
 in morbidly obese, 421
Venous thromboembolism (VTE), 744–746
 diagnosis of DVT, 746
 incidence of, 744–745
 inferior vena cava filters, 745–746
 in pregnancy, 386–387
 diagnosis of, 386
 predisposition, 386
 prevention of, 386–387
 risk factors, 386, 386*t*
 pregnancy and, 408
 prevalence of, 744–745
 prophylaxis of
 mechanical, 745
 pharmacologic, 745
 principles of, 744
 risk factors of, 744
 treatment of DVT, 746
Venous thrombosis, 894. *See also* Mesenteric venous thrombosis
 in pancreatitis, 816
Ventilation, physics of, 703–704
Ventilation/perfusion (V/Q), 419
 in morbidly obese, 419
Ventilator-associated pneumonia (VAP), 469–470, 532–540
 antibiotic treatment of, 536–538
 causes fever in ICU, 446–447
 causes of nonresolution/deterioration in, 39*t*
 defined, 532
 diagnosis of, 535–536
 etiology of, 534–535
 incidence of, 532–533
 incidence of in ICU, 533*t*
 micro-organisms causing, 534*t*
 pathogenesis of, 533
 prevention of, 539–540
